Abstract

USB provides ubiquitous plug-and-play connectivity for a wide range of devices. However, the complex nature of USB obscures the true functionality of devices from the user, and operating systems blindly trust any physically-attached device. This has led to a number of attacks, ranging from hidden keyboards to network adapters, that rely on the user being unable to identify all of the functions attached to the host. In this paper, we present USBFILTER, which provides the first packet-level access control for USB and can prevent unauthorized interfaces from successfully connecting to the host operating system. USBFILTER can trace individual USB packets back to their respective processes and block unauthorized access to any device. By instrumenting the host’s USB stack between the device drivers and the USB controller, our system is able to filter packets at a granularity that previous works cannot — at the lowest possible level in the operating system. USBFILTER is not only able to block or permit specific device interfaces; it can also restrict interfaces to a particular application (e.g., only Skype can access my webcam). Furthermore, our experimental analysis shows that USBFILTER introduces a negligible (3-10 μ s) increase in latency while providing mediation of all USB packets on the host. Our system provides a level of granularity and extensibility that reduces the uncertainty of USB connectivity and ensures unauthorized devices are unable to communicate with the host.

1 Introduction

The Universal Serial Bus (USB) provides an easy-to-use, hot-pluggable architecture for attaching external devices ranging from cameras to network interfaces to a single host computer. USB ports are pervasive; they can often be found on the front, back, and inside of a common desktop PC. Furthermore, a single USB connector may connect multiple device classes. These composite

devices allow disparate hardware functions such as a microphone and speakers to appear on the same physical connector (e.g., as provided by a headset). In the host operating system, technologies such as USBIP [21] provide the capability to remotely connect USB devices to a host over a network. The result is a complex combination of devices and functionalities that clouds the user’s ability to reason about what is actually connected to the host.

Attacks that exploit this uncertainty have become more prevalent. Firmware attacks such as BadUSB [27] modify benign devices to have malicious behavior (e.g., adding keyboard emulation to a storage device or perform automatic tethering to another network). Hardware attacks [1] may inject malware into a host, provide RF remote control capabilities, or include embedded proxy hardware to inject and modify USB packets. Attackers may also exfiltrate data from the host by leveraging raw I/O (e.g., using libusb [14]) to communicate with the USB device directly, or bypass the security mechanism employed by the USB device controller by sending specific USB packets to the device from the host USB controller [4]. Unfortunately, the USB Implementers Forum considers defending against malicious devices to be the responsibility of the user [44], who is unlikely to be able to independently verify the functionality and intent of every device simply by its external appearance, and may just plug in USB devices to take a look [43].

Modern operating systems abstract USB authorization to physical control, automatically authorizing devices connected to the host, installing and activating drivers, and enabling functionality. We believe that a finer-grained control over USB is required to protect users. In this paper, we make the following contributions:

- **Design and develop a fine-grained USB access control system:** We introduce USBFILTER, a packet-level firewall for USB. Our system is the first to trace individual USB packets back to the source or destination process and interface. USBFILTER

rules can stop attacks on hosts by identifying and dropping unwanted USB packets before they reach their destination in the host operating system.

- **Implement and characterize performance:** We demonstrate how USBFILTER imposes minimal overhead on USB traffic. As a result, our system is well-suited for protecting any USB workload.
- **Demonstrate effectiveness in real-world scenarios:** We explore how USBFILTER can be used to thwart attacks and provide security guarantees for benign devices. USBFILTER can pin devices (e.g., webcams) to approved programs (e.g., Skype, Hangouts) to prevent malicious software on a host from enabling or accessing protected devices.

USBFILTER is different from previous works in this space because it enables the creation of rules that explicitly allow or deny functionality based on a wide range of features. GoodUSB [41] relies on the user to explicitly allow or deny specific functionality based on what the device reports, but cannot enforce that the behavior of a device matches what it reports. SELinux [35] policies and PinUP [13] provide mechanisms for pinning processes to filesystem objects, but USBFILTER expands this by allowing individual USB packets to be associated with processes. This not only allows our system to permit pinning devices to processes, but also individual interfaces of composite devices.

Our policies can be applied to differentiate individual devices by identifiers presented during device enumeration. These identifiers, such as serial number, provide a stronger measure of identification than simple product and vendor codes. While not a strong authentication mechanism, USBFILTER is able to perform filtering without additional hardware. The granularity and extensibility of USBFILTER allows it to perform the functions of existing filters [41] while permitting much stronger control over USB devices.

The remainder of this paper is structured as follows: In Section 2, we provide background on the USB protocol and explain why it is not great anymore; in Section 3, we discuss the security goals, design and implementation of our system; in Section 4, we discuss how USBFILTER meets our required security guarantees; in Section 5, we evaluate USBFILTER and discuss individual use cases; in Section 6, we provide additional discussion; in Section 7, we explore related work; and in Section 8, we conclude.

2 Background

A USB device refers to a USB transceiver, USB hub, host controller, or peripheral device such as a human-interface

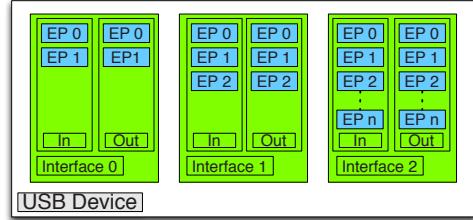

Figure 1: A detailed view of a generic USB device. Similar to a typical USB headset, this device has three interfaces and multiple endpoints.

device (*HID*, e.g., keyboard and mouse), printer, or storage. However, the device may have multiple functions internally, known as *interfaces*. An example device with three interfaces is shown in Figure 1. USB devices with more than one interface are known as composite devices. For example, USB headsets often have at least three interfaces: the speaker, the microphone, and the volume control functionalities. Each interface is treated as an independent entity by the host controller. The operating system loads a separate device driver for each interface on the device.

The USB protocol works in a master-slave fashion, where the host USB controller is responsible to poll the device both for requests and responses. When a USB device is attached to a host machine, the host USB controller queries the device to obtain the *configurations* of the device, and activates a single configuration supported by the device. For instance, when a smartphone is connected with a host machine via USB, users can choose it to be a storage or networking device. By parsing the current active configuration, the host operating system identifies all the *interfaces* contained in the configuration, and loads the corresponding device drivers for each interface. This whole procedure is called *USB enumeration* [10]. Once a USB device driver starts, it first parses the *endpoints* information embedded within this interface as shown in Figure 1.

While the interface provides the basic information for the host operating system to load the driver, the *endpoint* is the communication unit when a driver talks with the USB device hardware. Per specification, the endpoint 0 (EP0) should be supported by default, enabling *Control* (packet) transfer from a host to a device to further probe the device, prepare for data transmission, and check for errors. All other endpoints can be optional though there is usually at least EP1, providing *Isochronous*, *Interrupt*, or *Bulk* (packet) transfers, which are used by audio/video, keyboard/mouse, and storage/networking devices respectively. All endpoints are grouped into either *In* pipes, where transfers are from the device to the host,

or *Out* pipes, where transfers are from the host to the device. This in/out pipe determines the transmission direction of a USB packet. With all endpoints set up, the driver is able to communicate with the device hardware by submitting USB packets with different target endpoints, packet types, and directions. These packets are delivered to the host controller, which calls the controller hardware to encode USB packets into electrical signals and send them to the device.

2.1 Why USB Was Great

Prior to USB’s introduction in the 1990s, personal computers used a number of different and often platform-specific connectors for peripherals. Serial and parallel ports, PS/2, SCSI, ADB, and others were often not hot-pluggable and required users to manually set configuration options (such as the SCSI ID). The widespread industry adoption of USB fixed many of these issues by providing a common specification for peripherals. Hardware configuration is now handled exclusively by the host, which is able to manage many devices on a single port. The relative ease with which a USB peripheral can be installed on a host is simultaneously its greatest and most insecure property.

The USB subsystem has been expanded in software as well, with Virtio [30] supporting I/O virtualization in KVM, enabling virtual USB devices in VMs, and passing through the physical devices into VMs. USBIP [21] transfers USB packets via IP, making remote USB device sharing possible. Wireless USB (WUSB) [19] and Media Agnostic USB (MAUSB) [16] promote the availability of USB devices by leveraging different wireless communication protocols, making the distinction among local USB devices, virtual ones, and remote ones vanish.

Overall, the utility and complexity of USB has been steadily increasing in both hardware and software. Advances in circuit and chip design now allow hidden functionality to be placed inside the USB plug [1]. The ease-of-use that made USB great now threatens users by obscuring the individual interfaces in a USB device.

2.2 How USB Lost its Greatness

Attacks on USB prey on the fundamental misunderstanding of how devices are constructed from interfaces. Attacks such as BadUSB [27] and TURNIPSCHOOL [1] (itself designed on specifications from nation-state actors) use composite devices to present multiple interfaces to a host. Often these include one benign or expected interface and one or more malicious interfaces, including keyboards [9, 27] and network interfaces [27, 1]. Without communicating with the host operating system, a malicious USB device can only obtain power from the

host. While it may be possible to perform power analysis attacks without sending USB packets, we focus on the problem of connecting malicious devices to the host’s operating system. All of these attacks share a common thread: they attach an unknown interface to a host without the user’s knowledge. Since operating systems implicitly trust any device attached, these hidden functions are enumerated, their drivers are loaded, and they are granted access to the host with no further impediment.

Data exfiltration from host machines may be the main reason why USB storage is banned or restricted in enterprise and government environments. Current secure storage solutions rely on access control provided by the host operating system [23] or use network-based device authentication [22]. While access controls can be bypassed by raw I/O, which communicates to the device directly from userspace (e.g., using libusb [14]), network-based methods are vulnerable to network spoofing (e.g., ARP spoofing [32] and DNS spoofing [36]). It is thus unclear whether data exfiltration has occurred or not until the USB port is glued or locked [39]. The remainder of this paper will show how a packet-level filter for USB permits fine-grained access controls, eliminating the implicit trust model while providing strong guarantees.

3 USB Access Control

The complex nature of the USB protocol and the variety of devices that can be attached to it makes developing a robust and efficient access control mechanism challenging. Layers in the operating system between the process and the hardware device create difficulties when identifying processes. Accordingly, developing a system such as USBFILTER is not as simple as intercepting USB packets and dropping those that match rules. In this section, we discuss our security goals, design considerations, and implementation of USBFILTER while explaining the challenges of developing such a system.

3.1 Threat and Trust Models

We consider an adversary against our system who has restricted external physical or full network access to a given host. The adversary may launch physical attacks such as attaching unauthorized USB devices to the host system or tampering with the hardware of previously-authorized devices to add additional functionality. The physically-present adversary may not open the device or tamper with the internal storage, firmware, or any other hardware. This type of adversary might (for example) be present in an data center or retail location, where devices have exposed USB ports, but tampering with the chassis of the device would raise suspicion or sound alarms. The adversary may also launch network attacks in order

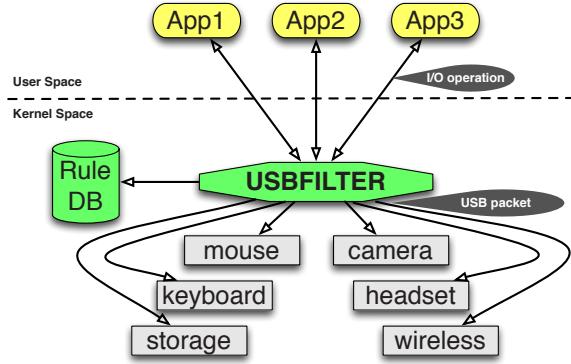

Figure 2: USBFILTER implements a USB-layer reference monitor within the kernel, by filtering USB packets to different USB devices to control the communications between applications and devices based on rules configured.

to enable or access authorized devices from unauthorized processes or devices. In either case, the adversary may attempt to exfiltrate data from the host system via both physical and virtual USB devices.

We consider the following actions by an adversary:

- **Device Tampering:** The adversary may attempt to attach or tamper with a previously-authorized device to add unauthorized functionality (e.g., BadUSB [27]).
- **Unauthorized Devices:** Unauthorized devices attached to the system either physically or virtually [21] can be used to discreetly interact with the host system or to provide data storage for future exfiltration.
- **Unauthorized Access:** The adversary may attempt to enable or access authorized devices on a host (e.g., webcam, microphone, etc.) via unauthorized software to gain access to information or functionality that would otherwise be inaccessible.

We assume that as a kernel component, the integrity of USBFILTER depends on the integrity of the operating system and the host hardware (except USB devices). Code running in the kernel space has unrestricted access to the kernel’s memory, including our code, and we assume that the code running in the kernel will not tamper with USBFILTER. We discuss how we ensure runtime and platform integrity in our experimental setup in Section 3.4.

3.2 Design Goals

Inspired by the Netfilter [40] framework in the Linux kernel, we designed USBFILTER to enable administrator-

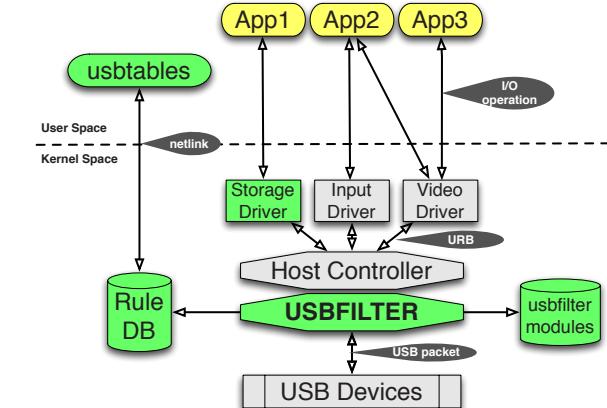

Figure 3: The architecture of USBFILTER.

defined rule-based filtering for the USB protocol. To achieve this, we first designed our system to satisfy the concept of a reference monitor [2], shown in Figure 2. While these goals are not required for full functionality of USBFILTER, we chose to design for stronger security guarantees to ensure that processes attempting to access hardware USB devices directly would be unable to circumvent our system. We define the specific goals as follows:

G1 Complete Mediation. All physical or virtual USB packets must pass through USBFILTER before delivery to the intended destination.

G2 Tamperproof. USBFILTER may not be bypassed or disabled as long as the integrity of the operating system is maintained.

G3 Verifiable. The user-defined rules input into the system must be verifiably correct. These rules may not conflict with each other.

While the above goals support the security guarantees that we want USBFILTER to provide, we expand upon these to provide additional functionality:

G4 Granular. Any mutable data in a USB packet header must be accessible by a user-defined rule. If the ultimate destination of a packet is a userspace process, USBFILTER must permit the user to specify the process in a rule.

G5 Modular. USBFILTER must be extensible and allow users to provide submodules to support additional types of analysis.

3.3 Design and Implementation

The core USBFILTER component is statically compiled and linked into the Linux kernel image, which hooks the

flow of USB packets before they reach the USB host controller which serves the USB device drivers, as shown in Figure 3. Like Netfilter, this USB firewall checks a user-defined rule database for each USB packet that passes through it and takes the action defined in the first matching rule. A user-space program, USBTABLES, provides mediated read/write access to the rule database. Since USBFILTER intercepts USB packets in the kernel, it can control access to both physical and virtual devices.

3.3.1 Packet Filtering Rules

To access external USB devices, user-space applications request I/O operations which are transformed into USB request blocks (URBs) by the operating system. The communication path involves the process, the device, and the I/O request itself (*USB packet*). Similarly, a USBFILTER rule can be described using the process information, the device information, and the USB packet information.

A USBFILTER rule R can be expressed as a triple (N, \mathcal{C}, A) where N is the name of the rule, \mathcal{C} is a set of conditions, and $A \in \{\text{ALLOW}, \text{DROP}\}$ is the action that is taken when all of the conditions are satisfied. As long as the values in conditions, action, and name are valid, this rule is valid, but may not be correct considering other existing rules. We discuss verifying the *correctness* of rules in Section 4.

3.3.2 Traceback

USB packets do not carry attribution data that can be used to determine the source or destination process of a packet. We therefore need to perform traceback to attribute packets to interfaces and processes.

Interfaces. As discussed in Section 2, a USB device can have multiple interfaces, each with a discrete functionality served by a device driver in the operating system. Once a driver is bound with an interface, it is able to communicate with that interface using USB packets.

Determining the driver responsible for receiving or sending a given USB packet is useful for precisely controlling device behaviors. However, identifying the responsible driver is not possible at the packet level, since the packets are already in transit and do not contain identifying information. While we could infer the responsible driver for simple USB devices, such as a mouse, this becomes unclear with composite USB devices with multiple interfaces (some of which may be served by the same driver).

To recover this important information from USB packets without changing each driver and extending the packet structure, we save the interface index into the kernel endpoint structure during USB enumeration.

This reverse mapping of interface to driver needs to be performed only once per device. The interface index distinguishes interfaces belonging to the same physical device and USB packets submitted by different driver instances. Once the mapping has been completed, the USB host controller is able to easily trace the originating interface back to the USB packets.

Processes. Similarly, tracking the destination or source process responsible for a USB packet is not trivial due to the way modern operating systems abstract device access from applications. For example, when communicating with USB storage devices, the operating system provides several abstractions between the application and the raw device, including a filesystem, block layer, and I/O scheduler. Furthermore, applications generally submit asynchronous I/O requests, causing the kernel to perform the communications task on a separate background thread.

This problem also appears when inspecting USB network device packets, including both wireline (e.g., Ethernet) dongles and wireless (e.g., WiFi) adapters. It is common for these USB device drivers to have their own RX/TX queues to boost the system performance using asynchronous I/O. In these cases, USB is an intermediate layer to encapsulate IP packets into USB packets for processing by the USB networking hardware.

These cases are problematic for USBFILTER because a naïve traceback approach will often only identify the kernel thread as the origin of a USB packet. To recover the process identifier (PID) of the true origin, we must ensure that this information persists between all layers within the operating system before the I/O request is transformed into a USB packet.¹

USBFILTER instruments the USB networking driver (*usbnet*), the USB wireless driver (*rt2x00usb*), the USB storage driver (*usb-storage*), as well as the block layer and I/O schedulers. Changes to the I/O schedulers are needed to avoid the potential merging of two block requests from different processes. By querying the rule database and USBFILTER modules, USBFILTER sets up a filter for all USB packets right before being dispatched to the devices.

3.3.3 Userspace Control

USBTABLES manages USBFILTER rules added in the kernel and saves all active rules in a database. Using udev, saved rules are flushed into the kernel automatically upon reboot. USBTABLES is also responsible for verifying the correctness of rules as we will discuss in Section 4. Once

¹USBFILTER does not overlap with Netfilter or any other IP packet filtering mechanisms which work along the TCP/IP stack.

verified, new rules will be synchronized with the kernel and saved locally.

If no user-defined rules are present, USBFILTER enforces default rules that are designed to prevent impact on normal kernel activities (e.g., USB hot-plugs). These rules can be overridden or augmented by the user as desired.

3.4 Deployment

We now demonstrate how we use existing security techniques in the deployment of USBFILTER. Attestation and MAC policy are necessary for providing complete mediation and tamperproof reference monitor guarantees, but not for the functionality of the system. The technologies we reference in this section are illustrative examples of how these goals can be met.

3.4.1 Platform Integrity

We deployed USBFILTER on a physical machine with a Trusted Platform Module (TPM). The TPM provides a root of trust that allows for a measured boot of the system and provides the basis for remote attestations to prove that the host machine is in a known hardware and software configuration. The BIOS’s core root of trust for measurement (CRTM) bootstraps a series of code measurements prior to the execution of each platform component. Once booted, the kernel then measures the code for user-space components (e.g., provenance recorder) before launching them using the Linux Integrity Measurement Architecture (IMA)[31]. The result is then extended into TPM PCRs, which forms a verifiable chain of trust that shows the integrity of the system via a digital signature over the measurements. A remote verifier can use this chain to determine the current state of the system using TPM attestation. Together with TPM, we also use Intel’s Trusted Boot (tboot)²

3.4.2 Runtime Integrity

After booting into the USBFILTER kernel, the runtime integrity of the TCB (defined in Section 3.1) must also be assured. To protect the runtime integrity of the kernel, we deploy a Mandatory Access Control (MAC) policy, as implemented by Linux Security Modules. We enable SELinux’s MLS policy, the security of which was formally modeled by Hicks et al. [20]. We also ensure that USBTABLES executes in a restricted environment and that the access to the rules database saved on the disk is protected by defining an SELinux Policy Module and compiling it into the SELinux Policy.

² See <http://sf.net/projects/tboot>

4 Security

In this section, we demonstrate that USBFILTER meets the security goals outlined in Section 3 using the deployment and configurations described in that section.

Complete Mediation (G1). As we previously discussed, USBFILTER must mediate all USB packets between devices and applications on the host. In order to ensure this, we have instrumented USBFILTER into the USB host controller, which is the last hop for USB packets before leaving the host machine and the first when entering it. Devices cannot initiate USB packet transmission without permission from the controller.

We also instrument the virtual USB host controller (*vhci*) to cover virtual USB devices (e.g., USB/IP). To support other non-traditional USB host controllers such as Wireless USB [19] and Media Agnostic USB [16], USBFILTER support is easily added via a simple kernel API call and the inclusion of a header file.

Tamperproof (G2). USBFILTER is statically compiled and linked into the kernel image to avoid being unloaded as a kernel module. The integrity of this runtime, the associated database, and user-space tools is assured through the SELinux policy as described in Section 3.4.2. Tampering with the kernel or booting a different kernel is the only way to bypass USBFILTER, and platform integrity measures provide detection capabilities for this scenario (Section 3.4.1).

Formal Verification (G3). The formal verification of USBFILTER rules is implemented as a logic engine within USBTABLES using GNU Prolog [11]. Instead of trying to prove that an abstract model of rule semantics is correctly implemented by the code, which is usually intractable for the Linux kernel, we limit our focus on rule correctness and consistency checking. Each time USBTABLES is invoked to add a new rule, the new rule and the existing rules are loaded into the logic engine for formal verification. This process only needs to be performed once when adding a new rule and USBFILTER continues to run while the verification takes place.

The verification checks for rules with the same conditions but different actions. These rules are considered conflicting and USBTABLES will terminate with error when this occurs. We define the correctness of a rule:

$$\begin{aligned} is_correct(R, \mathbb{R}) \leftarrow \\ & is_name_unique(R) \wedge \\ & are_condition_values_in_range(R) \wedge \\ & has_no_conflict_with_existing_rules(R, \mathbb{R}). \end{aligned}$$

where R is a new USBFILTER rule and \mathbb{R} for all other

existing rules maintained by USBFILTER. If the new rule has a unique name, all the values of conditions are in range, and it does not conflict with any existing rules, the rule is correct.

While the name and the value checks are straightforward, there are different conflicting cases between the conditions and the action, particularly when a rule does not contain all conditions. For example, a rule can be contradictory with, a sub rule of, or the same as another existing rule. As such, we define the general conflict between two rules as follows:

$$\begin{aligned} \text{general_conflict}(R_a, R_b) \leftarrow \\ \forall C_i \ni \mathcal{C}: \\ (\exists C_i^a \ni R_a \wedge \exists C_i^b \ni R_b \wedge \text{value}(C_i^a) \neq \text{value}(C_i^b)) \vee \\ (\exists C_i^a \ni R_a \wedge \nexists C_i^b \ni R_b) \vee \\ (\nexists C_i^a \ni R_a \wedge \exists C_i^b \ni R_b). \end{aligned}$$

A rule R_a is generally conflicted with another rule R_b if all conditions used by R_a are a subset of the ones specified in R_b . We consider a *general conflict* to occur if the new rule and an existing rule would fire on the same packet.

Based on the general conflict, we define *weak conflict* and *strong conflict* as follows:

$$\begin{aligned} \text{weak_conflict}(R_a, R_b) \leftarrow \\ \text{general_conflict}(R_a, R_b) \wedge \text{action}(R_a) = \text{action}(R_b). \\ \text{strong_conflict}(R_a, R_b) \leftarrow \\ \text{general_conflict}(R_a, R_b) \wedge \text{action}(R_a) \neq \text{action}(R_b). \end{aligned}$$

While weak conflict shows that the new rule could be a duplicate of an existing rule, strong conflict presents that this new rule would not work. The weak conflict, however, depending on the requirement and the implementation, may be allowed temporarily to shrink the scope of an existing rule while avoiding the time gap between the old rule removed and the new rule added. For instance, rule A drops any USB packets writing data into any external USB storage devices. Later on, the user decides to block write operations only for the Kingston thumb drive by writing rule B, which is weak conflicted with rule A, since both rules have the same destination and action. When the user wants to unblock the Kingston storage by writing rule C, rule C is strong conflicted with both rule A and B, since rule C has a different action, and will never work as expected because of rule A/B. By relying on the logic reasoning of Prolog, we are able to guarantee that a rule before added is formally verified no conflict with existing rules³.

³Note that all rules are monotonic by design, which means rules to be added cannot override existing ones. Future work will add general rules, which can be overwritten by new rules.

```

```

Figure 4: The output of “usbtables -h”. The permitted conditions are divided into 4 tables: the process table, the device table, the packet table, and the Linux USBFILTER Module (LUM) table.

Granular (G4). A USBFILTER rule can contain 21 different conditions, excluding the name and action field. We further divide these conditions into 4 tables, including the process, device, packet, and the Linux USBFILTER Module (LUM) table, as shown in Figure 4. The process table lists conditions specific to target applications; the device table contains details of USB devices in the system; the packet table includes important information about USB packets; and the LUM table determines the name of the LUM to be used if needed. Note that all LUMs should be loaded into the kernel before being used in USBFILTER rules.

Module Extension (G5). To support customized rule construction and deep USB packet analysis, USBFILTER allows system administrators to write Linux USBFILTER Modules (LUMs), and load them into the kernel as needed. To write a LUM, developers need only include the `<linux/usbfILTER.h>` header file in the kernel module, implement the callback `lum_filter_urb()`, and register the module using `usbfilter_register_lum()`. Once registered, the LUM can be referenced by its name in the construction of a rule. When a LUM is encountered in a rule, besides other condition checking, USBFILTER calls the `lum_filter_urb()` callback within this LUM, passing the USB packet as the sole parameter. The callback returns 1 if the packet matches the target of this LUM, 0 otherwise. Note that the current implementation supports only one LUM per rule.

5 Evaluation

The USBFILTER host machine is a Dell Optiplex 7010 with an Intel Quad-core 3.20 GHz CPU with 8 GB memory and is running Ubuntu Linux 14.04 LTS with kernel version 3.13. The machine has two USB 2.0 controllers and one USB 3.0 controller, provided by the Intel 7 Series/C210 Series chipset. To demonstrate the power of USBFILTER, we first examine different USB devices and provide practical use cases which are non-trivial for traditional access control mechanisms. Finally we measure the overhead introduced by USBFILTER.

The default behavior of USBFILTER in our host machine is to allow the USB packet if no rule matches the packet. A more constrained setting is to change the default behavior to drop, requiring each permitted USB device to need an allow rule. In this setting, malicious devices have to impersonate benign devices to allow communications, which are still regulated by the rules, e.g., no HID traffic allowed for a legit USB storage device. All tests use the same front-end USB 2.0 port on the machine.

5.1 Case Studies

Listen-only USB headset. The typical USB headset is a composite device with multiple interfaces including speakers, microphone, and volume control. Sensitive working environments may ban the use of USB headsets due to possible eavesdropping using the microphone [17]. Physically disabling the headset microphone is often the only mechanism for permanently removing it, as there is no other way to guarantee the microphone stays off. Users can mute or unmute the microphone using the desktop audio controls at any time after login. However, with USBFILTER, the system administrator can guarantee that the headset’s microphone remains disabled and cannot be enabled or accessed by users.

We use a Logitech H390 Headset to demonstrate how to achieve this guarantee on the USBFILTER host machine:

```
usbttables -a logitech-headset -v ifnum=2,product="Logitech USB Headset",manufacturer=Logitech -k direction=1 -t drop
```

This rule drops any incoming packets from the Logitech USB headset’s microphone. By adding the interface number (`ifnum=2`), we avoid breaking other functionality in the headset.

Customizing devices. To further show how USBFILTER can filter functionalities provided by USB devices, we use Teensy 3.2 [29] to create a complex USB device with five interfaces including a keyboard, a mouse, a joystick, and two serial ports. The keyboard contin-

ually types commands in the terminal, while the mouse continually moves the cursor. We can write USBFILTER rules to completely shutdown the keyboard and mouse functionalities:

```
usbttables -a teensy1 -v ifnum=2,manufacturer="Teensyduino",serial=1509380 -t drop  
usbttables -a teensy2 -v ifnum=3,manufacturer="Teensyduino",serial=1509380 -t drop
```

In these rules, we use condition “`manufacturer`” and “`serial`” (serial number) to limit the Teensy’s functionality. Different interface numbers represent the keyboard and the mouse respectively. After these rules applied, both the keyboard and the mouse return to normal.

Default-deny input devices. Next, we show how to defend against HID-based BadUSB attacks using USBFILTER. These types of devices are a type of *trojan horse*; they appear to be one device, such as a storage device, but secretly contain hidden input functionality (e.g., keyboard or mouse). When attached to a host, the device can send keystrokes to the host and perform actions as the current user.

First, we create a BadUSB storage device using a Rubber Ducky [18], which looks like a USB thumb drive but opens a terminal and injects keystrokes. Then we add following rules into the host machine:

```
usbttables -a mymouse -v busnum=1,devnum=4,portnum=2,  
    devpath=1.2,product="USB Optical Mouse",  
    manufacturer=PixArt -k types=1 -t allow  
usbttables -a mykeyboard -v busnum=1,devnum=3,  
    portnum=1,devpath=1.1,  
    product="Dell USB Entry Keyboard",  
    manufacturer=DELL -k types=1 -t allow  
usbttables -a noducky -k types=1 -t drop
```

The first two rules whitelist the existing keyboard and mouse on the host machine; the last rule drops any USB packets from other HID devices. After these rules are inserted into the kernel, reconnecting the malicious device does nothing. Attackers may try to impersonate the keyboard or mouse on the host machine. However, we have leveraged information about the physical interface (`busnum` and `portnum`) to write the first two rules, which would require the attacker to unplug the existing devices, plug the malicious device in, and impersonate the original devices including the device’s VID/PID and serial number. We leave authenticating individual USB devices to future work, however USBFILTER is extensible so that authentication can be added and used in rules.

Data exfiltration. To prevent data exfiltration from the host machine to USB storage devices, we write a LUM (Linux USBFILTER Module) to block the SCSI write command from the host to the device, as shown in Figure 9 in the Appendix. The LUM then registers itself with USBFILTER and can be referenced by its name in

rule constructions. In this case study, we use a Kingston DT 101 II 2G USB flash drive, and insert the following rule:

```
usbtables -a nodataexfil -v manufacturer=Kingston
    -l name=block_scsi_write -t drop
```

This rule prevents modification of files on the storage device. Interestingly, vim reports files on the device to be read-only, despite the filesystem reporting that the files are read-write. Since USBFILTER is able to trace packets back to the applications initiating I/O operations at the Linux kernel block layer, we are able to write rules blocking (or allowing) specific users or applications from writing to flash drive:

```
usbtables -a nodataexfil2 -o uid=1001
    -v manufacturer=Kingston
    -l name=block_scsi_write -t drop
usbtables -a nodataexfil3 -o comm=vim
    -v manufacturer=Kingston
    -l name=block_scsi_write -t drop
```

The first rule prevents the user with `uid=1001` from writing anything to the USB storage; the second blocks vim from writing to the storage. We can also block any writes to USB storage devices:

```
usbtables -a nodataexfil4
    -l name=block_scsi_write -t drop
```

USBFILTER logs dropped USB packets, and these logs can easily be used in a centralized alerting system, notifying administrators to unauthorized access attempts.

Webcam pinning. Webcams can easily be enabled and accessed by attackers from exploiting vulnerable applications. Once access has been established, the attacker can listen or watch the environment around the host computer. In this case study, we show how to use USBFILTER to restrict the use of a Logitech Webcam C310 to specific users and applications.

```
usbtables -a skype -o uid=1001,comm=skype -v
    serial=B4482A20 -t allow
usbtables -a nowebcam -v serial=B4482A20 -t drop
```

The serial number of the Logitech webcam is specified in the rules to differentiate any others that may be attached to the system as well as to prevent other webcams from being attached. The first rule allows USB communication with the webcam only if the user is `uid=1001` and the application is Skype. The following `nowebcam` rule drops other USB packets to the webcam otherwise. As expected, the user can use the webcam from his Skype but not from Pidgin, and other users cannot start video calls even with Skype.

USB charge-only. Another form of BadUSB attacks is DNS spoofing using smartphones. Once plugged into the host machine, the malicious phone automatically enables USB tethering, is recognized as a USB NIC by the host,

	Prolog Engine	Min	Avg	Med	Max	Dev
Time (20 rules)	128.0	239.8	288.0	329.0	73.2	
Time (100 rules)	132.0	251.7	298.0	485.0	78.6	

Table 1: Prolog reasoning time (μ s) averaged by 100 runs.

then injects spoofed DNS replies into the host. The resulting man-in-the-middle attack gives the attacker access to the host’s network communications without the authorization of the user. To prevent this attack, we use USBFILTER to prevent all USB packets from a Google Nexus 4 smartphone:

```
usbtables -a n4-charger -v product="Nexus 4" -t drop
```

This rule drops any USB packets to/from the phone, which enforces the phone as a pure charging device without any USB functionality. The phone is unable to be used for storage or tethering after the rule is applied.

We can construct a more specific charge-only rule:

```
usbtables -a charger -v busnum=1,portnum=4 -t drop
```

This rule specifies a specific physical port on the host and this port can only be used for charging. This type of rule is useful where USB ports may be exposed (e.g., on a point of sale terminal) and cannot be physically removed. It is also vital to defend against malicious devices whose firmware can be reprogrammed to forge the VID/PID such as BadUSB, since this type of rule only leverages the physical information on the host machine. USBFILTER can partition all physical USB ports and limit the USB traffic on each port.

5.2 Benchmarks

We first measure the performance of the user-space tool, USBTABLES. We then measure the overhead imposed by USBFILTER.

The measurement host is loaded with the rules mentioned in the case studies above before beginning benchmarking. When coupled with the default rules provided by USBFILTER, there are 20 total rules loaded in the kernel. We chose 20 because we believe that a typical enterprise host’s USB devices (e.g., keyboard, mouse, removable storage, webcam, etc.) will total less than 20. Then we load 100 rules in the kernel to understand the scalability of USBFILTER.

5.2.1 Microbenchmark

USBTABLES Performance. We measure the time used by the Prolog engine to formally verify a rule before it is added into the kernel. We loaded the kernel with 20 and

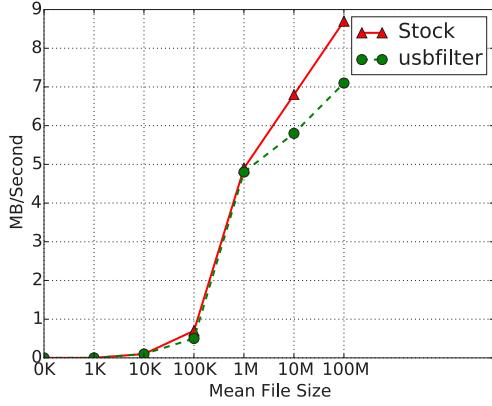

Figure 5: Filebench throughput (MB/s) using fileserver workload with different mean file sizes.

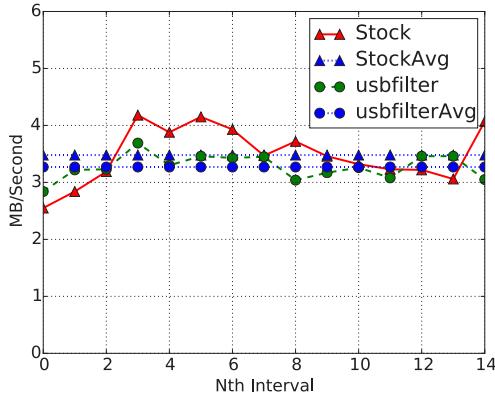

Figure 7: Iperf bandwidth (MB/s) using UDP with different time intervals.

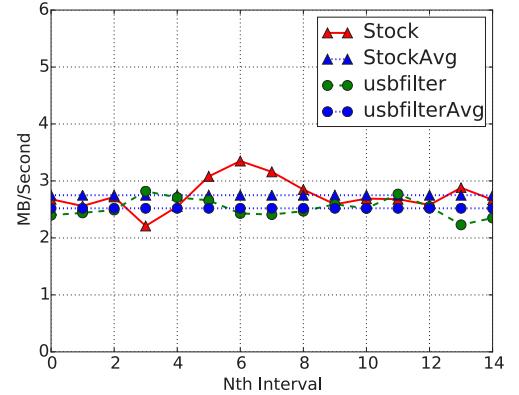

Figure 6: Iperf bandwidth (MB/s) using TCP with different time intervals.

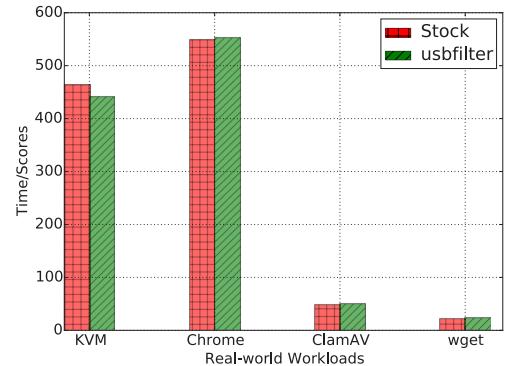

Figure 8: Performance comparison of real-world workloads.

Rule Adding	Min	Avg	Med	Max	Dev
Time (20 rules)	5.1	5.9	6.1	6.6	0.3
Time (100 rules)	4.9	5.9	6.1	6.8	0.4

Table 2: Rule adding operation time (ms) averaged by 100 runs.

100 rules and measured the time to process the rules. For each new rule, the Prolog engine needs to go through the existing rules and check for conflicts.

We measured 100 trials of each test. The performance of the Prolog engine is shown in Table 1. The average time used by the Prolog engine is $239.8 \mu s$ with 20 rules and $251.7 \mu s$ with 100 rules. This fast speed is the result of using GNU Prolog (`gplc`) compiler to compile Prolog into assembly for acceleration. We also measure the overhead for USBTABLES to add a new rule to the kernel space. This includes loading existing rules into the Prolog engine, checking for conflicts, saving the rule

USB Enumeration	Min	Avg	Med	Max	Dev	Cost
Stock Kernel	32.0	33.9	34.1	34.8	0.6	N/A
USBFILTER (20 rules)	33.2	34.4	34.3	35.8	0.7	1.5%
USBFILTER (100 rules)	33.9	34.8	34.6	36.0	0.5	2.7%

Table 3: USB enumeration time (ms) averaged by 20 runs.

locally, passing the rule to the kernel, and waiting for the acknowledgment. As shown in Table 2, the average time of adding a rule using USBTABLES stays at around 6 ms in both cases, which is a negligible one-time cost.

USB Enumeration Overhead. For this test, we used the Logitech H390 USB headset, which has 4 interfaces. We manually plugged the headset into the host 20 times. We then compare the results between the USBFILTER kernel with varying numbers of rules loaded and the stock Ubuntu kernel, where USBFILTER is fully disabled,

Packet Filtering	Min	Avg	Med	Max	Dev
Time (20 rules)	2.0	2.6	3.0	5.0	0.5
Time (100 rules)	2.0	9.7	10.0	15.0	1.0

Table 4: Packet filtering time (μ s) averaged by 1500 packets.

Configuration	1K	10K	100K	1M	10M	100M
Stock	97.6	98.1	99.2	105.5	741.7	5177.7
USBFILTER	97.7	98.2	99.6	106.3	851.5	6088.4
Overhead	0.1%	0.1%	0.4%	0.8%	14.8%	17.6%

Table 5: Latency (ms) of the `fileserver` workload with different mean file sizes.

as shown in Table 3. The average USB enumeration time is 33.9 ms for the stock kernel and 34.4 ms and 34.8 ms for the USBFILTER kernel with 20 and 100 rules preloaded respectively. Comparing to the stock kernel, USBFILTER only introduces 1.5% and 2.7% overheads, or less than 1 ms even with 100 rules preloaded.

Packing Filtering Overhead. The overhead of USB enumeration introduced by USBFILTER is the result of packet filtering and processing performed on each USB packet, since there may be hundreds of packets during USB enumeration, depending on the number of interface and endpoints of the device. To capture this packet filtering overhead, we plug in a Logitech M105 USB Optical Mouse, and move it around to generate enough USB packets. We then measure the time used by USBFILTER to determine whether the packet should be filtered/dropped or not for 1500 packets, as shown in Table 4. The average cost per packet are 2.6 μ s and 9.7 μ s respectively, including the time to traverse all the 20/100 rules in the kernel, and the time used by the benchmark itself to get the timing and print the result. The 100-rule case shows that the overhead of USBFILTER is quadrupled when the number of rule increases by one order of magnitude. As we mentioned before, most common USB usages could be covered within 20 rules. We assume it is rare for a system to have 100 rules for different USB devices. To search in hundreds of rules efficiently, we can setup a hash table using e.g., USB port numbers as keys to save rules instead of a linear array (list) currently implemented.

5.2.2 Macrobenchmark

We use filebench [37] and iperf [42] to measure throughputs and latencies of file operations, and bandwidths of network activities, under the stock kernel and the USBFILTER kernel, using different USB devices. The

USBFILTER kernel is loaded with 20 rules introduced in the case studies before benchmarking.

Filebench. We choose the `fileserver` workload in filebench, with the following settings: the number of files in operation is 20; the number of working threads is 1; the run time for each test case is 2 minutes; the mean file size in operation ranges from 1 KB to 100 MB; all other settings are default provided by filebench. These settings emulate a typical usage of USB storage devices, where users plug in flash drives to copy or edit some files. All file operations happen in a SanDisk Cruzer Fit 16 GB flash drive. The throughputs under the stock kernel and the USBFILTER kernel are demonstrated in Figure 5. When the mean file size is less than 1 MB, the throughput of USBFILTER is close to the one of the stock kernel. Since there is at most 20×1 MB data involved in block I/O operations, both the stock kernel and USBFILTER can handle this data size smoothly. When the mean file size is greater than 1 MB, USBFILTER shows lower throughputs comparing to the stock kernel, as the result of rule matching for each USB packet. Compared to the stock kernel, USBFILTER imposes 14.7% and 18.4% overheads when the mean file sizes are 10 MB and 100 MB respectively. That is, when there is 20×100 MB (2 GB) involved in block I/O operations, the throughput decreases from 8.7 MB/s to 7.1 MB/s, when USBFILTER is enabled.

The corresponding latencies are shown in Table 5. The latency of USBFILTER is higher than the stock kernel. Following the throughput model, the latencies between the two kernels are close when the mean file size is less than 1 MB. The overhead introduced by USBFILTER is less than 1.0%. When the mean file sizes are 10 MB and 100 MB, USBFILTER imposed 14.8% and 17.6% overheads in latency, comparing to the stock kernel. That is, to deal with 20×100 MB data, users need one more second to finish all the operations with USBFILTER enabled, which is acceptable for most users.

iperf. We use iperf to measure bandwidths of upstream TCP and UDP communications, where the host machine acts as a server, providing local network access via a Ralink RT5372 300 Mbps USB wireless adapter. The time interval for each transmission is 10 seconds, and each test runs 5 minutes (30 intervals). For TCP, we use the default TCP window size 64 KB; for UDP, we use the default available UDP bandwidth size 10 MB. The TCP bandwidths of the two kernels are shown in Figure 6, where we aggregate each two intervals into one, reducing the number of sampling points from 30 to 15, and the average bandwidths are also listed in dot lines. Though having different transmission patterns, the average bandwidths of both are close, with the stock kernel at 2.75 Mbps and USBFILTER at 2.52 Mbps. Comparing to

the stock kernel, USBFILTER introduces 8.4% overhead.

The UDP benchmarking result closely resembles TCP, as shown in Figure 7. Regardless of transmission patterns, average bandwidth of the two kernels is similar, with the stock kernel at 3.48 Mbps and USBFILTER at 3.27 Mbps. Comparing to the TCP transmission, UDP transmission is faster due to the simpler design/implementation of UDP, and USBFILTER introduces 6.0% overhead. In both cases, USBFILTER has demonstrated a low impact to the original networking component.

5.3 Real-world Workloads

To better understand the performance impact of USBFILTER, we generate a series of real-world workloads to measure typical USB use cases. In the KVM [24] workload, we create and install a KVM virtual machine automatically from the Ubuntu 14.04 ISO image file (581 MB) saved on USB storage. In the Chrome workload, we access the web browser benchmark site [5] via a USB wireless adapter. In the ClamAV [25] workload, we scan the unzipped Ubuntu 14.04 ISO image saved on the USB storage for virus using ClamAV. In the wget workload, we download the Linux kernel 4.4 (83 MB) via the USB wireless adapter using wget. The USB storage is the SanDisk 16 GB flash drive, and the USB wireless adapter is the Ralink 300 Mbps wireless card. All time measurements are in seconds except the Chrome workload, where scores are given, and are divided by 10 to fit into the figure. Figure 8 shows the comparison between the two kernels when running these workloads. In all workloads, USBFILTER either performs slightly better than the stock kernel, or imposes a small overhead compared to the stock kernel in our test. It is clear that USBFILTER approximates the original system performance.

5.4 Summary

In this section, we showed how USBFILTER can help administrators prevent access to unauthorized (and unknown) device interfaces, restrict access to authorized devices using application pinning, and prevent data exfiltration. Our system introduces between 3 and 10 μ s of latency on USB packets while checking rules, introducing minimal overhead on the USB stack.

6 Discussion

6.1 Process Table

We have successfully traced each USB packet to its originating application for USB storage devices by passing the PID information along the software stack from the

VFS layer, through the block layer, to the USB layer within the kernel. However, it is not always possible to find the PID for each USB packet received by the USB host controller. One example is HID devices, such as keyboards and mouses. Keystrokes and mouse movements happen in the interrupt (IRQ) context, where the current stopped process has nothing to do with this USB packet. All these packets are delivered to the Xorg server in the user space, which then dispatches the inputs to different applications registered for different events. USBFILTER is able to make sure that only Xorg can receive inputs from the keyboard and mouse. To guarantee the USB packet delivered to the desired application, we can enhance the Xorg server to understand USBFILTER rules.

The other example comes from USB networking devices. Though we have enhanced the general USB wire-line driver `usbnet` to pass the PID information into each USB packet, unlike USB storage devices sharing the same `usb-storage` driver, many USB Ethernet dongles have their own drivers instead of using the general one. Even worse, there is no general USB wireless driver at all. Depending of the device type and model, one may need to instrument the corresponding driver to have the PID information, like what we did for `rt2800usb` driver. Future work will introduce a new USB networking driver framework to be shared by specific drivers, providing a unified interface for passing PID information into USB packets.

Another issue of using process table in USBFILTER rules is TOCTTOU (time-of-check-to-time-of-use) attacks. A malicious process can submit a USB packet to the kernel and exit. When the packet is finally handled by the host controller, USBFILTER is no longer able to find the corresponding process given the PID. Fortunately, these attacks does not impact rules without process tables. When process information is crucial to the system, we recommending using `USBTABLES` to change the default behavior to “drop”, make sure that no packet would get through without an explicit matching rule.

6.2 System Caching

USBFILTER is able to completely shut down any write operations to external USB storage devices, preventing any form of data exfiltration from the host machine. Similarly, one can also write a “`block_scsi_read`” LUM to stop read operations from storage devices. Nevertheless, this LUM may not be desired or work as expected in reality. To correctly mount the filesystem in the storage device, the kernel has to read the metadata saved in the storage. One solution would be to delay the read blocking till the filesystem is mounted. However, for performance considerations, the Linux kernel also reads ahead some data in the storage, and brings it into the system

cache (page cache). All following I/O operations will happen in the memory rather than the storage. While memory protection is out of scope for this paper, we rely on the integrity of the kernel to enforce the MAC model it applies. Write operations, even though in the memory, will be flushed into the storage, where USBFILTER is able to provide a strong and useful guarantee.

6.3 Packet Analysis From USB Devices

Because of the master-slave nature of the USB protocol, we do not setup USBFILTER in the response path, which is from the device to the host, due to performance considerations. However, enabling USBFILTER in the response path provides new opportunities to defend against malicious devices and users, since the response packet could be inspected with the help of USBFILTER. For example, one can write a LUM to limit the capability of a HID device, such as allowing only three different key actions from a headset’s volume control button, which is implemented by GoodUSB as a customized keyboard driver, or disabling sudo commands for unknown keyboards. Another useful case is to filter the spoofing DNS reply message embedded in the USB packet sent by malicious smart phones or network adapters, to defend against DNS cache poisoning. We are planning to investigate these new case studies in future work.

6.4 Malicious USB Drivers and USB Covert Channels

While BadUSB is the most prominent attack that exploits the USB protocol, we observe that using USB communication as a side channel to steal data from host machines, or to inject malicious code into hosts, is another technically mature and plausible threat. On the Linux platform, with the development of libusb [14], more USB drivers run within user space and can be delivered as binaries. On Windows platform, PE has been a common format of device drivers. To use these devices, users have to run these binary files without knowing if these drivers are doing something else in the meantime.⁴ For instance, USB storage devices should use bulk packets to transfer data per the USB spec. However, a malicious storage driver may use control packets to stealthily exfiltrate data as long as the malicious storage is able to decode the packet. This works because control transfers are mainly used during the USB enumeration process. With the help of USBFILTER, one can examine each USB packet, and filter unrecognized ones without breaking the normal functionality of the device.

⁴N.B. that there are ways to instrument DLL files on Windows platform, though this does not appear to be commonly done with drivers.

6.5 Usability Issues

To write USBFILTER rules, one needs some knowledge about the USB protocol in general, as well as the target USB device. The `lsusb` command under Linux provides a lot of useful information that can directly be mapped into rule construction. Another tool `usb-devices` also helps users understand USB devices. Windows has a GUI program `USBView` to visualize the hierarchy and configuration of USB devices plugged into the host machine. While users can write some simple rules, we expect that developers will provide useful LUMs, which may require deep understanding of the USB protocol and domain specific knowledge (e.g., SCSI, and will share these LUMs with the community. We will also provide more useful LUMs in the future.

7 Related Work

Modern operating systems implicitly approve all interfaces on any device that has been physically attached to the host. Due to this, a wide range of attacks have been built on USB including malware and data exfiltration on removable storage [15, 34, 46], tampered device firmware [27, 7], and unauthorized devices [1]. These attacks fall into two major categories: those that involve data ingress and egress via removable storage and those that involve the attachment of unknown USB interfaces.

Proposals for applying access control to USB storage devices [12, 28, 38, 48] fall short because they cannot guarantee that the USB write requests are blocked from reaching the device. Likewise, defenses against unauthorized or malicious device interfaces [41, 33] and disabling device drivers are coarse and cannot distinguish between desired and undesired usage of a particular interface. Another solution employed by the Windows Embedded platform [26] binds USB port numbers with the VID/PID/CID (device class ID) information of devices to accept/reject the device plugged in. While CID helps limit the usage of the device, this solution does not work for composite devices equipped with multiple interfaces (with different CIDs). Besides, users may have to update the policy each time when different devices are plugged into the same port. Given the increasing ubiquity of USB, this is not a sustainable solution. Guardat demonstrates a means of expressing a robust set of rules for storage access but requires substantial new mechanisms for operation within a host computer, such as implementation within a hybrid disk microcontroller [45].

Netfilter [40] has become the de facto network firewall standard on Linux due to its ability to perform fine-grained filtering on network packets between applications and the physical network interface. Netfilter

can prevent compromise of a program by preventing unwanted packets from reaching the process. Similarly, our system can defend processes by denying USB traffic before it reaches its destination.

Furthermore, fine-grained filtering has been applied to the usage of filesystem objects by applications [13, 35], however, these filters take place *after* the host and operating system have enumerated the device and loaded any device drivers. USBFILTER applies filtering at the USB packet layer, preventing unauthorized access to interfaces regardless of whether they have been approved elsewhere. Since our system operates between the device drivers and the USB host controller and traces packets back to their source or destination application, USBFILTER can uniquely filter access to any USB interface.

While USBFILTER working in the host operating system directly, other USB security solutions make use of virtualization. GoodUSB [41] leverages a QEMU-KVM as a honeypot to analyze malicious USB devices, while Cinch [3] separates the trusted USB host controller and untrusted USB devices into two QEMU-KVMs, between which a gateway is used to apply policies on USB packets. By mitigating the need for additional components for standard operation, we believe that USBFILTER is better suited for adoption within operating system kernels.

USBFILTER protects the host machine from malicious USB devices, but there are solutions as well for exploring the protection of devices from malicious hosts. USB fingerprinting [6] establishes the host machine identity using USB devices, while Kells [8] protects the USB storage device by attesting the host machine integrity.

Wang and Stavrou [47] suggest that a “USB firewall” might protect against exploitation attacks but do not discuss the complexities of how such a mechanism could be designed or implemented.

8 Conclusion

USB attacks rely on hosts automatically authorizing any physically-attached device. Attackers can discreetly connect unknown and unauthorized interfaces, causing device drivers to be automatically loaded and allowing malicious devices access to the host. In this paper, we prevent unauthorized devices from accessing a host with USBFILTER, the first packet-level access control system for USB. Through tracing each packet back to its associated process, our system can successfully block unauthorized interfaces and restrict access to devices by process. With a default deny policy for new devices, administrators can restrict connection of unknown devices using granular identifiers such as serial number. Our experiments test USBFILTER using a range of I/O benchmarks and find that it introduces minimal overhead. The result is a host that is unresponsive to attacks that may try

to discreetly introduce unknown functionality via USB while maintaining high performance.

Abstract

Spraying is a common payload delivery technique used by attackers to execute arbitrary code in presence of Address Space Layout Randomisation (ASLR). In this paper we present *Graffiti*, an efficient hypervisor-based memory analysis framework for the detection and prevention of spraying attacks. Compared with previous solutions, our system is the first to offer an efficient, complete, extensible, and OS independent protection against all spraying techniques known to date. We developed a prototype open source framework based on our approach, and we thoroughly evaluated it against all known variations of spraying attacks on two operating systems: Linux and Microsoft Windows. Our tool can be applied out of the box to protect any application, and its overhead can be tuned according to the application behavior and to the desired level of protection.

1 Introduction

Memory corruption vulnerabilities are currently one of the biggest threat to software and information security. Education plays a very important role in this area, making programmers aware of common threats and teaching them how to avoid mistakes that may lead to exploitable bugs in their code. However, education alone is not enough, and a good defense in depth approach requires also to put in place multiple layers of mitigation, detection, and exploit prevention mechanisms.

In this field, over the past decade we have witnessed a constant arms race, with the system designers of compilers and operating systems on one side, and the attackers on the other. Over the years, the former have introduced many new security features to increase the complexity of exploiting memory corruption vulnerabilities [31, 6, 41, 9, 40]. This list includes stack canaries [13, 12], data execution prevention (DEP) [2], Address Space Layout Randomization (ASLR) [43, 7, 26, 8], Structured Ex-

ception Handling Overwrite Protection (SEHOP) [29], and Control Flow Integrity [3]—just to name some of the most popular solutions. Even though the combination of all these techniques have certainly increased the security of modern operating systems, no matter how high the bar was set, attackers have always found a way to overcome it to take control of a vulnerable system.

ASLR is certainly one of the most common and successful techniques adopted by modern operating systems. In fact, the objective of the majority of memory corruption exploits is to allow the attacker to execute arbitrary code in the context of a vulnerable process. The code can be injected by the attacker herself, or it can be constructed by reusing instructions already present in memory (e.g., in the case of return-to-libc or return oriented programming). Either way, the attacker needs to know where such code is located in memory, in order to divert the control flow of the application to that precise address. And here is where ASLR plays its role: by completely randomizing the layout of the process memory, it makes much harder for the attacker to predict where a certain buffer (or an existing code gadget) will be located at run-time. Unfortunately, attackers found a very simple and effective solution to overcome this protection: fill the memory with tens of thousands of identical copies of the same malicious code, and then jump to a random page¹, hoping to land in one of the pre-loaded areas. This makes this payload delivery technique, called *spraying*, one of the key elements used in most of the recent memory corruption exploits.

Researchers have been looking for ways to mitigate this technique. Unfortunately, the few solutions proposed so far [36, 16, 21] were all tailored to defend 1) a particular application (typically the JavaScript interpreter in Internet Explorer), 2) using a given memory allocator, 3) in a specific operating system, and 4) against

¹Often a fixed address located on the process heap.

a single form of heap spraying. This made these solutions difficult to port to other environments, and unable to cope with all possible variations of heap spraying attacks. In fact, the original heap spraying attack is now just the tip of the iceberg. The technique has rapidly evolved in different directions, for example by taking advantage of just in time compilers (JIT), by focusing on the allocation of pools in the OS kernel, or by relying on stack pivoting to spray data instead of code. We strongly believe that the increased adoption and sophistication of heap spraying techniques clearly demonstrate the need for a general and comprehensive solution to this problem.

In this paper we present Graffiti, a hypervisor-based solution for the detection and prevention of all known variations of spraying attacks. We decided to implement our solution at the hypervisor level to obtain the first *OS-independent, allocator-agnostic* approach to track memory allocations that does not depend on the knowledge of the protected process, or system. By leveraging a novel micro-virtualization technique, Graffiti proposes an efficient and OS-agnostic framework to monitor memory allocations of arbitrary applications. The system is modular, and relies on a set of plug-ins to detect suspicious patterns in memory in realtime. For example, we developed a set of different detection modules based on statistical inference, designed to precisely identify all known spectrum of spraying attacks known to date. Moreover, while all the previous techniques [36, 21] focused on the defense of a particular application or memory allocator against a single form of heap spraying, our system offers the first general and portable solution to the problem.

Graffiti also offers a hot-plugging capability and therefore it can be installed on-the-fly without rebooting the machine and without modifying the native operating system. Our experiments, conducted both on Linux and Microsoft Windows, show that Graffiti has no false negatives and low false positives, with an overhead similar to the one of previous, much more limited, solutions.

In summary, our work makes the following contributions:

- We present the principles, design, and implementation of an effective real-time memory analysis framework. On top of our framework, we developed a set of heuristics to detect existing heap spraying techniques. To the best of our knowledge, we are the first to present a general, efficient, and comprehensive framework that can be applied to all modern operating systems and all existing applications.
- We propose a novel micro-virtualization technique that allows Graffiti to monitor the entire system in

terms of both processes and kernel threads, with low overhead.

- We have developed a prototype tool, and performed an experimental evaluation on several existing real-world spraying techniques. Our experiments show that the system is able to detect all the classes of spraying attacks we analyzed with low false positives and acceptable performance.
- We released the source code of the current Graffiti prototype, which is available at the following link: <https://github.com/graffiti-hypervisor/graffiti-hypervisor>

The rest of the paper is organized as follows. Section 2 provides background information on spraying attacks. Section 3 provides preliminary notions about Intel VT-x technology. Section 4, Section 5, Section 6 describe our solution from an architectural point of view. Section 7 reports results on evaluating Graffiti. Section 8 discusses about the security evaluation of our system. Section 9 compares our work with other relevant research and Section 10 discusses future directions and concludes the paper.

2 Spraying Attacks

Heap spraying is a payload delivery technique that was publicly used for the first time in 2001 in the telnetd remote root exploit [44] and in the eEye’s ISS AD20010618 exploit [15]. The technique became popular in 2004 as a way to circumvent Address Space Layout Randomization (ASLR) in a number of exploits against Internet Explorer [46, 47, 38].

Since 2004, spraying attacks have evolved and became more reliable thanks to improvements proposed by Sotirov [42] and Daniel [14] for a precise heap manipulation. Spraying can now be classified in two main categories, based on the protection mechanisms in place in the target machine: *Code Spraying* and *Data Spraying*. If Data Execution Prevention [2] (DEP) is not enabled, the attacker can perform the exploit by directly spraying the malicious code (e.g., the shellcode) in the victim process memory. On the other hand, when the system uses the DEP protection, the attacker would not be able to execute the injected code. To overcome this problem, two main approaches have been proposed: (a) perform the heap spraying by taking advantage of components that are not subjected to DEP, such as Just in Time Compilers (JITs), or (b) inject plain data that points to Return Oriented Programming (ROP) gadgets. While the internal details between the three aforementioned approaches

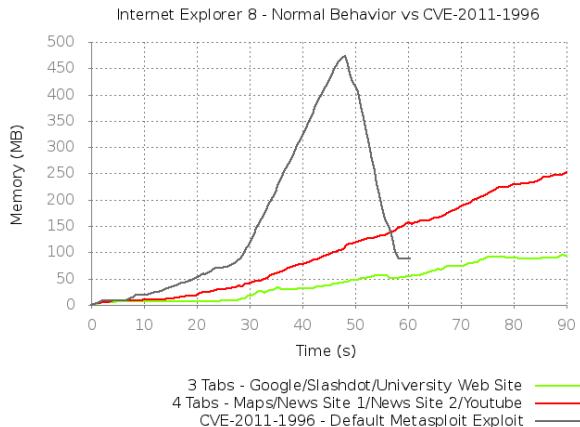

Figure 1: Heap Spraying attack

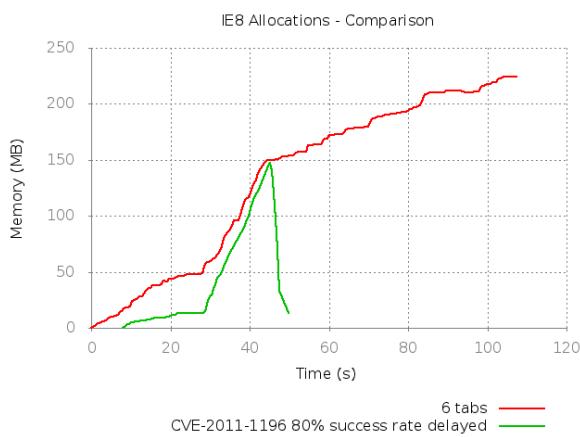

Figure 2: Mimicry attack

may be quite different, what is important for our research is that all these techniques share the same goal, i.e., to control the target dynamic memory allocation in order to obtain a memory layout that allows arbitrary code execution in a reliable way.

It is important to note that spraying is still a valuable technique also in x86_64-based operating systems. In particular, this is the case for user-after-free vulnerabilities – but spraying can also be used in conjunction with vulnerabilities in the ASLR implementation [10], in particular types of vulnerabilities [20], or because of the wide adoption of 32bit processes in 64bit operating systems (as recently shown by Skylined [39]).

2.1 Memory Footprint

The first characteristic of a heap spraying attack that comes to mind is the large amount of memory that is suddenly allocated by a process. Therefore we could erroneously believe that this unusual behavior alone (i.e., many pages allocated in a very short amount of time) could be sufficient to implement a solution to detect spraying attacks. For example, a simple approach could measure the speed of memory allocation and the average amount of memory usually allocated by the application under analysis. The first parameter would react to a quick memory increase, a common aspect of most of the existing attacks. The second parameter, once properly tuned for the application to protect, would act as a threshold of memory allocation, beyond which the behavior becomes suspicious and an alert is raised. It seems reasonable to believe that, by checking these two parameters, a detector could successfully prevent spraying attacks.

One of the main motivation of our work is to prove that the use of these two parameters is not sufficient for designing an effective spraying detection system. To prove our point, we designed a set of experiments to show that an attacker can tune the memory allocation behavior of an exploit to mimic the one of a normal application.

In our tests we used as a case study a classic heap spray attack against Internet Explorer 8 (described in CVE-2011-1996) but it is possible to replicate similar results with any applications where the memory allocation depends on input data. The first test we performed aimed at measuring the memory allocation curve while the user was visiting a small set of web sites. Figure 1 shows that the parallel execution of four common web applications (using parallel browser’s tabs) boosts the memory allocation of Internet Explorer to around 200MB. The same graph also shows the allocation curve of the CVE-2011-1996 exploit launched by Metasploit. In this case, the malicious behavior is easy to detect since it produces a huge allocation of memory in a short period of time – that then drops drastically after the success of the exploit. The drop is due to the fact that the shellcode spawns a process and releases the system resources of the previous execution thread along with its own memory. Other spraying attacks exhibit similar curves, a weakness that could be used to identify an ongoing malicious activity.

In the second experiment we wanted to answer two separate questions: i) how the total amount of memory allocated by the exploit affects the reliability of a spraying attack; and ii) whether it is possible for an attacker to slow down the attack in order to mimic the slope of the allocation curve observed on benign web pages. To

this end, we first modified our exploit to decrease the amount of sprayed memory. As we expected, reducing the number of allocated pages also reduces the probability of landing on one of them, thus making the exploit less reliable. We measured this phenomenon by running each exploit configuration ten consecutive times, counting in each case the number of successful attacks. The results of our tests show that the memory used by the original exploit can be largely reduced maintaining an acceptable success rate. For instance, the attack was still successful in 80% of the cases with a total memory consumption of only 131 MB – that is considerably less than what IE8 used in our benign scenario.

We then modified again the original exploit, this time introducing a delay between each memory allocation to mimic the behavior of a benign application. This change had no impact on the success rate of the attack. Figure 2 shows the allocation curve of our modified exploit, compared with a base line obtained by running Internet Explorer with six open tabs. From this experiment, it is clear that neither the speed nor the amount of memory can be used as the only criteria to detect a potential heap spraying exploit. By setting the threshold too low, the system would generate too many false alarms, and by raising the threshold too high the system would be vulnerable to evasions.

This conclusion motivates our further investigation to design a better memory monitoring and spraying attacks detection technique.

3 Preliminary Notions on Intel VT-x

Before we discuss our solution, we need to briefly introduce some virtualization concepts that we will use in the rest of the paper. Intel VT-x is a technology available in various Intel CPUs to support virtualization [23, 30].

VT-x defines two particular *transitions*: *vmexit*, to move from the guest to the hypervisor, and *vmentry*, to move in the opposite direction. As a result, the hypervisor is executed only when particular events in the guest trigger an exit transition. The set of events causing these transitions is extremely fine grained and can be configured by the hypervisor itself. Such events include exceptions, interrupts, I/O operations, and the execution of privileged instructions (e.g., accesses to control registers). Exits can also be *explicitly* requested by in-guest software, using the *vmcall* instruction. Because of its similarity to system calls, this approach is commonly called *hypercall*. Whenever an exit occurs, the hardware saves the state of the CPU in a data structure called Virtual Machine Control Structure (VMCS). The same structure also holds the set of exit-triggering events that

are currently enabled, as well as other control information of the hypervisor.

Another technology we need to introduce is the *Extended Page Tables* (EPT). This technology has been introduced to support memory virtualization, which is the main source of overhead when running a virtualized system. If enabled, the standard *virtual-to-physical* address translation is modified as follows. When a software in the guest references a virtual address, the address is translated into a physical address by the Memory Management Unit (MMU). However, the result of this operation is not a real physical address, but a *guest physical address* (*gpa*). The hardware then walks the EPT paging structures to translate the *gpa* into a *host physical address*, that corresponds to the actual physical address in the system memory. The EPT technology also defines two new exit transitions: *EPT Misconfiguration* and *EPT Violation*, respectively caused by wrong settings in EPT paging entries and by a guest attempting to access memory areas it is not allowed to. By altering the EPT entries, the hypervisor has full control of how the guest accesses physical memory. For example, it can remove write permissions from an entry, so that any write-access by the guest triggers a violation.

Threat Model

Our threat model considers an attacker that is able to exploit (either locally or remotely) an application running on the machine and to perform a spraying payload delivery. The use of a hypervisor-based technology is motivated by the goal of providing an OS-independent detection system and a more secure reference monitor.

Since we leverage late-launching to deploy our solution on operating systems running on physical machines, without requiring a reboot, we assume that the machine to be protected is clean when Graffiti is loaded. Thus, we consider the protection of already infected systems to be out of the scope of this paper.

4 Architecture Overview

In order to considerably improve over the state of the art, we set five main requirements for our detection system. First, it should be completely independent from the memory allocator used by the protected applications (R1). Second, it has to operate system-wide, i.e., it should be able to detect any memory allocation and deallocation that occurs in the system (R2) and it must be able to recognize any memory page that gets executed in the operating system (R3). Fourth, in order to operate correctly, our system should not require any OS-

dependent information (R4). Finally, the overhead introduced by the system should be reasonable, in line with other system-wide protection mechanisms. In particular, we consider a “reasonable” overhead, anything comparable to the one introduced by other virtualization systems such as XEN or VMware (R5).

To satisfy these five requirements, our system was designed to be easily extensible and configurable, and to tune its behavior (and therefore its overhead) to match the current level of risk of the monitored system. This is achieved by using two separate modes of operation.

Our monitoring platform is based on a custom hypervisor that normally runs in what we call *monitor mode*. In this mode, the hypervisor intercepts every new memory page that is allocated in the system, along with the CR3 register associated to the process that is requesting the memory. Whenever the total amount of memory requested by a single process exceeds a certain threshold (computed experimentally as described in Section 2.1) the system switches to *security mode* and starts performing additional checks to detect the presence of a possible attack for that particular application (while remaining in monitor mode for the other applications). In Section 2.1 we proved that a fixed threshold is not able to properly capture all the possible variations of spraying attacks. For this reason, in our system we use a threshold not for detection, but only to improve the performance of the system by disabling expensive checks when the total memory used by the process is too low for an attack to be successful. It is important to stress that in our solution, lowering the threshold for a given application does not introduce any false positives from the detection point of view, but only increases the overhead for that particular application alone (and not for the rest of the running system or for any other application).

When a process exceeds this minimum allocation threshold, the hypervisor performs two main tasks. First, using the EPT, it removes the execution permission from all the allocated pages, so that any attempt to execute code will be intercepted by the system. Second, it invokes the static analyzer component to check for the presence of a potential spraying attack. The actual detection is delegated to a configurable number of analysis plugins.

Figure 3 provides an overview of the system architecture and shows the interactions among the different components. The figure is divided in three parts, with user space on top, kernel space in the middle, and our custom hypervisor at the bottom. When an application (in this case a web browser) requests new memory, the kernel searches for a free page and it allocates it. At this point, when the OS tries to update the page table, the operation is intercepted by our hypervisor. If our system is

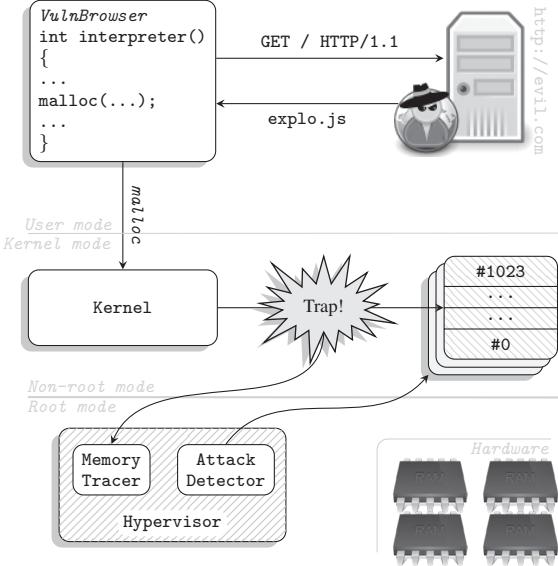

Figure 3: Architecture of the Memory Allocation Tracer.

running in monitor mode, the hypervisor only tracks the new memory allocation and gives back control to the operating system. If instead the application has already requested enough memory to trigger the security mode, our attack detection routines are executed to inspect the memory and flag any heap spraying attempt.

System Deployment

The main component that enables the protections enforced by Graffiti needs to keep an accurate track of all the allocation and deallocation operations that occur in the system. The main motivation of using a hypervisor is that, from a low level perspective, memory allocation is strictly dependent only on the hardware architecture, and not on the operating system itself. Thus, by working *below* the operating system, Graffiti avoids all the intricacies introduced by the various allocation engines, and therefore it does not require to modify or instrument the protected system (e.g., to place hooks inside OS components). Graffiti leverages late-launching to load its protection mechanism while the target is running. This hot-plug capability is achieved without rebooting the system, so it is transparent to the native OS. Finally, it is important to note that Graffiti is a very flexible system and can be configured according to the target needs. For instance, it can be deployed to monitor only a single sensitive process (e.g., a browser, or a PDF viewer), a set of thereof, or even the entire running system.

Our current prototype is implemented as an extension of HyperDbg, an open-source hardware-assisted hypervisor framework [17]. In Sections 5 and 6 we present

the design and implementation of the two main components of the system: the *Memory Tracer* and the *Attack Detection Routines*.

5 Memory Tracer

To implement our heap spraying protection technique, we must first keep track of all the allocation and deallocation operations that occur inside the system. Ideally, the most obvious solution to track memory allocations would be to modify the allocator itself, by extending the operating system with a new tracking feature. By doing so, however, our system would need to be customized for a particular operating system, and we would need to constantly update our tracker according to any OS upgrade.

To avoid this problem, we decided to implement our tracking approach at the hypervisor level (requirements R1 and R4), i.e., below the operating system. Since our approach is based on virtualization, from now on we will refer to the protected system alternatively with the term *guest* or *target*.

5.1 Tracer Design

Our system is designed to intercept every modification that is made by the guest OS to paging structures, and to recognize when the change corresponds to the creation or to the elimination of a page. To better illustrate our tracing technique, we will often refer to the paging structures that are used in the Intel architectures [23].

Whenever a process requires a new page, the kernel walks the paging structures of the requesting process looking for a usable Page Table Entry (PTE) in one of the Page Tables of the process (i.e., the second level structures). If none is found, it either allocates a new Page Table, by altering an entry on the first level paging structure (also known as the Page Directory), or it swaps some of the pages of the process to disk to create some empty slots. Once it has found or created a usable PTE, the kernel modifies it to map the allocated physical page to a virtual address, sets the lower 12 bits of the PTE to match the attributes of the page (e.g., `read/write`, `user/supervisor`), and returns the virtual address to the requesting process.

Our defense mechanism needs to keep a fine-grained view of every allocation to protect the system against spraying attacks. In particular, according to the address translation and new page allocation we need to intercept six different events: (1) Creation (2) Modification and (3) removal of a page. (4) Creation (5) Modification (6) Removal of a page table.

Whenever one of these six events is triggered by the kernel, our hypervisor intercepts the operation and acts accordingly. The first triple of events is traced to keep track of which pages a process allocates. The second group, on the other hand, must be traced to ensure that our system maintains a complete view of the allocated pages and does not miss any event in the first category.

5.2 Page Table Monitoring

Since Graffiti operates at the hypervisor level, it leverages the EPTs to write-protect all the page structures of a process. By doing so, it can intercept all modification attempts, as part of any of the six cases enumerated above. At first, the hypervisor detects when a new process is created by intercepting write operations to the CR3 register. As soon as a process is spawned by the kernel, a process will have just a limited number of paging structures, possibly inherited by its parent process (e.g., on Linux this depends on the flags of the `clone()` syscall that is used to spawn the process). To protect all its paging structures, Graffiti needs to traverse the page directory (pointed by the value of the CR3 register) and write-protect all the page tables pointed by each PDE. Page tables are scanned as well, to keep track of the physical pages allocated to the process by the kernel. After this setup phase is completed, each attempt to modify one of the pages would cause a trap in our hypervisor system.

Implementing the approach we just described while maintaining an acceptable overhead is a challenging task. At first, we use the EPTs to write-protect every paging structure of a target process. By doing so, whenever the OS kernel attempts to modify such structures because the process requires it (1), an EPT violation transfers the execution to the memory tracer component of our hypervisor framework (2). The violation is handled by removing the write protection and keeping a copy of the value of the entry (PTE or PDE) being modified (3), and re-executing the faulting instruction by performing an entry with the monitor trap flag (MTF [23]) raised (4). After the instruction has been executed, the hypervisor obtains again the control thanks to the exit caused by MTF (5), compares the new value stored in the entry with the old one and uses this information to infer which of the six kernel operations described previously has occurred (6). Eventually, the protection is restored (7) and the control is given back to the guest kernel (8).

To make the tracing mechanism clearer, consider the following scenario: the hypervisor intercepts a write attempt to the 2nd PTE of the 1st page table. This PTE originally contains the value 0. After single-stepping through the write instruction, we collect the new value of the PTE: `old:0x00000000 new:0xaffe007`.

This means that the guest kernel is mapping a physical page (at address 0xcaffe000) with a `rw` permission and making it accessible to both user and kernel space. In fact, the three lowest bits are set, making the entry present, writable, and accessible to user mode processes. For our framework, this operation corresponds to a *create page* event. To intercept when a process is created, we catch CR3 write operations in the guest. When the CR3 value that is going to be written corresponds to the one of a process we want to protect, we apply the protection to its paging structure, as explained above. It is important to stress that our approach is completely OS independent, as the only knowledge we rely on is the meaning of the bits stored in the paging structures, and those solely depend on the CPU architecture.

5.3 Graffiti Micro-Virtualization

The system described so far does not satisfy the requirement R2. In fact our solution should be able to monitor the entire system, and not only a few processes at a time. Unfortunately, by extending the previous approach to the whole guest operating system (all user-space processes and kernel threads), we observed a thrashing [4] phenomenon that introduced a large overhead in the memory allocation. This phenomenon creates a large number of context switches between OS and hypervisor, thus increasing the system overhead.

This phenomenon happens when a modification of a memory page of the running process creates as a side effect a modification of a memory page of another non-running process. This is a consequence of the fact that some memory pages are shared among processes, and some kernel tasks perform operations on memory pages of different processes. We refer to this problem as the *interference problem*.

The impact of this interference can be measured by running two simple tests. In the first, we computed the overhead introduced by our system while protecting a single process (Internet Explorer 10) and in the second we protected other two processes (Acrobat and Firefox) on top of Internet Explorer. The overhead on Internet Explorer alone went from 22% in the first test to 63% in the second, just as a side effect of monitoring two additional applications. Unfortunately, the interference of protecting more processes and the kernel itself would quickly slow down the entire system to a point in which it would not be usable anymore.

Ideally, we would like to design our system to avoid the interference problem, so that the overhead would not depend on the number of monitored processes. To achieve this goal, we propose a novel *micro-virtualization* technique, where each process runs inside

its own virtual memory sandbox and our tracking system enables the memory protection of just the process which is currently running. More in details, our micro-virtualization technique bases its approach on the fact that the VMCS contains a pointer to the EPT (EPTP) currently used by the hypervisor (see Section 3). Since we use the EPT to protect the processes (as explained in Section 5), our idea is to create a different EPT for each of the processes we protect, and change the EPTP in the VMCS at every context switch. From a low level perspective, this corresponds to intercepting every CR3 write operation (also easily trappable through VT [17]) and modifying the VMCS so that the EPTP points to the EPT of the process that has been scheduled for execution. Protected processes will have their own EPTs, while un-protected ones will just use a common EPT. To this end, every time a new process is created, the system creates a new EPT and associates it to the new process. It is important to note that the creation of this new EPT is not very costly, since the page table at the process creation is tiny and we only need to identify and protect some of them. By using such a mechanism, the hypervisor automatically disables the memory tracking of the other unprotected processes and enables the trapping only for the pages that are related to the currently protected processes, thus avoiding the thrashing side effect. Since this solution requires only to change the EPT pointer when a context switch occurs, it does not increase the overhead of the system.

In order to validate our micro-virtualization mechanism we performed two main experiments by using three applications: IE10, Acrobat Reader and Firefox. During our first experiment we only protect one application (IE10) and we compute the execution time and the overhead obtained by surfing several web pages in three main cases: (1) without hypervisor (2) with out hypervisor but without micro-virtualization and (3) with hypervisor and micro-virtualization enabled. From this first experiment the micro-virtualization does not introduce any additional overhead to the system when is used to protect a single process (23% in both cases with and without micro-virtualization). The only overhead introduced by the micro-virtualization occurs during the first loading of the new process. In this case the hypervisor needs to build up the EPT table for the new process by walking the process page tables. The overhead introduced during the loading time is 8%.

In the second experiment we test the scalability of our system with the new micro-virtualization mechanism enabled. This time we protect all three applications and we compute, like in the previous experiment, the execution time and the overhead obtained by surfing several web pages in the same three main cases: (1) with-

out monitoring the application (no hypervisor enabled) (2) with hypervisor but without micro-virtualization and (3) with hypervisor and micro-virtualization enabled. The overhead was 63% without micro-virtualization and 23% with micro-virtualization, confirming that the micro-virtualization is able to remove the overhead introduced by the *interference* problem.

As a result of our novel micro-virtualization architecture, our system is able to monitor an arbitrary number of different applications, without any increase in the system overhead. More specifically the overhead only applies to a particular protected application and it does not propagate to the rest of the system. For instance, if the user wants to protect only the browser and the PDF viewer against heap spraying attacks, any other application would not suffer any side effect or slowdown from our tracking system.

6 Detection Components

Whenever the total memory dynamically allocated by a process raises over a certain configurable threshold, the tracer switches to security mode and triggers a configurable number of static analysis routines to verify if a spraying attack is ongoing in the system.

Our current prototype includes three different components, presented in details in the next sections. These serve only as possible examples of the heuristics that can be easily plugged into our platform, and they could therefore be improved or extended with other techniques.

Malicious Code Detector

The aim of this component is to detect the simplest form of heap spraying. In this case, we assume the heap is randomized but executable, and therefore the attacker can spray the memory of the vulnerable target with multiple copies of a shellcode. Thus, the goal of this detector is to identify the presence of shellcodes inside the memory allocated by a process.

Our technique works as follows. First, the detector scans a fraction n of the most recently allocated memory pages and tries to disassemble them starting at twenty randomly selected offsets. For simplicity, any sequence of assembly instructions that terminates with a control transfer instruction that invokes a library call or system call is marked as a potential shellcode. To avoid cases where an attacker tries to obfuscate its attack by using an indirect control transfer instruction (iCTI), we consider each iCTI as a potential shellcode terminator.

The scan process is repeated for each allocated page and the detector finally reports the distribution of the

number of potential shellcode detected in each page. If the average number is higher than a given value, it raises an alarm. This approach derives from the observation that in the normal operation of a benign program only a small portion of the *analyzed* memory pages would contain a relevant fraction of valid instructions sequences. In an exploitation scenario, instead, most of the analyzed pages would contain close to 20 potential shellcode sequences. It is important to note that when the system starts disassembling from one page it continues till it reaches a code pointer, that may as well be located in a different page. If multiple pages are involved in such analysis they are all considered and marked as a shellcode container.

Self-unpacking Shellcode Detector

In this second scenario, we assume the same environment described before (ASLR enabled, DEP disabled), but we now consider the case in which an attacker packs her shellcode to make the detection more difficult. For example, all Metasploit payloads in spraying-assisted exploits are packed by default, e.g., by using the *shikata-ga-nai* encoder. Packed shellcodes are typically made up of a number of seemingly meaningless bytes, prepended with a small unpacking routine. The routine and the packed code are usually adjacent (i.e., they are located in the same memory page), as splitting them would lead to a waste of space and consequent loss of effectiveness when mounting the spraying attack.

Our second detection plugin is designed to detect packed shellcodes as soon as they start unpacking, and is tightly binded to the memory tracer. The component enforces what we call a *dynamic W \oplus X protection*. As soon as the memory tracer detects a new page allocation, it modifies the EPT entry corresponding to the newly allocated page so that a violation will be triggered when a write access to that page is attempted (R-X). The detector intercepts these attempts and modifies the EPT entry of the accessed page so that write accesses are enabled, but not execution accesses (RW-). If this new protection triggers a violation, we have a *write-then-execute* situation, which is fairly common in nowadays systems (especially with JIT engines). However, this mechanism allows to observe the more anomalous situation in which code modifies the same memory page in which it resides, that indicates the presence of self modifying code, used by packed shellcodes as described above. This technique is also effective when DEP is enabled on the heap memory, and the attacker uses a JIT-spraying attack. In fact, if the JIT-sprayed payload is packed, it will need to unpack itself and thus will trigger our detection heuristic.

Data Spraying Detector

When DEP is enabled, and JIT spraying is not a viable solution (e.g., there is no JIT engine in the vulnerable process), a possible exploit solution is to use return oriented programming. In this case, the attacker no longer sprays the heap with executable code but instead with multiple copies of a ROP chain. To trigger the code, the attacker then uses a *pivoting sequence* to move the stack pointer into the heap and let execution slide down the ROP chain, as we explained in Section 2.

To detect data spraying attacks, we designed a component that samples the most recently allocated memory pages of a process, and it considers any word inside them as a potential memory address. For each of these candidate addresses, the data spraying detector checks whether this address points to a valid executable page, and, if so, marks it as a *potential code pointer*. In case the total number of code pointers for each page is over a threshold, the system raises an alarm.

Unfortunately, even though this policy may sound reasonable at a first glance, we observed that in practice it suffers from a large amount of both false positives and false negatives. The first problem is related to the fact that modern operating systems use different techniques to load pages, one of which is called *Demand Paging* [4]. In this case the pages are only brought into memory when the running-process demands them. This optimization creates an issue for our detection method because when the system extracts the potential code pointers from the memory pages and checks if they point to a valid code page, the page may not be present in the page table (even if it is properly allocated). We observed this behavior during our experiments, and the result is that certain addresses would be discarded—thus potentially creating *false negatives* by missing a page that is part of a spraying attack.

To avoid this issue, we modified our hypervisor to intercept page faults in the guest system when Graffiti switches to security mode for a given process. When the detector checks an address that points to a memory page that is not mapped, the system does not discard it but keeps it as a potential code pointer into the memory structures of the hypervisor. Afterwards, when the process gets access to the demanded page, the system loads it and our detection system intercepts the page faults and it checks if the potential code pointer points to this memory page. If true, the system marks all the memory pages previously allocated that contain such address as suspicious and then it re-applies again the previous technique on the new set of pages.

The second problem of our original technique is the high number of false positive we observed in the experiments because benign memory pages also contain a sig-

nificant number of code pointers (e.g., in case of C++ classes or arrays). To reduce the false positives created by those benign memory pages, we improved our detector algorithm by replacing the pointers counter with a more sophisticated pointers frequency analysis. The idea is to compute the frequency of the code pointers that *every* page of the entire set contains, instead of analyzing every page individually. While the absolute number of code pointers may be deceiving, we observed that the distribution of those pointers in case of benign applications is really diverse, while in case of an attack the distribution tends to be quite uniform.

7 Experimental Results

The goal of our experiments is to first measure the overhead of the system in a realistic environment and then to show how effective our heuristics are in distinguishing spraying attacks from a normal allocation behavior.

Our code is composed by three main software components: a core hypervisor framework based on HyperDBG, the micro-virtualization implementation, and the detector plugins. The core hypervisor framework is written in a combination of C (17353 LoC) and assembly (545 LoC). The micro-virtualization and detector components account for 1435 lines of C programming language.

All tests presented in this section were performed on two machines, equipped with an Intel Core i5-2500 @ 3.3 GHz and 8GB of RAM, running respectively Windows 7 Professional 32bit and Debian Wheezy 32bit (kernel 3.2).

Activation Threshold and Overhead

Our system is designed to be adaptive. Consequently, the only part that is always active is the Memory Tracer. Our micro-virtualization solution confines the overhead to a single process and allows our system to monitor an arbitrary number of different applications without any increase in the overhead of the rest of the system.

During normal operation, the tracker overhead is negligible, and it is only noticeable when the monitored application allocates tens of megabytes of memory at a time – typically at start up or when a large document is open. To measure this worst case scenario, we used the stress suite to simulate a program that intensively allocates memory on a Windows 7 and on a Linux 3.2 hosts at a rate of 8MB every 2 seconds. The overhead we observed during the allocation phase was of 24% on Windows and 25% on Linux for a single process without considering context switch. Again, it is important to

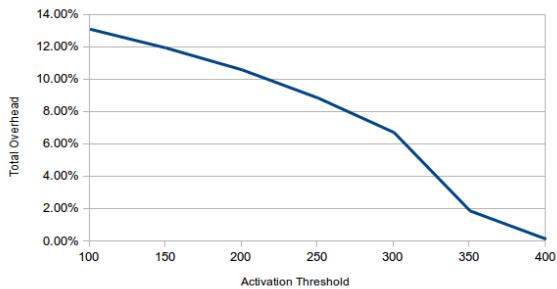

Figure 4: Detection Overhead for Internet Explorer 8

note the experiments performed in these tests produced a very intensive memory allocation activity and it is not representative of the memory behavior of the entire life of a process.

On top of this overhead, each application can observe a different overhead when Graffiti switches to security mode and enables the detection modules to scan the application memory. The frequency at which this happens depends on the value of the activation threshold. The lower the threshold, the hardest it is for an attacker to evade detection – but the higher the *potential* overhead for the application. “Potential” in this context means that the actual overhead also depends on the application: some use so little memory during their normal operation that the security mode would never be triggered - also for very low values of the threshold. Moreover, most of the applications only allocate large amount of memory when the user opens a document, but then the use of memory becomes quite constant - and therefore Graffiti’s negative impact tends to be concentrated only on the few initial seconds, and becomes negligible after that.

To measure this trade-off we performed two experiments. In the first, we asked some users to surf the web by using Internet Explorer 8 on Windows 7 with our detection system activated. We choose IE8 since this application usually uses a large amount of memory and it represents one of the main targets of spraying attacks. To mimic a realistic behavior, the users kept a tab open on GMail, and then alternately opened three other tabs performing memory intensive activities: watching videos on YouTube, browsing Facebook, and checking hundreds of pictures on 9gag. In the second experiment, we used Acrobat Reader for Linux to open 100 benign PDF files including conference papers, books, Ph.D. dissertations, and very large manuals (i.e., the Intel Manuals).

Following the approach used by Nozzle [36], we selected a sampling rate of 10% (number of pages checked

by our detection module over the total number of pages allocated). As a reference, with this value Nozzle introduced an overhead of 20% to Internet Explorer. The overhead obtained with our system is shown in Figure 4 for different values of threshold. Also in the worst case with the activation threshold set to 150MB, the overhead was only 12%. Moreover, the heuristic responsible for most of this overhead is the one that requires to randomly disassemble the content of the memory pages. Since this component is useless on any modern OS when DEP is enabled, the detection overhead of Graffiti becomes barely noticeable.

Moreover, our experiments with Acrobat Reader never reached the activation threshold, even when it was set at the conservative value of 100MB. In this case, the overhead of Graffiti on the normal use of the application was constantly zero – showing that for some popular applications our framework can provide a very complete protection against known and unknown attacks with no additional overhead.

Detection Accuracy

To test the effectiveness of our system, we measured the true and false positives rates for each individual detection technique that is currently included in the Graffiti prototype. To test the detection rate we used several real world exploits that cover all the different spraying techniques and variations mentioned in this paper. It is important to note that the six attacks that we chose for our experiments, summarized in Table 3, are representative for the entire spectrum of the techniques used by the spraying attacks described in Section 2. On top of this qualitative test, we also performed a quantitative test using over 1000 different malicious PDF documents that rely on heap spraying in the exploitation phase.

In the first test we show the effectiveness of our system to detect exploits based on stack pivoting, by using the attack described in CVE-2011-1996. The attack first sprays the stack frames on the heap and then executes a number of ROP gadgets in order to disable the DEP protection. During the spraying phase the attack allocates on average 384MB.

In this case, the static analyzer applied the code pointers frequency analysis on the attack memory pages. The component detected a high number of code pointers with a variance close to 0 in all the allocated memory pages, and thus it raised an alert successfully preventing the attack. To evaluate the false positive of such technique, we instructed our detector to track all the memory pages allocated by Internet Explorer 8 while browsing the first 1000 top Alexa domains [1]. In this case, the frequency of code pointers had a very high variance on all memory pages captured by the system, thus generating zero

Web Domain	Average	Variance

Table 2: Shellcode Frequency Analysis Results.

false alarms (Table 1 reports the results for the first 14 domains analyzed).

In the second set of experiments we tested the effectiveness of the Malicious Code detection component. In this case we used the exploit for CVE-2009-2477 affecting the Javascript interpreter of Mozilla Firefox 3.5. This attack exploits a memory corruption vulnerability in the Firefox browser, in which the Javascript interpreter fails to preserve the return value of the `escape()` function and results in the use of an uninitialized memory area. During the exploit, Graffiti reported that the average number of analyzed pages containing a potential shellcode was 100% – thus raising an alarm and stopping the attack. To test the false positive of the same detection technique, we used the same browser to visit the top 1000 Alexa domains. In this case, the average number of potential shellcodes per page was always below 50% and therefore no false alert were raised in the test. In table 2 we reported results about the first 14 domains analyzed, the number of pages that present potential shellcode and the average on shellcode found in the first 500 allocated memory pages. As we can see from the table, our malicious code detector component does not present any false positive.

CVE	Application	Exploit Technique	Detected
2010-0248	Adobe Flash player	ROP + packed sc	Yes
2011-0609	Adobe Reader	JIT + packed sc	Yes
2011-2462	Adobe Reader	ROP + packed sc	Yes
2010-2883	Adobe Reader	Ret2Lib + packed sc	Yes
2011-1996	IEexplorer	ROP	Yes
2009-2477	Firefox	Plain Shellcode	Yes

Table 3: Exploitation Detection Results.

In our third experiment, we analyzed the Self-unpacking Shellcode Detector component. In this case we selected different CVEs and we used the metasploit [35] tool to exploit them with packed payloads. In particular, we used two packing methods: the shikata-ga-nai packer and a simple xor algorithm. Our detection system was always able to intercept the first execution of the packed code and consequently detect the attacks without any false negative. Also for this component, we tested the false positive rate by browsing the top 1000 domains from the Alexa dataset. We did not observe any false positive, even though several website included obfuscated Javascript code. A further investigation on obfuscated java-script shows that the de-obfuscation routine is implemented at the compiler level so it does not present any problem or generate any false positive in our system.

To conclude, Table 3 reports all the vulnerabilities we used for our tests, along with the type of payload delivery and the detection results of Graffiti. Even though our detectors had a very high precision in all our tests, an attacker equipped with knowledge about the internals of our detectors could try to mimic the behavior of a benign application to evade detection. A further analysis of such attacks is presented in Section 8.

Aggregated Experiments

So far, we tested each piece of our infrastructure in isolation. In our final experiments, we put all pieces together. In the first test, we used Graffiti to analyze three datasets: a set of 1000 malicious PDF documents, a set containing 1000 benign web pages, and one containing 1000 benign PDFs. The first dataset was collected by a company working on malware analysis, while the other included the top Alexa web pages and random documents collected from various sources. All experiments were conducted with a very conservative activation threshold of 150MB and a sampling rate of 10%. Graffiti successfully detected all malicious documents, with zero false alarms. Moreover, the overhead on loading the web pages was in average of 23% (a value in line with previous OS-specific approaches that were only able to protect the web browser).

In the second experiment, we asked real users to use a Graffiti-protected system during their everyday activities for a total of 8-to-10 hours per day in a 7-days period. Graffiti was installed on two Windows 7 machines, configured to monitor Internet Explorer 8 with an activation threshold of 150 MB. All three spraying attacks detectors were enabled during the experiments (even though the first was not necessary on this setup). Overall, the real users visited a total of 492 distinct web pages and the detectors were activated 55 times, with an average of ≈ 8 times per day. On the same period, Graffiti raised 12 alerts on pages that seemed to be benign. A closer inspection of the FPs showed the data spraying detector (Section 6) to be the only responsible. This component is in charge of detecting data spraying attacks and bases its detection on the number of potential code pointers present in memory.

It is important to stress the fact that the three detection plugins are not the main contribution of our work, and our micro-virtualization framework allows other researchers to easily improve, extend, and replace them with other techniques. For instance, a possibility to decrease the false positive rate of this component could be to check not only if the code pointer points to a correct executable page, but also whether it points to a dangerous machine instruction sequences (e.g., a gadget). We manually inspected the websites that raised the false alarms and we found that applying such simple method would be able to prevent all the alerts. This check could be activated only when the data spraying detector identifies a possible attack, to prevent a significant increase of the overhead.

8 Security Evaluation

It is possible that an attacker, knowing the internals of our three detectors, could mount a mimicry attack that can successfully evade detection. For instance, an attacker can elude the code pointers frequency analysis by mimicking the variance of benign memory pages. Although this technique can be successful, it has two restrictions. The first is related to the minimum number of gadgets that the attacker needs to connect to perform a useful attack. To be useful, an attack should execute either an API call or a system call. Based on the number of API call parameters, we estimate that a useful number of gadgets for a standard shellcode is around 20 (i.e., to call the `VirtualProtect` function, commonly used in Windows shellcodes to remap a page as executable) even though some previous works show that the length of the gadgets for useful shellcode may vary from 8 to 12 [32]. The second restriction is related to the maximum number of gadgets that an attacker can include to

build a shellcode. Theoretically this number could be infinite. In case of spraying attacks, to increase the chance of success, the size of the shellcode should be smaller than the size of the NOP-sled, otherwise the probability to divert the control-flow of the application to the appropriate entry points decreases. In our experiments, for benign applications the range of code pointers in memory varies between 0 and 1024, with the vast majority of pages on the left end of the scale. These values are hard to mimic in a real attack. It may be possible in certain particular cases, but still our component would have considerably raised the bar making the exploitation much more difficult.

Another way an attacker can avoid detection is by evading the shellcode frequency analysis. To this end, the attacker can act on two parameters. She can decrease the number of successful entry points for each page – but this would drastically decrease the success rate of the attack. A second, more subtle, technique would consist in spraying the memory only with NOP instructions, and inject only one copy of the shellcode in a second time, when Graffiti already concluded its analysis. In this case we could extend our component to postpone the analysis when long nop sequences are identified. It is important to note that the attacker cannot wait for a long time in order to inject the shellcode, since any additional memory allocation done by the application would break the continuity of the nop sled.

A current limitations of Graffiti is that it cannot handle the case when an application allocates a big chunk of memory at the beginning of the process and then uses its own allocation functions to perform memory operations. However, since none of the applications that we tested in our experiments exhibited such behavior, we left this case for a future improvement.

To summarize, we believe that evading our three heuristics is not easy but it is certainly possible. However, the contribution of this paper is not in the heuristics per se, but in the underlying monitoring framework. Graffiti offers the first comprehensive, multi-OS solution, and this is an important step forward compared with existing defense solutions and compared with other techniques presented in previous papers.

9 Related Work

Several solutions have been proposed so far to cope with single instances of the spraying problem. In the following we summarize the existing works that address heap, JIT, and data spraying techniques.

Heap Spraying

Researchers have proposed several approaches for detecting heap-spraying attacks [36, 16, 21]. For example, Egele et al. [16] used x86 emulation techniques to defend web browsers against drive-by download attacks that use heap-spraying code injection. More in details, the authors proposed to check for the presence of a shellcode by monitoring all the strings that are allocated by the JavaScript interpreter. Their goal is similar to that of NOZZLE [36], which uses static analysis of the objects on the heap to detect heap-spraying attacks. In particular, NOZZLE scans memory objects looking for a sequence of instructions that includes a NOP sled and ends with a malicious shellcode. However, as the authors point out, the tool presents several drawbacks. For example, attackers can evade detection by avoid using large NOP sleds. Moreover, NOZZLE is also specific for the Java Script Engine Memory Allocator and it cannot be applied to a generic application. Another work to defend against heap spraying attack is BuBBLE [21]. In this case, the authors start from the assumption that an attack needs to spray a large part of the Heap memory with homogeneous data (i.e. NOP sled). BuBBLE breaks such an assumption by inserting special values in a random position inside strings before storing them in memory, and removing them when a string is used by the application. Again this solution is specific for the Javascript language and it cannot be easily ported for the protection of other applications.

Our approach is different since it does not require to know how the memory allocator of a particular interpreter engine works, and consequently it does not require access to source code and it is operating system independent. Moreover, it can protect any system application as well as kernel subsystems without any assumption about internals of the protected component.

JIT Spraying

Bania [5] proposed a detection technique based on the fact that in order to force the JIT compiler to generate code, an attacker should use ActionScript arithmetic operators. However, it is not mandatory for JIT spraying attacks to use arithmetic operations.

Another JIT spraying defense has been proposed by Hu et al. [22]. This solution consists of a kernel patch, JITsec, that tests for several conditions when a system call is invoked. In particular, the authors argue that an application can maintain its security properties and execute code from the stack and heap by decoupling sensitive from non-sensitive code and allowing the latter to run from writable memory pages. As a result, such detector only detects attacks that directly issue system

calls. Mimicry attack and ROP attacks are therefore not covered by this model.

JITDefender [11] is another work based on hardware-assisted technologies which aims at defeating JIT Spraying attacks. The system protects the Virtual Machine dynamic memory pages created by the JIT-Compiler and allows to execute only the pages requested by the VM. This approach is strictly VM dependent, and it can only detect JIT-spraying attack.

Our solution is orthogonal to the type of attack, and therefore it can successfully detect JIT-spraying attacks without any assumption about the instructions that are used by the attacker.

Finally, Lobotomy [27] proposes to mitigate JIT spraying attacks by applying the principle of least-privilege to the Firefox JIT engine: by splitting the compiler and executor modules of the engine, indeed, it greatly reduces the amount of code that needs to access writable *and* executable pages. The main drawbacks of Lobotomy, with respect to Graffiti, are: 1) its overhead, that is sensibly high if compared with ours, and 2) the need to re-design the JIT engine of the protected process. The latter is particularly hindering because it greatly limits the portability of Lobotomy to other JIT engines. On the contrary, Graffiti can seamlessly protect *any program*, without modifying any of its inner components.

Data Spraying

Several defensive solutions have been proposed to avoid pivoting-based techniques [28, 33, 34]. One of the most deployed is part of EMET [28], a solution designed by Microsoft. EMET is a utility that helps to prevent vulnerabilities in software from being successfully exploited. Among other features, EMET also addresses the problem of stack pivoting attacks by checking if the stack pointer points outside of a process stack boundaries whenever a dangerous API is invoked. However, several researchers proved that it is possible to bypass the EMET technology in many ways [24, 18, 37]. The impact of these studies show that technologies that operate at the same level of execution of the malicious code need to be extensively tested and carefully designed to offer the desired protection and avoid possible bypasses. Consequently, these studies also shows the importance of designing reference monitors that operate at a lower level (e.g., at the hypervisor level) such as Graffiti to avoid these trivial attacks.

Moreover, Microsoft recently introduced two new countermeasures to hinder browser exploitation: isolated heap and delayed free [25, 45]. Both these techniques raise the bar for use-after-free attacks; as stated by the Fortinet Labs researchers [19], they also make

heap manipulation harder, but they are not a general solution as they protect only the Internet Explorer browser.

10 Conclusion

In this paper we propose an efficient and comprehensive solution to defeat spraying attacks by tracking the memory allocations of the system in an OS-independent way.

Overall, our paper makes several contributions: we introduce the concept of micro-virtualization that allows us to design an efficient and effective memory allocator tracker. We presented Graffiti, a general and extensible memory analysis framework that has good performance and it is freely available and open source. On top of it, we created three heuristics to detect and prevent spraying attacks. However, we believe that in the future Graffiti can also be extended and adopted in other domains, such as malware analysis or memory forensics.

Request and Conquer: Exposing Cross-Origin Resource Size

Tom Van Goethem, Mathy Vanhoef, Frank Piessens, Wouter Joosen
iMinds-DistriNet, KU Leuven, 3001 Leuven, Belgium
first.lastname@cs.kuleuven.be

Abstract

Numerous initiatives are encouraging website owners to enable and enforce TLS encryption for the communication between the server and their users. Although this encryption, when configured properly, completely prevents adversaries from disclosing the content of the traffic, certain features are not concealed, most notably the size of messages. As modern-day web applications tend to provide users with a view that is tailored to the information they entrust these web services with, it is clear that knowing the size of specific resources, an adversary can easily uncover personal and sensitive information.

In this paper, we explore various techniques that can be employed to reveal the size of resources. As a result of this in-depth analysis, we discover several design flaws in the storage mechanisms of browsers, which allows an adversary to expose the exact size of any resource in mere seconds. Furthermore, we report on a novel size-exposing technique against Wi-Fi networks. We evaluate the severity of our attacks, and show their worrying consequences in multiple real-world attack scenarios. Furthermore, we propose an improved design for browser storage, and explore other viable solutions that can thwart size-exposing attacks.

1 Introduction

In 1996, Wagner and Schneier performed an analysis of the SSL 3.0 protocol [67]. In their research, the authors make the observation that although the content is encrypted, an observer can still obtain the size of the requested URL as well as the corresponding response size. The researchers further elaborate that because it is possible to make an inventory of all publicly available data on a website, knowing the size of requests and responses allows an attacker to determine which web page was visited. Although content is increasingly being served over secure SSL/TLS channels [55], the length of requests

and responses remains visible to a man-in-the-middle attacker. Consequently, the attack that was described by Wagner and Schneier two decades ago remains universally applicable. However, due to the various transitions the web underwent, the consequences of uncovering the size of remote resources have shifted drastically.

With the advent of online social networks, the dynamic generation of web pages goes even further. When browsing, each user is now presented with a personalized version, tailored to their personal preferences and information they, or members of their online environment, (un)willingly shared with these online services. Consequently, the resource that is returned when a user requests a certain URL will often reflect the state of that user.

Two types of size-exposing attacks, namely traffic analysis and timing attacks, have been widely studied. In traffic analysis, an adversary passively observes the network traffic that is generated by the victim's browsing behavior. Based on the observed size, sequence, and timing of requests and responses, an attacker can learn which website was visited by the victim [13, 25, 68], or uncover which search queries the user entered [12, 40]. In contrast to traffic analysis, where the threat model is typically defined as a passive network observer, launching a web-based timing attack requires the adversary to trick the victim in making requests to certain endpoints, which is typically achieved by running JavaScript code in the victim's browser. The attacker then measures the time needed for the victim to download the specified resources, which, depending on the victim's network condition, allows him to approximate the resource size, and ultimately obtain information on the state of the user [19, 7, 14].

Motivated by the severe consequences on the online privacy of a vast amount of users, we present a systematic analysis of possible attack vectors that allow an adversary to uncover the size of a resource. As a result of this evaluation, we discover design flaws in various browser features that allow an adversary to uncover the exact size

of any resource. Furthermore, we demonstrate that by intercepting and manipulating encrypted Wi-Fi traffic, an adversary can uncover the exact size of an HTTP response. By leveraging these techniques, we show that when an attacker can make the victim send requests to arbitrarily chosen endpoints, the potential consequences of traffic monitoring become significantly more severe. In contrast to prior attacks, where adversaries could typically only obtain a rough estimate of the resource size, or were unable to attribute network traffic to specific requests, our size-exposing attacks show that the capabilities of an adversary are worryingly extensive, as we exemplify by the means of several real-world attack scenarios. Finally, we explore the viability of several defense mechanisms, leading to an improved browser design and a variety of possibilities for websites to thwart size-exposing attacks.

Our main contributions are:

- We perform an in-depth analysis at the level of the browser, network and operating system, and explore techniques that can expose the size of resources either directly or through a side-channel attack.
- We introduce several new attack vectors that can be leveraged to uncover the exact response size of arbitrarily chosen endpoints.
- By the means of several attack scenarios on high-profile websites, we demonstrate that an adversary can reveal the unique identity of an unwitting visitor within mere seconds, and extract sensitive information that the user shared with a trusted website.
- We propose an improvement to the specification of the Storage API, and explore various existing solutions that can be used to mitigate all variations of size-exposing attacks.

The remainder of the paper is structured as follows: in Section 2 we provide a high-level overview of the technical aspects related to recently introduced browser features. In Section 3 we present an in-depth analysis on potential size-exposing techniques, and elaborate on how these can be used in various attack scenarios. In Section 4, we discuss how adversaries can leverage these techniques against a number of real-world services. Furthermore, in Section 5 we propose and explore methods that can thwart size-exposing attacks. Section 6 covers related work, and Section 7 concludes this paper.

2 Background

One of the most important security concepts of modern browsers, is the notion of Same-Origin Policy [64, 73].

Despite what its name may suggest, it is not strictly defined as a policy, but rather represented as certain principles that ensure websites are restricted in the way they can interact with resources from a different origin. Although it is possible to initiate a cross-origin request, the Same-Origin Policy prevents reading out the content of the associated response, which is obviously imperative in order to provide online security. Naturally, the content of resources is not the only part that should be shielded off from other origins; the size of a resource should also be considered sensitive, as evidenced by the several case studies presented in Section 4 and prior work [7, 20, 60]. As such, it comes as no surprise that the browser APIs that are responsible for making HTTP requests will only report the length of a response when the associated request was to the same origin.

The Fetch API, which is currently implemented by Google Chrome, Firefox and Opera, and is under development by other browser vendors [39, 69], introduces a set of new semantics that aim to unify the fetching process in browsers. In short, the `fetch()` method is given a `Request` object, and a second, optional parameter that specifies additional options for the request. For instance, when the `credentials` option is set to "`include`", the user's cookies will be sent along with the request, even when it is cross-origin. The `fetch()` operation will return a `Promise` that yields a `Response` object as soon as the response has been fetched. In case the request was authenticated, cross-origin, and did not use the CORS mechanism, i.e., the `mode` was set to its default value "`no-cors`", the `Response` will be marked as "`opaque`", which will mask all information (status code, response headers, cache state, body and length) of the response to prevent cross-origin information leakage. In the following sections we will show how certain browser mechanisms can be abused to uncover the length of cross-origin responses.

Although the content of an opaque `Response` can not be accessed, it is possible to force the browser to cache that resource. The Cache API, which is part of the Service Worker API [66], can be used to place `Response` objects in the browser's cache. For security purposes, the cache that is accessed by the Cache API is completely isolated from the browser's HTTP cache, and is not shared across different origins. The cache is accessed by opening a `Cache` object, which can then be used to store `Response` objects with their associated `Requests`. Note that *any* response can be stored, regardless of the `Cache-Control` headers sent out by the web server. To prevent a malicious entity from completely filling up the user's hard disk, certain quota rules apply. The details of these rules will be explained in more detail in Section 3.4.

3 Size-exposing Techniques

As demonstrated by prior research, the size of a website’s resources is often related to the state of the user at that website [7, 38, 60]. Consequently, knowing the size of these resources allows an adversary to (partially) uncover the state of the user, which often yields sensitive information. In order to detect the presence of size-exposing attack vectors, we performed an in-depth analysis on all operations in which resources are involved. In this section, we present the results of this analysis and discuss the various techniques that can be used to infer the size of cross-origin resources. Next to the size-exposing methods that were discovered in prior research, we also introduce various novel techniques and re-evaluate methods in the light of recent protocol evolutions.

Throughout this section, we consider different attacker models based on the evaluated resource operation. As a rule of thumb, for each resource operation we considered all the attacker models in which the adversary is able to make observations about the operation. For instance, when analysing the transfer of a resource over the network, multiple attacker models were taken into account: an eavesdropper might inspect the encrypted network traffic directly, or Wi-Fi packets could be examined when the adversary is in physical proximity of the victim, or the attacker might simply use JavaScript to measure the time it took to complete the request.

Our evaluation mainly focuses on attacks in which the adversary infers sensitive information from the size of the resources that are returned to the victim when requesting specific endpoints. As such, we evaluate potential attack techniques under the assumption that an adversary can trigger the victim’s browser to send authenticated requests to arbitrarily chosen endpoints. This can be easily achieved by a moderately motivated attacker due to the plethora of methods that can be used to execute arbitrary JavaScript code in a cross-origin context (with regard to the target endpoint). For instance, an attacker can trick the user in visiting his website using phishing via e-mail or social networks [29], register a typosquatting domain [41], launch an advertising campaign where JavaScript code or an iframe containing the attacker’s web page is included [54], register a stale domain from which a JavaScript file is included [43], redirect insecure HTTP requests [37], ... Note that recent attacks on TLS also assume an attacker can execute JavaScript code in the victim’s browser [16, 1, 62].

3.1 Operations Involving Resources

By looking at their typical “lifetime”, we identified six different operations that involve resources, as shown in Figure 1. In the first step, a resource is generated at the

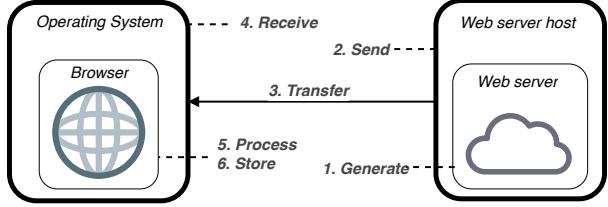

Figure 1: Overview of operations that involve resources.

side of the web server, as a result of the request initiated by the browser. Here the web server will associate the user’s state with the included cookie, produce the requested content, and pour it into an HTML structure. Although several attacks have been presented that can extract sensitive information from this generation process, e.g., direct timing attacks [7], our research focuses on methods that can expose the size of the generated content. Since the length of the response is only known *after* it has been generated, attacks against the resource generation process are excluded from our evaluation.

Once a resource has been dynamically generated, the machine where the web server is hosted on will send it back to the user that requested it. This means that if an adversary is able to observe the amount of traffic generated by the web server, he could use this information to infer the size of the response. We discuss size-exposing techniques in this context in more detail in Section 3.2.

When the resource leaves the web server, it is sent over several networks before it reaches the client. In any of these networks, an adversary capable of intercepting or passively observing the network traffic could be present. Because size-exposing attacks can be considered to be superfluous when an adversary can inspect the contents of a resource, we only consider encrypted traffic in our evaluation. Prior work has shown that popular encryption schemes such as SSL and TLS do not conceal the length of the original HTTP request and response, leading to various attacks [67, 12]. In our analysis, we extend this existing work by re-evaluating the feasibility of size-exposing attack methods when the new HTTP version (HTTP/2) is used. Furthermore, we explore possible size-exposing attack techniques in the context of Wi-Fi networks, where another layer of encryption is added, and elaborate on our findings in Section 3.3.

As soon as the response reaches the client’s machine, it is first received by the network interface, and then sent to the browser, where it is processed and possibly cached. Similar to the server-side, an adversary with a foothold in the operating system, can leverage traffic statistics to uncover the resource’s length. In Section 3.2, we investigate these types of attack techniques under various threat models, both for mobile devices as well as desktops.

Table 1: An overview of size-exposing attack techniques with their associated resource operations (as per Figure 1) and whether the techniques can be used to obtain the exact size of a resource.

Cross-site timing attacks	3		[7, 20]
Browser-based timing attacks	5		[60]
Storage side-channel leaks	6	✗	Section 3.4

After receiving the response, the browser will first signal the completion of the request by firing an Event. In the threat model we consider, the request is initiated by the malicious JavaScript code, and thus, its completion is signaled to the attacker. It is known that the time it takes for a request to complete is correlated with its size, giving rise to so-called timing attacks. However, these attacks have several limitations, and can only be used to obtain a rough estimate of a resource’s size. While a rough estimate is sufficient to perform certain attacks [7, 20], most of the real-world attacks we present in Section 4 require knowing the exact size of resources.

In a recent study, Van Goethem et al. found that the next step of a resource’s lifetime, i.e., parsing by the browser, is susceptible to timing attacks as well [60]. In contrast to classic timing attacks, these browser-based attacks do not suffer from network irregularities, and thus provide attackers with a more accurate and reliable estimate. Nevertheless, the maximum accuracy that can be achieved with these methods is still in the range of a few kilobytes, which is insufficient for some of the novel attacks presented in Section 4.

Finally, browsers may store resources in the cache, allowing them to be retrieved much faster in future visits. Motivated by the potentially nefarious consequences of caching resources chosen by an adversary, we analyzed the specification of the various APIs that are involved in this process. Surprisingly, we found multiple design flaws that allow an adversary to uncover the *exact* size of any resource. In Section 3.4, we elaborate in detail on these newly discovered vulnerabilities, and their presence in modern browsers.

An overview of all size-exposing techniques we discovered during our evaluation is provided in Table 1.

3.2 OS-based Techniques

In this section, we elaborate on size-exposing techniques that occur at the level of the operating system, on the side of the web server and client. In our analysis, we

considered four types of hosting environments for the web server, namely dedicated hosting, shared hosting, and cloud-based solutions (VMs and PaaS). To be able to observe the length of resources in the case of a dedicated hosting environment, an attacker would need to have either physical access, or infect the machine with a malicious binary. In both cases, we argue that the capabilities of the attacker far surpass what is required for a size-exposing attack, thereby making other attack vectors more appealing to the attacker.

The same argument applies to cloud-based hosting. It has been shown that cache-based side-channels attacks can extract sensitive information, including traffic information, in a cross-tenant or cross-VM environment [48, 76, 72]. However, if an attacker would have the capabilities to leverage a cache-based attack to accurately determine the size of a requested resource, this would mean that the attacker could also leverage the cache-based attack to determine (part of) the execution trace, which can be considered as significantly more severe in most scenarios. Given the lack of incentive for an attacker to uncover the resource size by launching a cross-tenant or cross-VM attack, we do not consider this in more detail.

In a shared hosting environment, web requests for several customers are served by the same system. Next to cross-process cache-based side-channel attacks, which can be considered similar to the above-mentioned cross-VM attacks, adversaries can typically also access the system-wide network statistics. These network statistics can be obtained by either running the `ifconfig` command, or by reading it directly from system pseudo-files such as `/proc/net/dev`. As these network statistics report the exact amount of bytes sent and received by a network interface, an adversary could leverage this information to uncover the size of a response. The attacker’s accuracy will of course depend on the amount of background traffic, but the ability to coordinate with the victim’s browser gives the adversary a strong advantage. Because shared hosting environments are typically used by less popular websites, we consider this type of attack scenario to be unlikely, and thus do not explore this issue further.

On the side of the client, we explored various size-exposing techniques, but found that most techniques either require too many privileges, e.g., infecting the system with a malicious binary, or yield inaccurate results [44]. An interesting exception is the Android operating system, which also keeps track of network statistics. In addition to the global network statistics, Android also exposes network statistics *per user*, which, surprisingly, can be read out by any application without requiring

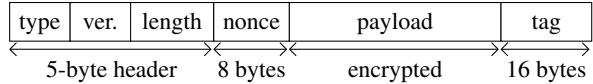

Figure 2: TLS record layout when using AES-GCM.

ing permissions¹. In their work, Zhou et al. showed that by passively monitoring network statistics on Android, an adversary can infer sensitive information from the requests made by other applications. We make the observation that these attacks can be extended when considering an attacker model in which the adversary can actively trigger specific requests in the victim’s mobile browser. As a proof-of-concept application, we created an HTTP service, which reports the number of bytes received by the user associated with the `com.android.chrome` application. Finally, our application triggers the mobile browser to open a web page, which first contacts the local service, next downloads an external resource, and then obtains the network statistics again, allowing us to determine the exact size of the external resource.

3.3 Network-based Techniques

We now show the size of a resource can be uncovered by monitoring its transmission over a secure connection. First we do this for TLS, and then we evaluate the case where Wi-Fi encryption is used on top of TLS. Although Wi-Fi hides individual connections, effectively offering a secure channel similar to that of VPNs or SSH tunnels, we show attacks remain possible. We also study the impact of the new HTTP/2 protocol.

3.3.1 Transport Layer Security (SSL / TLS)

Web traffic can be protected by HTTPS, i.e., by sending HTTP messages over TLS [47, 15]. Once the TLS handshake is completed, TLS records of type application data are used to send HTTP messages. The type and length of a record is not encrypted, and padding may be added if block ciphers are used. Since nowadays more than half of all TLS connections use AES in Galois Counter Mode (GCM) [27], we will assume this cipher is used unless mentioned otherwise. The layout of a TLS record using AES-GCM is shown in Fig. 2. Note that for this cipher no padding is used. An HTTP message can be spread out over multiple TLS records, and in turn a TLS record can be spread out over several TCP packets. An endpoint can freely decide in how many records to divide the data being transmitted.

¹These statistics can be read out from the pseudo-files `/proc/uid_stat/[uid]/tcp_rcv`, or, since Android 4.3, can be obtained from the `getUidRxBytes()` interface.

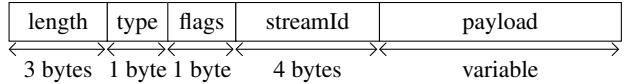

Figure 3: Simplified HTTP/2 frame layout.

To determine the length of a resource sent over TLS, we first need to know when it is being transmitted. We accomplish this by using JavaScript to make the victim’s browser fetch a page on our server, signaling that the next request will be to the targeted resource. We then monitor any TLS connections to the server hosting this resource, which is possible because the TCP/IP headers of a TLS connection are not encrypted. Once the resource has been received, we again signal this to our server. This enables us to identify the (single) TLS connection that was used to transmit the resource. Finally we subtract the overhead of the TLS records (see Figure 2) to determine the length of the HTTP response. If the connection uses a cipher that does not require padding, this reveals the precise length of the HTTP response. Otherwise only a close estimate of the response length can be made. By subtracting the length of the headers from this HTTP response, whose value can be easily predicted, we learn the length of the requested resource.

We tested this attack against two popular web servers: Apache and nginx. Even when the victim was actively browsing YouTube and downloading torrents, our attack correctly determined the length of the resource. Interestingly, we noticed that Apache puts the header of an HTTP response in a single, separate, TLS record. This makes it trivial to determine the length of the HTTP response header sent by Apache: it corresponds exactly to the first TLS record sent by the server.

We also studied the impact of the HTTP/2 protocol [4] on our attacks. HTTP/2 does not change the semantics of HTTP messages, but optimizes their transport. In HTTP/2, each HTTP request and response pair is sent in a unique stream, and multiple parallel streams can be initiated in a single TCP connection. The basic transmission unit of a stream is a *frame* (see Figure 3). Each frame has a *streamId* field that identifies the stream it belongs to. Several types of frames exist, with the two most common being header and data frames. Header frames encode and compress HTTP headers using HPACK [45], and data frames contain the body of HTTP messages. Nearly all other frames are used for management purposes, and we refer to them as control frames. Most browsers only support HTTP/2 over TLS. Usage of HTTP/2 is negotiated using the Application Layer Protocol Negotiation (ALPN) extension of TLS. This extension is sent unencrypted, meaning we can easily detect if a connection uses HTTP/2.

To determine the size of a resource transmitted using HTTP/2 over TLS, we have to predict the total overhead created by the 9-byte frame header (see Figure 3). Moreover, we need to be able to filter away control frames. Both Apache and nginx send control frames in separate TLS records, and these records can be detected by their length and position in the TLS connection, allowing us to recognize and filter these frames. To calculate the overhead created by the 9-byte frame header, we need to predict the number of HTTP/2 data frames that were used to transmit the resource. For Apache this is easy since it always sends data frames with a payload of 2^{14} bytes, except for the last frame. For nginx, the number of data frames can be predicted based on the number of TLS records. This means that for both servers we can predict the amount of overhead HTTP/2 introduces. The size of the HTTP/2 header frame can be predicted similar to the HTTP/1.1 case, with the addition that the HPACK compression has to be taken into account. Finally, we found that multiple streams are active in one TCP connection only when loading a page. By waiting until the HTTP/2 connection is idle before letting the victim’s browser fetch the resource, the only active stream will be the one downloading the resource. All combined, these techniques allowed us to accurately predict the size of resources sent using HTTP/2. Note that if the server uses gzip, deflate, or similar, we learn the compressed size of the resource. In Section 4, we show that this is sufficient to perform attacks, and can even be used to extend an attacker’s capabilities.

3.3.2 Encrypted Wi-Fi Networks

Wireless networks are an attractive target for traffic monitoring attacks. For instance, our attack against TLS can be directly applied against open wireless networks. However, these days many wireless networks are protected using WPA2 [71]. This means that all packets, including their IP and TCP headers, are encrypted. Hence we can no longer use these headers to isolate and inspect TLS connections. Nevertheless, we show it is possible to uncover the size of an HTTP message even when Wi-Fi encryption is used on top of TLS.

In the Wi-Fi protocol, the sender first prepends a fixed-length header to the packet being transmitted, and then encrypts the resulting packet [28]. To encrypt and protect a packet, the only available ciphers in a Wi-Fi network are WEP, TKIP, or CCMP. Note that WPA1 and WPA2 are not ciphers, but certification programs by the Wi-Fi Alliance, and these programs mandate support for either TKIP or CCMP, respectively. Since both WEP and TKIP use RC4, and CCMP uses AES in counter mode, padding is never added when encrypting a packet. Therefore, no matter which cipher is used, we can always determine the

precise length of the encrypted plaintext. Finally, Wi-Fi encryption is self-synchronizing, meaning that a receiver can decrypt packets even if previous ones were missed or blocked.

Similar to our attack against TLS, we determine when the resource is being transmitted by signaling our own server before and after we fetch the targeted resource. However, we can no longer easily determine which packets correspond to the requested resource as Wi-Fi encrypts the IP and TCP headers. Consequently, any background traffic will interfere with our attack. One option is to execute the attack only if there is no background traffic. Unfortunately, if the user is actively browsing websites or streaming videos, periods without traffic are generally too short. In other words, it is hard to predict whether a period without traffic will be long enough to fetch the complete resource. Our solution is to wait for a small traffic pause, and extend this pause by blocking all packets that are not part of the TCP connection that will fetch the resource. Blocking packets in a secure Wi-Fi network is possible by using a channel-based man-in-the-middle (MitM) attack [61]. Essentially, the attacker clones the Access Point (AP) on a different channel, and forwards or blocks packets to, and from, the real AP. The channel-based MitM also has another advantage: if the adversary misses a packet sent by either a client or AP, the sender will retransmit the packet. This is because the cloned AP, and cloned clients, must explicitly acknowledge packets. Hence our attack is immune to packet loss at the Wi-Fi layer. Once we start measuring the size of the resource, we only forward packets that could be part of the connection fetching this resource. First, this means allowing any packets with a size equal to a TCP SYN or ACK. Second, we have to allow the initial TLS handshake and the HTTP request that fetches the resource. Since both can be detected based on the length of Wi-Fi packets, it is possible to only forward packets that belong to the first TLS handshake and HTTP request. By blocking other outgoing requests, servers will refrain from replying with new traffic. Hence we can still fetch our targeted resource, but all other traffic is temporarily halted.

In experiments the above technique proved highly successful. Even when the victim was browsing websites or streaming YouTube videos, it correctly isolated the TLS connection fetching the resource. We also tested the attack when the victim was constantly generating traffic by sending ping requests of random sizes. Since the size of these packets rarely matches that of a TCP ACK/SYN or TLS handshake packet, all ping requests were blocked, and the correct connection was still successfully isolated.

The next step is to subtract the overhead added by Wi-Fi and TLS. Since none of the cipher suites in Wi-Fi use padding, it is straightforward to remove padding added by the Wi-Fi layer. However, we cannot count the

number of TLS records sent as their headers are now encrypted. Nevertheless, for both nginx and Apache with HTTP/1.1, we found that a new TLS record is used for every 2^{14} bytes of plaintext. This allows us to predict the number of TLS records that were used, and thereby the overhead created by these records. We discovered only one exception to this rule. If an Apache server uses chunked content encoding, each chunk is sent in a separate TLS record. This means that the number of TLS records become application-specific, and the attacker has to fine-tune his prediction for every targeted resource. We remark that this behavior of Apache is not recommended, because it facilitates chunked-body-truncation attacks against browsers [5].

When HTTP/2 is used, the situation becomes more tedious. Here we have to predict both the number of TLS records, as well as the number, and types, of HTTP/2 frames. We found that these numbers are predictable for the first HTTP/2 response in a TLS connection. Since all browsers limit the number of open TCP connections, we first close existing connections by requesting several pages hosted on different domains. After doing this, a new connection will be used to fetch the targeted resource, meaning we can predict the amount of overhead. Apache always uses HTTP/2 data frames with a payload of 16348 bytes, even when chunked content encoding is used. Furthermore, the TLS records always have a payload length of 1324, except for every 100th TLS record, which has a length of 296. Finally, Apache always sends the same three HTTP/2 control frames, spread over two TLS records, before sending the resource itself.

For new TLS connections, nginx sends three initial HTTP/2 control frames in either one or two TLS records, where most of the time only one TLS record is used. Then it enters an initialization phase where the first 10 TLS records have a predictable size, with each size taken from the set {8279, 8217, 4121, 4129}. After this initial phase, it repeats the sequence [16408, 16408, 16408, 16408, 96], with the exception that at relatively infrequent and random times a TLS record of size 60 is used instead of 96. However, as this is only a small difference, it generally affects the number of TLS records by at most one. All combined, if we assume the least number of TLS records are used, we underestimate the actual number of TLS records by at most two. In fact, most of the time no extra records are used. Hence an attacker can make multiple measurements, and pick the most common length as being the one without the extra (one or two) records.

3.4 Browser-based Techniques

Over the last few years, one of the most important evolutions on the web is the increase of support for mobile

Algorithm 1 Uncover the size of resources by abusing the per-site quota limit

```

response ← fetch(url)
fillStorage()
size ← 0
loop
    freeByteFromCache()
    size ← size + 1
    storageResult ← cache.put(response)
    if storageResult == True then
        return size
    end if
end loop

```

devices. This advancement requires that all the characteristics that are specific to mobile devices are properly accommodated. For instance, mobile devices travel along with their users, which means that every now and then the devices become disconnected, preventing the user from accessing any web-based content. Recent advancements in browser design aim to tackle this problem with a promising API named ServiceWorker [66]. The core idea behind the ServiceWorker API is to allow websites to gracefully handle offline situations for their users. For example, a news website might download and temporarily store news articles when users are connected, allowing them to still access these while being disconnected. Note that although we mainly focus on the ServiceWorker API, all attacks can also be applied by using ApplicationCache [63], the caching mechanism that ServiceWorker aims to replace.

3.4.1 Per-site quota

For caching operations, the ServiceWorker API provides a specific set of interfaces, named Cache API, which can be used to store, retrieve and delete resources. A noteworthy aspect of the Cache API is that it allows one to cache any resource, including cross-origin responses. Furthermore, to limit misuse cases where a malicious player takes up all available space, the per-site² storage is restricted. This restriction is shared among a few other browser features that allow persistent data storage, for instance localStorage and IndexedDB. The way per-site quota is applied, is decided by the browser vendor; for the most popular browsers this is either a fixed value in the range of 200MB to 2GB, or a percentage - typically 20% - of the global storage quota [22, 42, 32].

For the purpose of exposing the size of resources, having full control over the cache, and the fact that this cache

²According to the current specification of the Storage API, a site is defined as eTLD+1, meaning `foo.example.org` and `bar.example.org` belong to the same site, whereas `foo.host.com` belongs to a different site [70].

is limited by a fixed quota, are two very interesting aspects. An adversary can directly leverage these two features to expose the size of any resource by means of the pseudo-code listed in Algorithm 1. In the attack, the resource is first downloaded using the Fetch API, which will result in an "opaque" Response. Next, the adversary makes sure that the site's available storage is filled up to the quota. In practice, we found that by storing large data blobs using the IndexedDB API, the storage speed approaches the maximum writing speed of the hard disk, allowing the attacker to reach the quota in a few seconds. In a final step, the adversary will free up one byte from the cache and attempt to store the response. This storage attempt will only succeed if sufficient quota is available, otherwise more bytes should be freed. Eventually, the attacker learns the exact size of the resource by the number of bytes that were freed until the resource could be stored. Note that the resource only needs to be downloaded once, resulting in a significant speed-up of the attack. In our experimental setup, the initial attack could be executed in less than 20 seconds, and subsequent size-exposing attempts were performed in less than a second as the quota had already been reached.

3.4.2 Global quota

In addition to the storage restrictions of sites, browsers also enforce a global storage quota to ensure normal system operations are not affected. When this global quota is exceeded, the storage operation will not be canceled, but instead the storage of the least-recently used site will be removed. As a result, the two features required to expose the size of a resource, i.e., full control over the cache and an indication when the quota is exceeded, are present. In comparison to the size-exposing attack that leverages the per-site quota, this vulnerability is considerably harder to successfully exploit: the attacker needs to reach the global quota limit, which needs to be spread over multiple sites, and has to take into account that the global quota can fluctuate as a result of unrelated system operations. Nevertheless, for the purpose of creating an improved design, it is important to consider all flaws of the current system. Furthermore, on systems with a limited storage capacity, e.g., mobile devices, some of these restrictions may not apply, increasing the feasibility of an attack.

A simplified, unoptimized method that can be used to expose the size of an arbitrary resource is provided in Algorithm 2. Similar to the per-site quota attack, the adversary first downloads the resource and temporarily stores it in a variable. Next, a site is filled with a certain amount of bytes ($storageAmount$) which should be larger than the size of the resource. In a following step, the adversary will need to fill the complete quota. Since

Algorithm 2 Uncover the size of resources by abusing the global quota limit

```

response ← fetch(url)
storageAmount ← 5MB
site0.addBytes(storageAmount)
i ← 1
while !isEvicted(site0) do
    storageResult ← sitei.addBytes(1)
    if storageResult != True then
        i ← i + 1
    end if
end while
site0.cache.put(response)
remainingBytes ← 0
while !isEvicted(site1) do
    site0.addBytes(1)
    remainingBytes ← remainingBytes + 1
end while
size ← storageAmount – remainingBytes

```

for most major browsers, the global quota is set to 50% of the total available space on the device, and the per-site quota is set to either a percentage of the global quota or a fixed size, the adversary will need to divide this over multiple domains. As soon as the eviction of the first site is triggered, the adversary knows the exact amount of freed space, namely $storageAmount$. Finally, the adversary adds the resource to an empty site and fills it until the global quota is reached again, which can be observed by checking for the eviction of the next least-recently used site, i.e., $site_1$. The size of the resource can then be calculated as the original size of the first site subtracted by the number bytes required to reach the global quota again ($remainingBytes$).

3.4.3 Quota Management API & Storage API

The last attack involving browser storage abuses the Quota Management API [65], and the similar Storage API [70]. These APIs aim to give web developers more insight into their website's storage properties, more specifically the number of bytes that have been stored and the space that is still available. At the time of writing, the Storage API is still being designed, and will consolidate the storage behavior of all browsers into one agreed-upon standard.

The functionality provided by the Quota Management API is the direct source of a size-exposing vulnerability that is worryingly trivial to exploit. An adversary can simply request the current storage usage, add a resource to the cache, and retrieve the storage usage again. Since the Quota Management API will return the usage in bytes, the *exact* resource size can be obtained by subtracting the two usage values. Although the Quota

Management API has only been adopted by the Google Chrome browser, this browser alone accounts for approximately 48% of the market share [56], leaving hundreds of millions of internet users vulnerable to this highly trivial size-exposing attack vector. Despite our efforts of reporting these findings to the Chrome team, all up-to-date versions of the Google Chrome browser remain allowing this API to be used by any website, without the user’s knowledge.

Because the per-site quota is related to the global quota³, the Quota Management API can also be used to infer the caching operations of a different website. For instance, a malicious iframe that is embedded on a website could observe changes in the available quota, and infer the length of cached resources. This information could in turn be used to either analyze the interactions of the user on the website, or disclose private information based on the length of the cached resources. A similar attack scenario is discussed in more detail in Section 4.4. Another interesting case occurs when making the observation that the per-site quota is also related to the total free disk space. The byproduct of this behavior is that an adversary can also observe the disk operations of other, possibly security-sensitive, processes. As this issue is unrelated to size-exposing techniques, we do not explore this vulnerability in more detail.

The functionalities provided by the Quota Management API are directly responsible for the vulnerabilities discussed in this section. It is unclear why this API was developed without taking into account potential security and privacy implications. In essence, these findings serve as a strong indicator that new browser features should be thoroughly reviewed for security and privacy flaws. Since the Storage API provides the same functionality as the Quota Management API, the same issues arise there as well. At the time of writing, the Storage Standard deviates from the Quota Management API in the sense that it states that a “rough estimate” should be returned. Because the term “rough estimate” is not formally defined, implementations of this specification are likely to still be vulnerable to statistical attacks, as the quota limit can easily be requested thousands of times. In Section 5.1 we propose a new API design that protects against all browser-based size-exposing techniques we discussed in this paper.

4 Real-world Consequences

In contrast to prior work on size-exposing techniques, which is mainly focused on passive network observation, the attacks presented in this paper leverage the abil-

ity to request arbitrarily chosen resources in the victim’s browser. To provide more insight into the consequences and potential attack scenarios, we explore a selection of real-world cases where one of the size-exposing techniques can be used to extract private and sensitive information from the victim. The list of attacks that are discussed, is by no means the exclusive list of possible targets. Instead, we made a selection of attack scenarios to provide a variety in methodology, type of disclosed information, and category of web service.

Ethical Considerations To evaluate the severity and impact of size-exposing techniques on internet users, it cannot be avoided to evaluate these attacks on real-world services. To prevent any nefarious consequences of this evaluation, all attacks were manually tested, and were performed exclusively against our own accounts. As a result, from the perspective of the tested services our analysis only generated a restricted amount of legitimate traffic. Moreover, users of the analyzed websites were not directly involved in our attacks. For the quantitative case-studies, we only obtained publicly available information, and present it in anonymized form. Given the above-mentioned precautions, we believe our evaluation of real-world services did not have any adverse effects on the tested subjects.

4.1 User Identification

Virtually every online social network provides its users with their own profile page. Depending on the user’s privacy settings, these profile pages typically are completely or partially available to anyone. In the attack scenario where the adversary is interested in learning the identity of the victim, the adversary first collects the publicly available data from (a subset of) the users of the social network. Later, during the actual size-exposing attack, he tries to associate the data obtained from the victim to a single entry from the public data, allowing him to expose the victim’s identity. To evaluate the feasibility in a real-world environment, we exemplify the attack scenario on Twitter, one of the largest social networks.

By default, the profile of each Twitter user is public, and contains information on the latest tweets that were created by the user, the list of followers and followees, the tweets that were “liked” by the user, and the lists he/she follows and is a member of. Except for the user’s tweets, each type of information can be accessed by a link that is shared by all Twitter users, e.g., the page located at <https://twitter.com/followers> lists the last 18 accounts that follow the user. For each follower, the name, account name and short biography is shown.

The main assumption in this attack scenario is that the combined length of all parts that constitute to the

³The per-site quota is 20% of the global quota in Google Chrome; for Firefox this is the case as well when the disk space is less than 20GB.

resource, i.e., the names, account names and bios of the last 18 followers, is relatively unique. To validate this assumption, we performed an experiment that reflects an adversary’s actions in an actual attack scenario. For this experiment, we obtained publicly available information of 500,000 users, which were selected at random from the directory of public profiles provided by Twitter⁴. More specifically, we downloaded the resources located at `/following`, `/followers`, `/likes`, `/lists` and `/memberships`, and recorded the associated resource size, both with and without gzip compression.

Next, we grouped together Twitter accounts that share the same resource length, e.g., if the `/following` resource is 281026 bytes for only two users, these users form a group of size 2. In Figure 4 we show the percentage of Twitter accounts for all group sizes, for the compressed and uncompressed resource size. Note that a logarithmic scale is used for the percentage of Twitter accounts on the y-axis. This graph clearly shows that when the size of multiple resources is combined, the majority of Twitter accounts can be uniquely identified. By exposing the size of the uncompressed `/following` and `/followers` resources, 89.66% of the 500,000 Twitter accounts can be uniquely identified. When the size of all five resources is known, the identity of 97.62% of the Twitter accounts can immediately be uncovered. The graph also clearly shows that when gzip compression is applied, the group sizes of individual resources becomes larger, which is most likely due to the reduction in entropy of resource sizes. Nevertheless, when the size of multiple compressed resources are combined, a uniqueness comparable to the size of uncompressed resources is achieved: 81.69% Twitter accounts can be uniquely identified when the size of the `/following` and `/followers` resources is combined; for all five resources, this is 99.96%. The most likely explanation for this is that in case a resource is virtually empty, i.e., the account name is the only dynamic part of the resource, not only the length but also the content of the account name is reflected in the compressed resource size.

Although the viability of this attack was only evaluated on a subset of all Twitter accounts⁵, this experiment does suggest that adversaries can immensely narrow down the number of possible candidates for the user’s identity by knowing the size of just five resources. Furthermore, various techniques exist that can uniquely identify a user among a limited set of accounts [33, 26], making user-identification by exposing the size of resources well within the reach of a moderately motivated attacker.

⁴<https://twitter.com/i/directory>

⁵Twitter has approximately 320 million active accounts.

4.2 Revealing Private Information

Next to revealing the identity of a web user, adversaries may also be interested in learning private information. A particular type of information that, in general, is considered highly sensitive, is information concerning medical conditions. To evaluate whether our novel size-exposing techniques can be used to also disclose this type of data, we explored the performance of such techniques on WebMD, one of the leading health information services websites. One of the features provided by WebMD is “Health Record”, a web service that allows users to organize their personal health records⁶. More precisely, users can add, and keep track of, their medical conditions, medications, allergies, etc. For each entry, the user can choose among an exhaustive list of terms. For instance, there are 4,105 different medical conditions that can be selected.

At any point in time, users can download their own medical report, either as automatically generated PDF or in plain text format. It should be noted that the types of medical records that are shown in this report is specified by the user (or attacker), and that the PDF is sent without compression, whereas the textual report is served with gzip compression. Although there is some variety in the length of the possible terms, it is insufficient for an adversary to determine which medical conditions the user suffers from: on average, a certain length is shared among 124.59 possible medical conditions. However, if the adversary can obtain the resource size both with and without compression, this can significantly improve his attack: in this case, the group size can be limited to 35.50 on average. This can be achieved by various methods, e.g., by obtaining the length from two resources that share the same content, where one is served with compression and the other without, or by tricking the server in sending the resource without compression⁷, or even by combining the browser-based attacks with the network-based attacks. In case the sensitive content is present on multiple compressed resources (in this case, this can be triggered by varying the types of medical records that are reported), the group size can be reduced even further. In the attack scenario against WebMD, a single iteration of this technique, i.e., including the medical condition on a compressed resource with other known content, reduces the average group size to 18.73. By applying multiple iterations, each with slightly different content, it becomes possible to uniquely identify the user’s medical condition in most cases.

⁶<https://healthmanager.webmd.com/>

⁷When a resource is included as a `<video>` element, the `Accept-Encoding` header will be either absent or set to `identity`, causing most web servers to send it without compression.

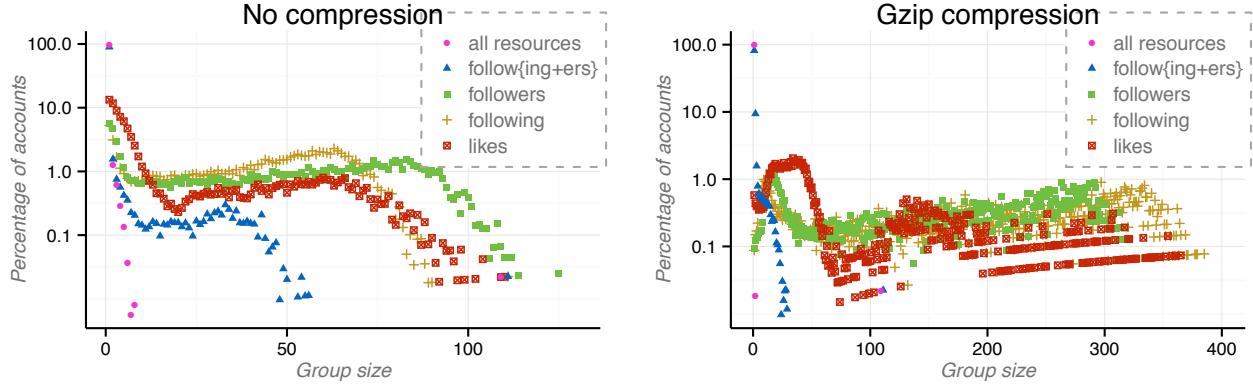

Figure 4: Percentage of Twitter accounts that share the same resource length with a group of varying size.

4.3 Search-Oriented Information Leakage

Many web applications allow their users to search the data they (in)directly entered. For instance, web-based e-mail clients provide the functionality to search for certain messages. In a recent study, Gelernter et al. show that this functionality can be abused by attackers to disclose sensitive information, such as the user’s identity and credit-card numbers [20]. In their attacks, the researchers leverage the fact that in certain cases query parameters are reflected in the results. Consequently, when a search query has several matches, the resulting resource size will be considerably larger than with an empty result-set, allowing an adversary to resort to timing attacks to determine whether a certain search query yielded results. Several service providers that were shown to be vulnerable to these attacks implemented a mitigation by preventing query parameters to be reflected in the search results. Although these measures effectively thwart the above-mentioned attacks, the web services remain vulnerable to the size-exposing attacks proposed in this paper, as these disclose the size of a resource with 1-byte precision.

4.4 Cross-Origin Cache Operations

Telegram is a popular cloud-based instant messaging service, particularly known for its security and encryption features. Not surprisingly, these features have attracted terrorist organizations to use the service as a secure communication channel [53]. This, in turn, makes Telegram a valuable target for intelligence agencies to find members of terrorist groups. Since all exchanged messages are encrypted using MTProto, which was shown to only suffer from minor theoretical attacks, plaintext-recovery is considered to be unlikely [30].

Next to the mobile and desktop versions of the Telegram application, a web-based version is provided as well⁸. An interesting feature of this web-based version is that when a photo is shared in a group, the web appli-

cation will use the File API [46] to cache two thumbnails of the photo. Because the storage used by the File API counts towards the global cache quota, it is possible to infer whether a resource is being cached as per the attacks discussed in Section 3.4.2 and Section 3.4.3.

In an attack scenario where the adversary tries to determine group membership of the victim, the attacker first lures the victim to his malicious web page. On this web page, the adversary includes the page of the target group in an iframe. Telegram does not use the X-Frame-Options header, but instead makes the content invisible by default through CSS, and uses JavaScript to make it visible in case no framing is detected (a popular Clickjacking defense proposed by Rydstedt et al. [51]). As a result, the page’s content will be loaded, but remains invisible, and impossible to interact with⁹. If the user is member of the targeted group, the Telegram website will download and cache thumbnails of the latest media items that have been shared in the group, resulting in a change of the available quota. Otherwise, a message is shown stating that the user is not a member of the group. As an additional verification step, the adversary could post another photo in the group, and witness a change in the available quota. By leveraging our novel size-exposing techniques, we found it was trivial to detect group membership. Because the MTProto scheme only provides very limited padding, group membership can also easily be detected by analyzing the size of HTTP responses.

5 Defense Mechanisms

In this section we discuss various mechanisms that can be used to thwart size-exposing attacks. Due to space limitations, we only focus on a limited set of defense mechanisms, which were selected on the basis of completeness, novelty, amount of overhead and ease of adoption.

⁸The <iframe> element should have a sandbox attribute set to "allow-scripts allow-same-origin" to prevent top level navigation, while ensuring the page is loaded properly.

⁹<https://web.telegram.org>

5.1 Hardening Browser Storage

As was shown in Section 3.4, several features related to the storage operations in browsers can be abused to expose the size of cross-origin resources. At the time of writing, there exists no universal specification that standardizes these operations. However, the Storage API specification is being developed with the purpose of designing a unified definition that will be adopted by all browsers. In its current state, the Storage API consolidates the current browsers behavior regarding the quota limit per website. Furthermore, it incorporates the functionalities offered by the Quota Management API.

We propose a countermeasure that extends the Storage API. To make adoption by browsers feasible, we aim to provide a usable solution, i.e., normal application behavior should not be jeopardized. As a result of the feedback provided by the communication with specification editors and browser vendors, we opted for an approach where “virtual padding” is applied to resources. To prevent an adversary from learning the size of a resource, either by abusing the storage limit or by requesting the available quota, this size should be masked with a random value. However, it is a well-known fact that by adding a random value, the mechanism becomes subject to statistical attacks. Because resources can be added to the cache extremely fast, an adversary is able to obtain a large number of observations in a limited amount of time, putting him in a very strong position.

Inspired by a mitigation for web-based timing side-channels proposed by Schinzel [52], and by making the observation that in contrast to caching operations, downloading a resource takes a considerable amount of time, we propose the following defense. When a resource is downloaded as the result of a `fetch()` operation, we associate a unique identifier, `uid`, with the `Response` object. Next, we compute $q = \lceil \text{size} + \text{hash}(\text{secret} + \text{uid}) \rceil_{\Delta}$, where `size` is the size of the resource, `hash()` a uniformly distributed hash function yielding integers in the range $[0, p_{max}]$, and `secret` a cryptographic random number that is associated to a single browsing session¹⁰. The total size q is then rounded up towards the nearest multiple of Δ to prevent an attacker from learning the bounds of the added padding. When the `Response` is added to the cache, the per-site and global quota will be increased by q . This value should also be stored as part of the `Response` object to ensure that for each cache operation the same value is either added or subtracted from the quota. As a result, the only way for an adversary to obtain a new observation is to download the same resource again. It should be noted that the padding that is added for each cache operation is virtual, in the sense that these

¹⁰To prevent an adversary from linking two browser sessions, `secret` is changed whenever the browser session changes.

bytes are not actually written to the disk, but are just kept as a type of bookkeeping.

It is clear that the overhead on the quota and the security guarantees provided by this defense method are directly related to the values of p_{max} and Δ . In fact, this provides a trade-off between security/privacy and usability, for instance, the larger the value of p_{max} , the harder it will be for an adversary to uncover the size of resources (within certain boundaries), but on the other hand, a large p_{max} will entail a smaller storage capacity due to the amount of padding. We argue that with an analysis on the typical use-cases of caching operations, these values could be defined to accommodate legitimate behavior while preventing attacks. Furthermore, it could be taken into account that this mechanism generates a virtual loss in storage capacity, and therefore the quota could be increased to account for this. In addition, it is possible to apply a rate-limiting approach to limit the amount of observations that can be made by an adversary. For instance, if the reported quota is only updated once every minute, statistical attacks can be largely mitigated, which in turn allows for smaller values of p_{max} , and restricts the (already virtual) overhead.

Given the generality of the defense, its strong security guarantees, and the low overhead, we feel confident that this approach, or a similar derivative thereof, will be incorporated into the HTML specification, and encourage browser vendors to mitigate the attacks presented in Section 3.4 in this manner.

5.2 Detecting Illicit Requests

In essence, the size-exposing techniques presented in this paper require the ability to initiate authenticated cross-origin requests, and rely on the targeted web service to handle the request in the same way it would for legitimate requests. This means that when either part is removed, i.e., either authenticated cross-origin requests are disabled, or the web server answers with a static error message, the complete class of size-exposing techniques will be mitigated. To accomplish this, it is possible to resort to existing, and well-established techniques in related research fields. For instance, by blocking third-party cookies, which is typically used to prevent tracking on the web [50], the cross-origin requests initiated by the adversary will be sent without the cookie. As a result, the website will handle the request as if the user was not logged in, preventing the adversary from learning anything about the user’s state at the website. Mozilla and the Tor Browser project are working on minimizing the limitations imposed by blocking third-party cookies, by implementing a feature name double-keyed cookies, which binds cookies to the origin pair (first-party, third-party), and aims to prevent the risks of breaking sites

caused by blocking cookies [9, 59]. Similarly, certain browsers provide the ability to attach third-party cookies only if these were set during top-level navigation, and block these otherwise. While this technique can be used to prevent tracking by unknown parties, it does not adequately prevent the attacks presented in this paper as the targeted third-party services are the ones that are actually used by the victim.

On the side of the server, solutions similar to those that prevent Cross-Site Request Forgery (CSRF) attacks could be applied. A well-known method, as proposed by Barth et al., to accomplish this, is to analyze the `Origin` and/or `Referer` headers and only allow requests from trusted origins [2].

5.3 Network-based Countermeasures

Padding can be used to hide the length of resources during their transmission. Since general-purpose padding schemes are already well-studied, we do not discuss them further. Instead, we focus on countermeasures that fit our use-case, where only the size of sensitive dynamically generated resources must be protected. This allows us to provide a countermeasure with low overhead and high security guarantees, at the cost of requiring some effort on the web administrator’s part.

Our idea is to add an amount of padding based on the hash of the session cookie, the URL, and any parameters that affect the generation of the resource. More formally, $\text{padding} = \text{hash}(\text{cookie} + \text{url} + \text{params})$. If the user is not logged in, no padding is added. For each resource, the parameters that influence the generation of the resource must be manually specified. Other parameters should not be included, otherwise an adversary can add bogus parameters to obtain a new padding value for the same resource. This construction assures that sensitive resources, for any specific user, receive an amount of padding that is unpredictable by an attacker. However, this padding remains identical over several requests, meaning it even guarantees protection against statistical attacks. Information can only be leaked if the resource changes over time. This can happen when the attacker was able to affect the generation of the resource on the server, or simply because the information contained in the resource has changed over time. In this situation an observer can learn the difference in resource size. If the resource does not contain variable content, such as dynamic advertisements, this attack can be mitigated by including the content of the resource in the hash function. Similar to hardening the browser (see Section 5.1), the security guarantees depend on the value of p_{\max} . Provided the hash function is uniformly distributed, this countermeasure introduces on average $\frac{p_{\max}}{2}$ bytes of overhead.

For wireless networks, where we assume Wi-Fi encryption is used on top of TLS, we can rely on the previously mentioned techniques to protect the TLS connection. Additionally, an identifier-free wireless protocol can be used, making it more difficult for an attacker to attribute Wi-Fi packets to specific clients [23, 18, 3, 8].

6 Related Work

Size-exposing techniques have surfaced in several research areas, ranging from timing attacks, to network traffic analysis, to browser-based and cross-VM side-channel leaks. As part of an in-depth analysis, which lead to the discovery of multiple novel attack methods, we already touched upon a variety of related work, as discussed in Section 3. In this section, we give a brief overview of the most relevant work, and discuss it in the context of our findings.

Prior research that analyses methods that can expose the size of an attacker-specified resource, is mainly focused on leveraging timing as a side-channel information leak [19, 7, 14, 20, 60]. Because timing attacks measure the time required to download or process a resource, which is often influenced by various factors such as network irregularities or background noise, these attacks have certain limitations with regards to the accuracy of the uncovered resource size. In our research, we presented novel techniques that leverage the browser-imposed quota to reveal the *exact* size of any resource.

An interesting class of vulnerabilities where the size of resources is exploited, are compression side-channel attacks [31]. These attacks generally leverage the compression rate that is achieved when compressing an unknown value in a larger corpus of known values, allowing an adversary to uncover information about the unknown value from the resource size after compression. More recently, researchers have shown how similar attacks can be applied to various compression mechanisms used on the web [49, 21].

In the context of privacy-violating cross-origin attacks, Lee et al. have shown that the `ApplicationCache` mechanism can be used to uncover the status code that is returned for cross-origin resources [34]. Their attack exploits certain intricacies of `ApplicationCache`, which exhibits a different behavior based on the returned status code of referenced endpoints. The researchers did not explore vulnerabilities originating from the imposed quota and storage limits. Another type of attack that violates the principle of Same-Origin Policy is Cross-Site Script Inclusion (XSSI), first introduced by Grossman in 2006 [24], and recently analyzed on a wide scale by Lekies et al. [35]. In XSSI attacks, a dynamically generated JavaScript (or CSV [58]) file from a vulnerable website is included as a `<script>` element on the web

page of the attacker. The often sensitive content that is present in these files can then be obtained out by the adversary as a result of the modifications the script makes to the attacker-controlled DOM.

Compared to prior work on the analysis of web traffic [57, 6, 12, 36, 11, 10, 17], our work is, to the best of our knowledge, the first to combine traffic analysis with the ability to execute code in the victim’s browser. Similarly, traffic analysis works on Wi-Fi also assume a passive, instead of an active, adversary [8, 23, 3, 75, 74]. That is, we believe our work is the first to actively block specific Wi-Fi packets in order to measure the size of HTTP messages.

7 Conclusion

The size of resources can be used to infer sensitive information from users at a large number of web services. In our research, we performed an extensive analysis on the various operations that are performed on resources. As a result of this evaluation, we identified several new techniques that can be used to uncover the size of any resource. In particular, an attack that abuses the storage quota imposed by browsers, as well as a novel technique against Wi-Fi networks that can be used to disclose the size of the response associated with an attacker-initiated request. To provide more insight into how these attack methods can be applied in real-world attack scenarios, we elaborated on several use cases involving widely used web services. Motivated by the severe consequences of these size-exposing attacks, we proposed an enhanced design for the browser storage, which is likely to be adopted by browser vendors, and discussed a variety of other options that could be employed to prevent adversaries from stealing sensitive information.

Trusted browsers for uncertain times

Abstract

JavaScript in one origin can use timing channels in browsers to learn sensitive information about a user’s interaction with other origins, violating the browser’s compartmentalization guarantees. Browser vendors have attempted to close timing channels by trying to rewrite sensitive code to run in constant time and by reducing the resolution of reference clocks.

We argue that these ad-hoc efforts are unlikely to succeed. We show techniques that increase the effective resolution of degraded clocks by two orders of magnitude, and we present and evaluate multiple, new implicit clocks: techniques by which JavaScript can time events without consulting an explicit clock at all.

We show how “fuzzy time” ideas in the trusted operating systems literature can be adapted to building trusted browsers, degrading all clocks and reducing the bandwidth of all timing channels. We describe the design of a next-generation browser, called Fermata, in which all timing sources are completely mediated. As a proof of feasibility, we present Fuzzyfox, a fork of the Firefox browser that implements many of the Fermata principles within the constraints of today’s browser architecture. We show that Fuzzyfox achieves sufficient compatibility and performance today by privacy-sensitive users.

In summary:

- We show how an attacker can measure durations in web browsers without querying an explicit clock.
- We show how the concepts of “fuzzy time” can apply to web browsers to mitigate all clocks.
- We present a prototype demonstrating the impact of some of these concepts.

1 Introduction

Web browsers download and run JavaScript code from sites a user visits as well as third-party sites like ad networks, granting that code access to system resources through the DOM. Keeping that untrusted code from taking control of the user’s system is the *confinement* problem. In addition, browsers must ensure that code running in one origin does not learn sensitive information

about the user’s interaction with another origin. This is the *compartmentalization* problem.

A failure of confinement can lead to a failure of compartmentalization. But JavaScript can also learn sensitive information without escaping from its sandbox, in particular by exploiting *timing side channels*. A timing channel is made possible when an attacker can compare a *modulated clock*—one in which ticks arrive faster or slower depending on a secret—to a *reference clock*—one in which ticks arrive at a consistent rate. For example, browsers allow web pages to apply SVG transformations to page elements, including cross-origin frames, via CSS. Paul Stone showed that a fast-path optimization in the `feMorphology` filter created a timing attack that allowed attackers to steal pixels or sniff a user’s browsing history, using `Window.requestAnimationFrame()` as a modulated clock [24]. More recently, Oren et al. showed that, in the presence of a high-resolution reference clock like `performance.now`, attackers could use JavaScript `TypedArrays` to measure instantaneous load on the last-level processor cache [19].

Browser vendors are aware of the danger that timing channels pose compartmentalization and have made efforts to address it.

First, they have attempted to eliminate modulated clocks by making any code that manipulates secret values run in constant time. In a hundred-message Bugzilla thread, for example, Mozilla engineers decided to address Stone’s pixel-stealing work by rewriting the `feMorphology` filter implementation using constant-time comparisons.¹

Second, they have attempted to reduce the resolution of reference clocks available to JavaScript code. In May, 2015, the Tor Browser developers reduced the resolution of the `performance.now` high-resolution timer to 100 ms as an anti-fingerprinting measure.² In late 2015, some major browsers (Chrome, Firefox) applied similar patches (see Figure 1), reducing timer resolution to 5 µs to defeat Oren et al.’s cache timing attack [19].

These efforts are unlikely to succeed, because they seriously underestimate the complexity of the problem.

First, eliminating every potential modulated clock would require an audit of the entire code base, an ambitious undertaking even for a much smaller, simpler system such as a microkernel [3]. Indeed, the Mozilla fix for `feMorphology` did not consider the possibility that

*dkohlbre@cs.ucsd.edu
†hovav@cs.ucsd.edu

floating-point instructions execute faster or slower depending on their inputs, allowing pixel-stealing attacks even in supposedly “constant-time” code [1].

Second, there are many ways by which JavaScript code might synthesize a reference clock besides naively querying `performance.now`. In this paper, we show that *clock-edge detection* allows JavaScript to increase the effective resolution of a degraded `performance.now` clock by two orders of magnitude. We also present and evaluate multiple, new *implicit clocks*: techniques by which JavaScript can time events without consulting an explicit clock like `performance.now` at all. For example, videos in an HTML5 `<video>` tag are decoded in a separate thread. JavaScript can play a simple video that changes color with each frame and examine the current frame by rendering it to a canvas. This immediately gives an implicit clock with resolution 60Hz, and the resolution can be improved using our techniques.

In short, timing channels pose a serious danger to compartmentalization in browsers; browser vendors are aware of the problem and are attempting to address it by eliminating or degrading clocks attackers would rely on, but their ad-hoc efforts are unlikely to succeed. Our thesis in this paper is that the problem of timing channels in modern browsers is analogous to the problem of timing channels in trusted operating systems and that ideas from the trusted systems literature can inform effective browser defenses. Indeed, our description of timing channels as the comparison of a reference clock and a modulated clock is due to Wray [28], and our fuzzy mitigation strategy technique is directly inspired by Hu [10]—both papers resulting from the VAX VMM Security Kernel project, which targeted an A1 rating [12].

In this paper, we show that “fuzzy time” ideas due to Hu [10] can be adapted to building trusted browsers. Fuzzy time degrades *all* clocks, whether implicit or explicit, and it reduces the bandwidth of all timing channels. We describe the properties needed in a trusted browser where all timing sources are completely mediated. Today’s browsers tightly couple the JavaScript engine and the DOM and would need extensive redesign to completely mediate all timing sources. As a proof of feasibility, we present Fuzzyfox, a fork of the Firefox browser that works within the constraints of today’s browser architecture to degrade timing sources using fuzzy time. Fuzzyfox demonstrates a principled clock fuzzing scheme that can be applied to both mainstream browsers and Tor Browser using the same mechanics. We evaluate the performance overhead and compatibility of Fuzzyfox, showing that all of its ideas are suitable for deployment in products like Tor Browser and a milder version are suitable for Firefox.

```
// Find minor ticks until major edge
function nextedge(){
    start = performance.now();
    stop = start;
    count = 0;

    while(start == stop){
        stop = performance.now();
        count++;
    }

    return [count,start,stop];
}

// run learning
nextedge();
[exp,pre,start] = nextedge();

// Run target function
attack();

// Find the next major edge
[remain,stop,post] = nextedge();

// Calculate the duration
duration = (stop-start)+((exp-remain)/exp)*
grain;
```

Figure 2: Clock-edge fine-grained timing attack in JavaScript

2 Clock-edge attack

Web browser vendors have attempted to mitigate timing side channel attacks like [19] by rounding down the explicit clocks available to JavaScript to some grain g . For example, Google Chrome and Firefox have implemented a $5\mu s$ grain. Figure 1 shows the C++ code used for rounding a `performance.now` call in Google Chrome. Tor Browser makes a different privacy and performance tradeoff and has implemented an aggressive 100ms grain.

Unfortunately, rounding down does not guarantee that an attacker cannot accurately measure timing differences smaller than g . We present the *clock-edge* technique for improving the granularity of time measurements in the context of JavaScript clocks. Experi-

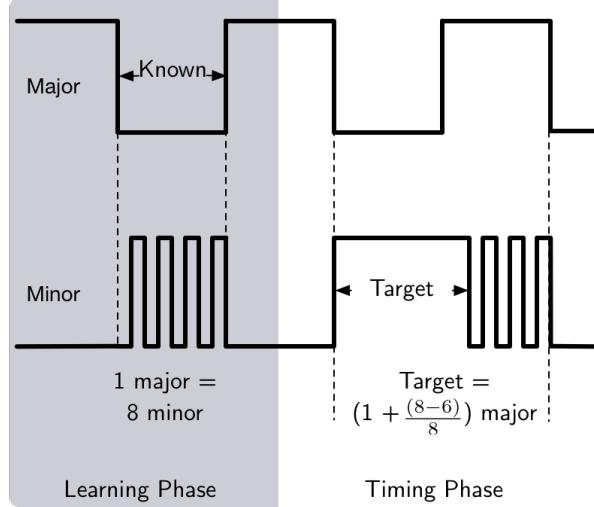

Figure 3: Clock-edge learning and timing

tally, this technique results in an increase in resolution of at least two orders of magnitude to large grained clocks. This technique can be generalized to any pair of clocks: a *major* clock, which has a known large period, and a *minor* clock, which has a short unknown period. The major clock is used to establish the period of the minor clock, and together they can time events with more accuracy than alone.

Consider the case of a page wishing to time some JavaScript function `attack()` with a granularity smaller than some known performance.now grain g . The major clock in this case is the degraded performance.now, and we use a tight incrementing `for` loop as the minor clock. Figures 2 and 3 show how a page might execute this technique and a visual representation of the process.

The page first learns the average number of loop iterations (L_{exp}) between the major clock ticks C_{l1} and C_{l2} . After learning, the page then runs until a major clock edge is detected (C_{start}) and then executes `attack()`. When `attack()` returns at major clock time C_{stop} , the page runs the minor clock (for L_{remain} ticks) until the next major clock edge (C_{post}) is detected. The page then calculates the duration of `attack()` as $(C_{stop} - C_{start}) + g * (L_{exp} - L_{remain}) / (L_{exp})$. In the case of g not remaining constant, we scale the L_{exp} by $(C_{post} - C_{stop}) / (C_{l2} - C_{l1})$ and set $g = C_{post} - C_{stop}$.

Since $(L_{exp} - L_{remain}) / (L_{exp})$ represents a fractional portion of g , the duration measurement can plausibly obtain measurements as fine grained as g / L_{exp} . Thus, as long as the attacker has access to a suitable minor clock, the degradation of a major clock to g by rounding does not ensure an attacker cannot measure at a grain less than g .

Grain(ms)	Minor	Measured Durations(ms)			
		0.003	0.030	0.298	3.033

Table 1: Results for running the clock-edge fine-grained timing attack against various grain settings. Averages for 100 runs shown.

Table 1 shows the results of applying the clock-edge technique on a degraded performance.now major clock on 4 different targets at different grains. The code in figure 2 is an abbreviated version of the testing code. Each duration column represents a different number of iterations in the `attack()` function, which is an empty `for` loop. The minor ticks column indicates the number of iterations the learning phase detected that each major tick takes. The “None” row indicates the runtime of attack with no rounding enabled, and other rows indicate the durations measured at different grain settings using the clock-edge technique. Measurements were performed with a modified build of Firefox that enabled setting arbitrary grains via JavaScript.

As table 1 shows, the clock-edge attack recovers durations significantly smaller than the grain settings. Notably, grains in the millisecond and higher range still permit the differentiation of events lasting only tens of μ s!

Simply rounding down the available explicit clocks only has a notable impact if the attacker is attempting to differentiate between events each lasting less than a microsecond, at which level the clock-edge attack often provides no additional resolution to the rounded clock.

3 Measuring time in browsers without explicit clocks

In this section, we demonstrate different methods an attacker can use to measure the duration of events in JavaScript. An attacker wishing to mount a timing attack against a web browser is not restricted to the use of performance.now for timing measurements, this section will present a number of alternative methods available. Browser features that enable these measurements are *implicit clocks*. Depending on the how the target and the clock interact with the JavaScript runtime, we define them as *existing* or *exitless*. We do not present an exhaustive list of implicit clocks. Rather, this section

should be considered the tip of the iceberg for clock techniques in browsers.

3.1 Measurement targets

Recall that the adversary’s goal in a timing attack is to measure the duration of some event and differentiate between two or more possible executions. We assume our adversary’s goal is to measure the duration of some piece of JavaScript `target()` or to measure the time until some event `target` fires a callback. There are many potential targets, exemplified by two different timing attacks on web browsers. We categorize targets and attacks into exiting and exitless and describe a canonical example for each.

3.1.1 Exiting targets: privacy breaches with `requestAnimationFrame`

Previous work [1] [24] has shown several different ways to achieve history sniffing or cross frame pixel reading via timing the rendering of an SVG filter over secret data. Andryscy et al [1] demonstrate a timing attack on privacy that differentiates pixels based on how long rendering an SVG convolution filter takes. This timing requires that the attacking JavaScript know exactly when the SVG filter is applied to the target and when the SVG filter finishes rendering. This is accomplished by sampling a high resolution time stamp (`performance.now`) when applying the CSS style containing the filter and when a callback for `requestAnimationFrame` fires. In this case, JavaScript must exit to allow some other computation to occur and then receives a notification via a callback that the event has completed. We refer to this type of target as an *exiting* target, as it exits the JavaScript runtime before completion.

3.1.2 Exitless targets: cache timing attacks from JavaScript

Conversely, there are *exitless* targets, such as Oren et al’s [19] cache timing attack. This attack does not need to exit JavaScript for the `target` to run, instead they need only perform some synchronous JavaScript function call, and measure the duration of it. Any exitless target can be scheduled in callbacks, thus making it an exiting target, but an exiting target cannot be run in an exitless manner.

3.2 Implicit clocks in browsers

Supposing that all explicit clocks were removed from the browser, it is still possible that a motivated attacker can measure fine-grained durations. Rather than query an explicit clock, the attacker can find some other feature of the browser that has a known or definable execution time and use that as an *implicit clock*.

We did not test any clocks that resolve durations at an external observer, such as a cooperating server. For ex-

Description	Clock type		
	Firefox	Chrome	Safari
Explicit clocks	L	L	L
Video frames	L	L	L
Video played	X	L	L
WebSpeech API	L	+	—
<code>setTimeout</code>	X	X	X
CSS Animations	X	X	X
WebVTT API	X	X	X
Rate-limited server	X	X	X

Table 2: Implicit clock type in different browsers
L Exitless , X Exiting , — Not implemented, + Buggy

ample, a piece of JavaScript could generate a network request, run a `target`, and then generate another network request. These clocks are mitigated by the defenses discussed in section 4.

We observe that just as with exiting and exitless targets, there are exiting and exitless implicit clocks. We will refer to a clock or timing method that does not need to leave JavaScript execution for the value reported by the clock to change as *exitless*. Similarly, a timing method that requires JavaScript execution to exit before time moves forward is *exiting*.

All exitless clocks can work for both exiting and exitless targets. However, an exitless target cannot function with an exiting clock, as the execution of the target will take control of the main thread, stopping regular callbacks or events that the exiting clock needs from firing. There may be exotic exiting clocks that do not have this restriction, but all of the ones detailed below do. An exitless attack requires using both an exitless target and clock (such as in the cache timing attack.)

Depending on the implementation of a browser feature, the clock technique may be exiting or exitless. A good example is the updating of the played information for an `<audio>` or `<video>` tag. This information is updated asynchronously to the main browser thread in Google Chrome but will not update during JavaScript execution in Firefox. Thus, it can be used to construct a exitless clock in Chrome but only an exiting clock in Firefox.

See table 2 for how the following clocks manifest in Chrome 48 (stable), Firefox³, and Safari 9.0.3.

3.2.1 Exitless clocks

Since JavaScript is single threaded and non-preemptable, exitless clocks do not have to worry about the scheduling of other JavaScript callbacks or any other events occurring between the target and timing measurements. By the semantics of JavaScript, an exitless clock is considered a run-to-completion violation[18] and is a bug. Any time JavaScript can observe changes caused externally during

a single callback qualifies as such a bug; it is only when their timing is dependable that we can construct a clock. Mozilla has explicitly stated their goal to make SpiderMonkey (the Firefox JavaScript engine) free of run-to-completion violations.

We found several exitless clocks available to JavaScript in different browsers.

1. Explicit clock queries. While expected, explicit clock queries are run-to-completion violations and expose the most accurate timing data. `performance.now` is the best source of explicit timing data in JavaScript.
2. Video frame data. By rendering a `<video>` to `<canvas>`, JavaScript can recover the current video frame. Since the video updates asynchronous to the browser event loop, this can be used to get a fine grained time-since-video-start value repeatedly.

On Firefox, video frame data updates at 60 FPS, giving a granularity of 17ms. We can load a video at 120FPS, which does not allow JavaScript access to new frames faster, but the frames JavaScript gets are a more accurate clock. We demonstrate this by generating a long-running video at 120FPS that changes the color of the entire video every frame. Thus, by sampling the current color via rendering the video to `<canvas>`, the page can measure how much time has elapsed since the video started. Video can be rendered off-screen or otherwise invisible to the user and will still update at 60FPS, making it an ideal choice for an implicit clock. We have also found that using multiple videos and averaging the reported time between them provides additional accuracy.

3. WebSpeech API. This can start/stop the speaking of a phrase from JavaScript and will give a high-resolution duration measurement when stopped. The WebSpeech API allows JavaScript to define a `SpeechSynthesisUtterance`, which contains a phrase to speak. This process can be started with `speak()` and then stopped at any time with `cancel()`. The cancellation can fire a callback whose event contains a high resolution duration of how long the system was speaking for. Thus, the attacker can start a phrase, run some target JavaScript function, and then cancel the phrase to obtain a timing target. Note that while the callback must fire to get the duration value, the duration measurement stops when `window.speechSynthesis.cancel()` is called, not when the callback eventually fires. This makes the WebSpeech API a pseudo-exitless clock in Firefox, even though we must technically wait for a callback to get back the duration measurement. Time moved forward, we just couldn't observe repeatedly. Since we can only measure the clock by stopping it,

the clock-edge technique cannot be used to enhance the accuracy of the clock.

The WebSpeech API is only supported in Firefox 44+, and on many systems will need to be manually enabled in `about:config`. Additionally, unless the OS has speech synthesis support, the clock cannot be used as it will never start speaking. Ubuntu can get this support by installing the `speech-dispatcher` package.

4. SharedArrayBuffers. While we did not test these, as the implementation is still ongoing, any sort of shared memory between JavaScript instances constitutes an exitless clock. As demonstrated in [23], this can be used as a very precise clock in real attacks.

3.2.2 Exiting clocks

Exiting clocks are far more numerous but also significantly less useful to an attacker, as their measurements and target execution are unlikely to be continuous.

1. `setTimeout`. Set to fire every millisecond, these then set a globally visible “time” variable when they do. This is the most basic of the exiting clocks. We set timeouts every millisecond as this is lowest resolution that can be set.
2. CSS animations. Set to finish every millisecond, these then set a globally visible “time” variable in their completion callback. These behave almost identically to `setTimeouts` and are measured in the same way.
3. WebVTT. This API can set subtitles for a `<video>` with up to millisecond precision and check which subtitles are currently displayed. The WebVTT interface provides a way for `<video>` elements to have subtitles or captions with the `<track>` element. These captions are loaded from a specified VTT file, which can specify arbitrary subtitles to appear for unlimited duration with up to millisecond precision. By setting a different subtitle to appear every millisecond, the page can determine how much time has elapsed since the video started by checking the `track.activeCues` attribute of the `<track>` element. This only updates when JavaScript is not executing.
4. A rate limited download. Using a cooperating server to send a file to the page at a known rate causes regular progress updates to be queued in callbacks. Using the `onprogress` event for XMLHttpRequests (XHRs), the page can get a consistent stream of callbacks to a clock update function. Note that the rate of these callbacks is related to the size of the file being retrieved, as well as the upload rate of the server.

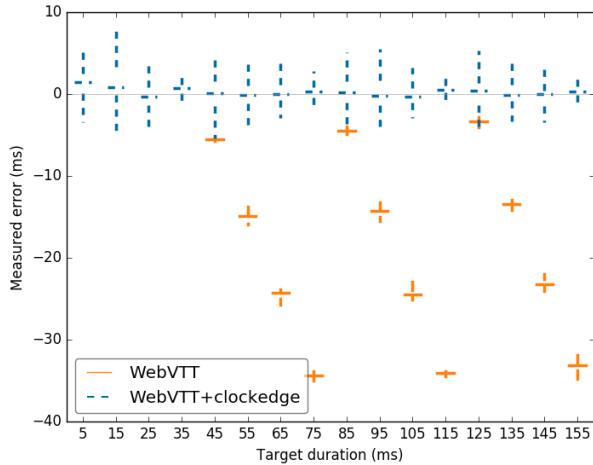

Figure 4: WebVTT error measurements with and without clock-edge technique

In our experiments, we used a file 100mB in size, with a server rate limited to 100kB/s using the Linux utility `trickle`. The page then assumes that the server is sending data at exactly 100kB/s and has an initial learning period to determine the rate at which the `onprogress` callbacks fire. After that is complete, the page can continue running as usual, with the assumption that it now has a regular callback firing at the calculated rate. Note that the `onprogress` events can also be requested to fire during the loading of `<video>` elements.

5. Video/audio tag played data. These contain the intervals of the media object that have thus far been played. By checking the furthest played point repeatedly, we can measure the duration of events. In Firefox, this only updates after JavaScript exits, but in Chrome, it updates asynchronously (making it an exitless clock for Chrome).
6. Cooperating iframes/popups from same origin. By creating a popup in the same origin, or by embedding iframes from the origin, two pages can cooperate and act on the same DOM elements. In our testing there was no way to get exitless DOM element manipulations updates in this situation. Thus, this case reduces to the `setTimeout` case or another similar method. We do not present any timing results for these clocks. Critically, if a method of sharing DOM element updates exitlessly were found this would become an exitless clock.

3.3 Performance of implicit clocks

The granularity, precision, and accuracy of implicit clocks varies widely by technique. We observe that

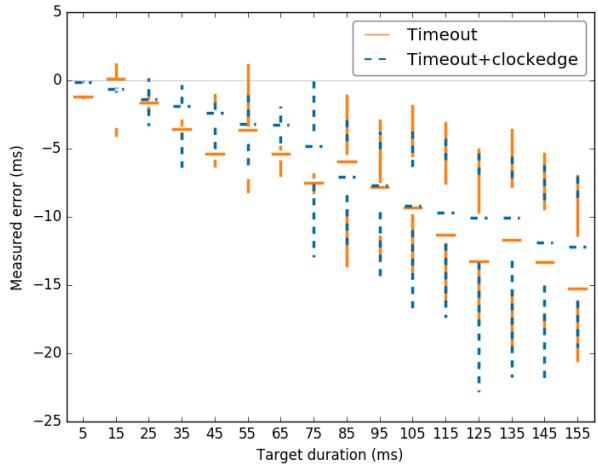

Figure 5: `setTimeout` error measurements with and without clock-edge technique

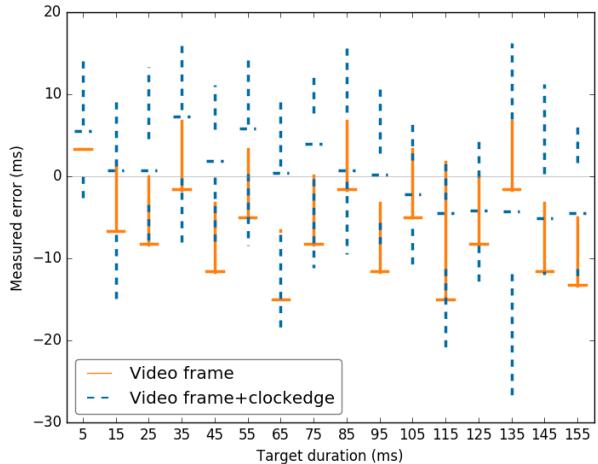

Figure 6: Video frame error measurements with and without clock-edge technique

most implicit clocks can be improved with the clock-edge technique from section 2. By substituting the `performance.now` major clock with the implicit clock technique, and using a suitable minor clock, most techniques showed notable improvements in accuracy. In this case, we want to examine how easy it would be to differentiate two different duration events. Thus, tight error bounds that are consistent are ideal.

Applying the clock-edge technique to exitless clocks only requires the replacement of the explicit `performance.now` call to some other exitless clock; no change to the minor clock is needed. Existing clocks require a new minor clock technique; instead of a tight loop, the minor clock must schedule regular timeouts that check the state of the implicit major clock. Otherwise, the exiting major clock would not change

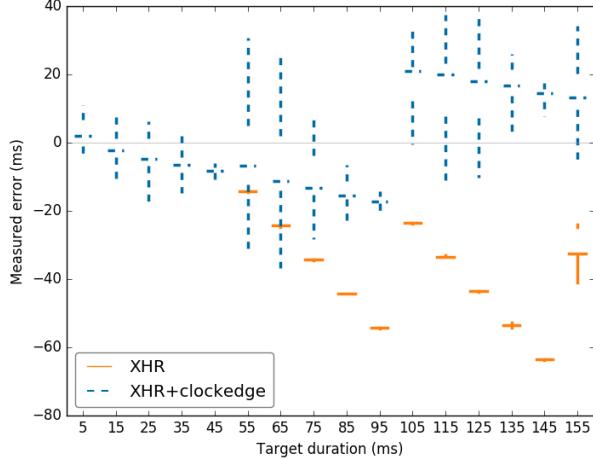

Figure 7: Throttled XMLHttpRequest error measurements with and without clock-edge technique

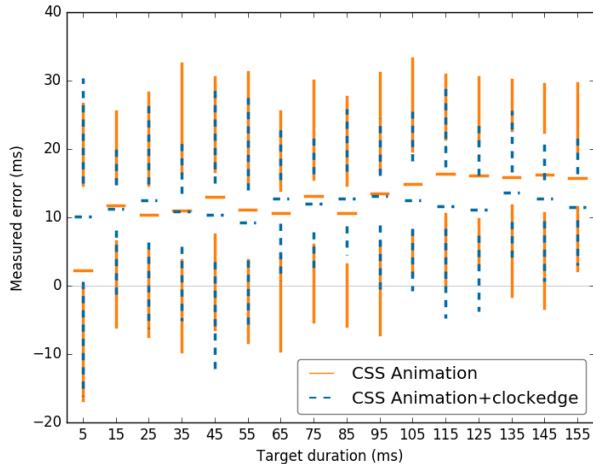

Figure 8: CSS animation error measurements with and without clock-edge technique

state while the minor clock is running. While repeated `setTimeout` calls would work, `setTimeout` of 0 is actually a 4ms timeout per the HTML5 spec, making it a major clock. Instead, we use repeated `postMessage` calls to the current window. These execute at a much higher rate, but the period is unknown. Thus the new implicit major clock now has a fast, unknown period minor clock, just as in the exitless case.

Measurements were done with the same Firefox as in section 2. Error (y values) was calculated as the difference between the clock technique measurement and the actual duration as reported by `performance.now`. Target durations (x values) are the expected duration (N milliseconds) of the target event, which may differ slightly from actual duration due to system load or even the implicit clocks themselves interfering in the case of

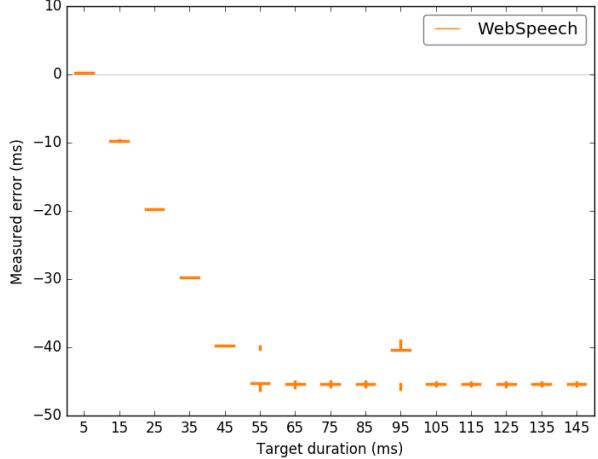

Figure 9: WebSpeech error measurements without clock-edge technique

existing clocks. Each target was measured 100 times, with measured durations of 0 or less removed. While actual durations varied slightly from expected, there was not considerable noise.

The exitless target we measure is a loop that runs for N milliseconds, as determined by `performance.now`. Our exiting target is a `setTimeout` for N milliseconds.

Figures 4, 5, 6, 7, 8, and 9 show the clock technique error with and without clock-edge improvements for a variety of clock techniques described above. WebSpeech has no clockedge data for the reasons detailed in 3.2.1. Note that the y-axis differs per figure, to allow for easier comparison between clock-edge and non-clock-edge results. As can be seen in WebVTT, throttled XHRs, and video frame data, many clock techniques have a large native period that they operate at. These large periods leave plenty of space for clock-edge to improve accuracy. WebVTT shows massive improvement in the clock-edge case due to the *precision* of its major clock ticks; the more precise the original technique, the more accurate clock-edge can be.

Figures 11 and 10 show the comparison of the averaged error for all techniques and all techniques with clock-edge respectively. The closer a line is to 0 on these graphs, the more accurate the averaged measurements will be for that technique. Again, the exceptional accuracy of WebVTT with clock-edge for long-duration events is evident.

4 Fermata

In this section we describe *Fermata*, a theoretical browser design that provably degrades all attacker visible clocks. Sections 5 and 6 describe our prototype implementation, Fuzzyfox, and an evaluation. Fermata is

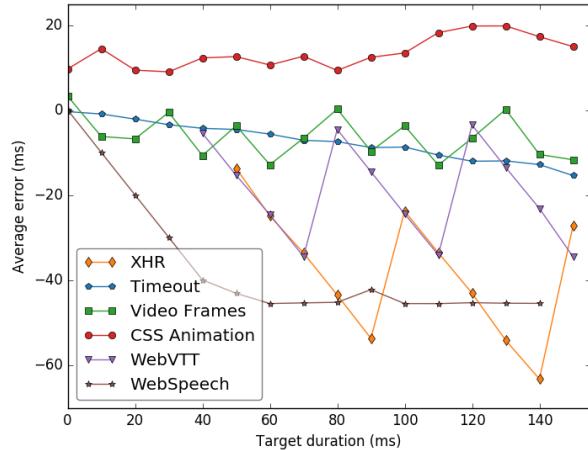

Figure 10: Average error for all clock techniques without clock-edge

an adaptation of the *fuzzy time* operating systems concept detailed in [10] to web browsers.

Since browser vendors have expressed an interest in degrading time sources available to JavaScript, we present Fermata as a design ideal for a browser that will provably degrade all clocks. Fermata’s goal is to provide the attacker with only time sources that update at a rate such that all possible timing side channels have a bounded maximum bandwidth. This includes the use of all the implicit clocks described in section 3 as well as any other such clock unknown to us.

4.1 Why Fermata?

We propose Fermata because we believe that attempting to audit and secure all possible channels in a modern web browser is infeasible. The evaluation of a provable security focused microkernel found several tricky timing channels [3]. In that case, the microkernel was designed to be audited and already had a number of concerns accounted for; this is not true in the case of a modern web browser. Rather than allow any unknown channel to leak data arbitrarily until fixed, Fermata restricts all known and unknown channels to leak at or below a target acceptable rate.

Fermata proposes a principled alternative to the “find and mitigate all clocks” methodology that Tor Browser has already begun. Rather than manually examine every DOM manipulation, extension, or new feature, Fermata requires minimal defined interfaces between all components. By automatically proving that all information passes through these interfaces and that all such interfaces are subject to the fuzzing process, Fermata will drastically reduce the burden of code that needs to be examined. This is analogous to other such approaches in

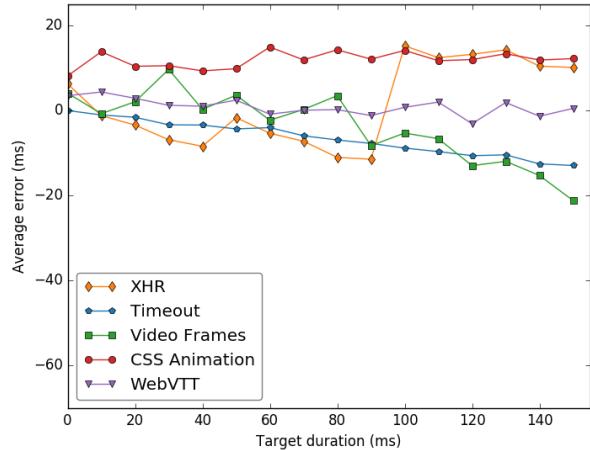

Figure 11: Average error for all clock techniques with clock-edge where available

the programming languages and formal software community.

Limiting the channel bandwidth for an attacker leaking information is not a complete solution to timing attacks on browsers, but it is a realistic one. Previous attacks on history sniffing [1] [24] have consistently cropped up. These privacy breaches are only as valuable as the amount of data they can collect. Learning that a user has visited 2-3 websites is not likely to create a unique profile of them. Learning tens of thousands of websites likely would [27]. History sniffing attacks are therefore classified based on how fast they can extract the visited status of a URL. By limiting the rate at which this information can leak, Fermata can make history sniffing impractical. As an example, [27] indicates that an attacker may need to sniff in excess of 10,000 URLs to create a reasonable fingerprint for a user. With an attack like [24] the attacker can read 60 or more URLs per second. Previous attacks not utilizing timing side channels read in excess of 30,000 URLs per second.

We expect that Fermata would allow a channel bandwidth of ≤ 50 bits per second in the general case, and ≤ 10 for security critical workflows. The protection is even stronger than initially obvious, as attacks that rely on small timing differences are entirely unusable. Only attacks that can scale their detection thresholds up (for example, Andryscy et al [1]) can still leak data. If the attack relies on a small, inherent microarchitecture timing, such as Oren et al’s [19] cache timing attack, which measured differences around 100ns, this timing difference may no longer be perceptible at all. An additional benefit is that many of these attacks require intensive learning phases, during which many measurements must be taken to establish timing profiles. Fermata would force this learning phase to take significantly longer, adding

to the time-per-bit of information extracted. From this survey of previous attacks, we believe that a strong limitation on channel bandwidth represents a powerful defense against timing attacks in browsers.

4.2 Threat model

We define our attacker as the canonical web attacker who legitimately controls some domain and server. They are able to cause the victim to visit this page in Fermata and run associated JavaScript. The attacker thus has two viewpoints we must consider: any external server controlled by the attacker and the JavaScript running in Fermata.

The attacker in our case possesses a timing side-channel vulnerability they wish to use on Fermata. The specific form of the vulnerability does not matter, only that it can be abstracted as a single JavaScript function that is called either synchronously or asynchronously. The attacker uses the duration of this function to derive secret information about the victim, possibly repeatedly.

We do not present a solution for plugins like Adobe Flash or Java applets. Significant changes to the runtime of these plugins on-par with Fermata itself would need to be made for them to be similarly resistant. Considering the number of known vulnerabilities and privacy disclosures in most of these plugins, we do not believe they should be a part of a browser design focusing on security and privacy. Alternatively, such plugins should be disabled during sensitive work flows.

The attacker succeeds against Fermata if they are able to extract bits using their side channel at a higher rate than the maximum channel bandwidth.

4.3 Design goals and challenges for Fermata

Fermata must mediate the execution of JavaScript to remove all exitless clocks and degrade all exiting clocks. This would include mediating and randomly delaying all network I/O, local I/O, communication between JavaScript instances (iframes, workers, etc), and communication to other processes (IPC). If Fermata were additionally able to make all DOM accesses by JavaScript asynchronous and delay them in the same principled fashion, this would accomplish our goals. The coupling of JavaScript’s globally accessible variables to the DOM represents the most significant challenge to such a design and presents a shared state problem not found in the model for this work [10].

Given this shared state problem, Fermata has two options for JavaScript: redesign JavaScript execution to be entirely asynchronous or degrade explicit clocks and mediate known APIs in a principled manner. The former provides a formal guarantee but cannot be done in current browser architectures. We explore options for the latter later in this section and in Fuzzyfox.

4.4 Fermata guarantees

We believe that the analysis of Hu’s fuzzytime by Gray in [5] applies to Fermata. The means that we can place an upper bound on the leakage rate of Fermata at $\frac{1}{g/2}$ symbols per second, assuming the median tick rate of $\frac{g}{2}$.

As in [5], we assume that increasing the size of the alphabet used will provide negligible benefits. Thus, this bound is an upper bound for the bits-per-second leakage rate of Fermata. We view the vulnerable functionality targeted by the attacker in the strongest possible way: the attacker has complete control over when and how it leaks timing information. This is effectively the high/low privilege *covert channel* scenario the fuzzytime disk contention channel is analyzed under. Similarly, in Fermata, the leaking feature may have access to the same fuzzy clock as the attacker. This allows them to synchronize instantly from “low to high” privilege as in the fuzzytime analysis. Thus, the side channel threat model Fermata operates under is a subset of the fuzzy time model.

There is further analysis of the capacity of covert channels with fuzzy time defenses in [6]. The general case problem of covert channel capacity under fuzzy time appears to be intractable but can be bounded under specific circumstances.

4.4.1 Transmitted bits vs information learned

Fermata makes a guarantee about the actual transmitted bitrate of some side channel. This has obvious benefits in the case of leaking a CSRF token or a cryptographic key: the bits the attacker needs to learn equals the number of bits in the key or token. However, this becomes trickier to quantify with a goal like history sniffing where the details of the side channel can influence what the attacker learns with each leaked bit.

Consider a timing side channel that can indicate if a single URL has been visited by the victim one at a time. Each time the channel is used one bit of information (visit status of the URL) is leaked. If the attacker wishes to learn the visit status of 10,000 URLs they must check each individually.

If instead a timing side channel could indicate if any URLs from an arbitrary set were visited, the attacker could use this along with prior knowledge that almost all URLs have not been visited to learn about more URLs in less bits. Given some set of 10,000 URLs, the side channel indicates that at least one was visited and then, in a divide-and-conquer approach, the first half indicates that none were visited. How many bits were leaked? Two bits were transmitted: that some URLs were visited in the 10,000, and that no URLs in the first 5,000 were visited. However, we have learned the visit status of 5,000 URLs. This is only possible because the attacker can assume the majority of URLs are not visited.

We believe that Fermata’s guarantees still constitute a

valuable defense against using timing side channels for history sniffing. First, not all history sniffing side channels have allowed checking the visit status of batches of URLs. In these cases Fermata limits learning the visit status of each URL individually. Second, if the attacker wishes to learn specific URLs from the browsing history (ex: to launch a targeted phishing attack), rather than just learn a rough fingerprint, they will still need to examine each individual URL regardless of how the side channel can operate.

Fermata cannot provably *prevent* a timing side channel from operating; it can only constrain the rate of bits transmitted across the channel. For any side channel it is important to consider the attacker’s goals along with how the side channel operates to understand what level of mitigation Fermata will provide. There are multiple reasons (compression, prior knowledge, etc.) that might lead to a side channel exhibiting behavior like described above. In all of these cases Fermata provides the same guarantee about channel bandwidth.

4.5 Isolating JavaScript from the world

A potential solution for JavaScript is to remove all run-to-completion violations, effectively ensuring that JavaScript cannot observe any state changes to the DOM or otherwise during a single execution. This necessarily includes all realtime clock accesses, as well as any other discovered exitless clocks. Since JavaScript will always have access to a fine grained minor clock (the `for` loop), it is critical that all exitless *major* clocks be removed. In the case of `performance.now`, this will result in the feature becoming an exiting clock, requiring that JavaScript stop execution before the available clock value changes.

The catch of the latter method is in how to remove all potential exitless clocks. If the upcoming SharedArrayBuffer API becomes available, this presents a highly accurate exitless clock that Fermata cannot mitigate without returning it to a message passing interface. Removing all of these potential exitless clocks requires an examination of all interfaces the JavaScript runtime has.

With all exitless clocks removed, the design need only focus on degrading exiting clocks to meet the target maximum channel bandwidth.

4.6 Degrading explicit clocks

Explicit clocks (ex: `performance.now`, `Date`, etc.) are degraded to some granularity g and update unpredictably. As in Hu [10], we accomplish this by performing updates to the clock value (at the granularity g) at randomized intervals. g is a multiple of the native OS time grain g_n (generally 1ns). Each randomized interval is a “tick,” during which the available explicit clocks do not change. At the beginning of each tick, we up-

date the Fermata clock to the rounded-down wallclock. Since the tick duration is not the same as g , the Fermata clocks will not always change in value every tick. This design guarantees that the available explicit clocks are only ever behind and are behind by a bounded amount of time, $g - g_n + (g/2)$. Note that a clock’s granularity does not alone define the accuracy to which it can be used to time some event, as seen with section 2.

Tick duration is not constant but is instead drawn from a uniform distribution with a mean of $g/2$. If intervals were constant and thus clock updates occurred exactly on the grain, the attacker could use the same clock-edge technique as in section 2.

4.7 Delaying events

The randomized update intervals (ticks) are further divided into alternating upticks and downticks for the purposes of delaying events and I/O. This mimics their usage in Hu [10]. Downticks cause outbound queued events to be flushed, and upticks cause inbound events to be delivered.

4.8 Tuning Fermata

Since the defensive guarantee provided by Fermata is only a maximum channel bandwidth, a few users may want to change the tradeoff between responsiveness and privacy. Fermata will provide this option via a tunable privacy setting that allows setting the acceptable leaking channel bandwidth. In turn, this will modify the average tick duration and the explicit time granularity, both of which affect usability. We expect that only developers (including of browser forks like Tor Browser) or users with specific privacy needs would interact with these settings.

5 Fuzzyfox prototype implementation

In this section we describe *Fuzzyfox*⁴, a prototype implementing many of the principles of the Fermata design in Mozilla Firefox. Fuzzyfox is not a complete Fermata solution but does show that the removal of exitless clocks and the delaying of events is a feasible design strategy for a browser.

Fuzzyfox attempts to mitigate the clocks of sections 2 and 3 by using the ideas in Fermata. Web browsers have an interest in degrading clocks available to JavaScript to reduce the impact of both known and unknown timing channel attacks. Fuzzyfox is a concrete demonstration of techniques that will make a browser more resistant to such timing attacks. As in Fermata, Fuzzyfox has a clock grain setting (g) and an average tick duration ($t_a = g/2$). All explicit clocks in Fuzzyfox report multiples of g .

We will refer to Firefox when discussing default behavior and Fuzzyfox when discussing the changes made.

5.1 Why Fuzzyfox?

We built Fuzzyfox for three reasons:

1. Building a new web browser is a monumental task.
2. We did not know if a Fermata-style design would result in a usable experience. It was entirely possible that the delays induced would render any Fermata-style designs unusable.
3. We want to deploy the insights of channel bandwidth mitigation to real systems like Tor Browser.

Fuzzyfox does *not* have the complete auditability advantages that Fermata would. However, we believe that our insights about principled fuzzing of explicit clocks can be directly applied to Tor Browser as an improvement to their ongoing efforts.

5.2 PauseTask

The core of the Fuzzyfox implementation is the PauseTask, a recurring event on the main thread event queue. The PauseTask provides two primary functions: it implicitly divides the execution of the event queue into discrete intervals, and it serves as the arbiter of uptick and downtick events.

Once Firefox has begun queuing events on the event queue, Fuzzyfox ensures that the first PauseTask gets added to the queue. From this point on, there will always be exactly one PauseTask on the event queue.

PauseTask does the following on each execution: determines remaining duration, generates retroactive ticks, sleeps remaining duration, updates clocks, flushes queues, and queues the next PauseTask.

Determine remaining duration

The PauseTask checks the current OS realtime clock (T_1) with microsecond accuracy using `gettimeofday`. Comparing this against the expected time between ticks (D_e) and the end of the last PauseTask (T_2) gives the actual duration (D_a). If $D_a \leq D_e$, PauseTask skips directly to sleeping away the remaining duration, $D_e - D_a$.

Optional: Retroactive ticks

Otherwise, PauseTask must retroactively generate the upticks and downticks that should have occurred. This ensures that even by being long running JavaScript cannot force a 0 sleep duration PauseTask.

Sleep remaining duration

PauseTask finishes out the remaining duration via `usleep`. `usleep` is not perfectly accurate, and has a fixed overhead cost. In our testing, `usleep` error varies based on the duration but is never enough to be an issue for Fuzzyfox.

Update all system clocks and flush queues

PauseTask now generates the new canonical system time. This is accomplished by taking the OS realtime clock and rounding down to the Fuzzyfox clock grain setting.

There are two underlying explicit time sources available to JavaScript, `Time` and `performance`. `PauseTask` directly updates the canonical `TimeStamp` time, which is used by `performance`, and delivers a message to the JavaScript runtimes to update `Time`'s canonical time. Our review found that all of the other time sources we knew of used `TimeStamp`.

In our prototype, the only I/O queue that needs to be flushed is the `DelayChannelQueue` (see section 5.3.) This only occurs if the currently executing `PauseTask` is a downtick.

Queue next PauseTask event

Finally, `PauseTask` queues the next `PauseTask` on the event queue. This sets the start time (T_1), marks the new `PauseTask` as either uptick or downtick, as well as drawing a random duration from the uniformly random distribution between 1 to $2 \times t_a$. `PauseTasks` are queued exclusively on the main thread to ensure they block JavaScript execution as well as all DOM manipulation events.

5.3 Queuing

All events visible to JavaScript must be queued in Fuzzyfox. Unfortunately, there is not a singular place or even explicit queues available for all events in Firefox. We use `PauseTask` to create implicit queues for all main thread events (including JavaScript callbacks, all DOM manipulations, all animations, and others) and construct our own queuing for network connections.

Timer events (including CSS animations, `setTimeout`, etc.) do not need to be explicitly modified from Firefox behavior, as they run in a separate thread that checks when timers should fire based on `TimeStamp`. As Fuzzyfox ensures all `TimeStamp`s are set to our canonical Fuzzyfox time, this is not a problem.

DelayChannelQueue

We implemented a simple arbitrary length queue for outgoing network connections called `DelayChannelQueue`. This queue contains any channels that have started to open and stops them from connecting to their external resource. In the Fuzzyfox prototype, we only queue outgoing HTTP requests, although it could easily be extended to more channel types. Upon receiving a downtick notification from `PauseTask`, the queue is locked and all currently queued channel connections are completed and flushed from the queue.

6 Fuzzyfox evaluation

We evaluated our prototype Fuzzyfox in both effectiveness (how it degrades clocks) and performance.

All evaluations are compared against a clean Firefox build without the Fuzzyfox patches. Firefox trunk⁵ was used as the basis and built with default build settings. Fuzzyfox patches are then applied on top of this commit and built with the same configuration. All tests were performed on an updated Ubuntu 14.04 machine with an Intel i5-4460 and 14GB of RAM. The only applications running during testing were the XFCE window manager and Fuzzyfox. Fuzzyfox and Firefox were both tested using the experimental e10s Firefox architecture. NSPR logging was enabled to capture data about Fuzzyfox internals.

6.1 Limitations

Fuzzyfox is not a complete Fermata implementation and is unable to guarantee a maximum channel bandwidth. Since we did not isolate the JavaScript engine from the DOM or all I/O operations, we did not interpose on all interfaces as would be required in a Fermata implementation. This is purely a practical decision, as accomplishing this in Firefox would require manually auditing the entire codebase. We do not, for example, interpose on synchronous IPC calls from JavaScript. See section 6.2.3 for an example of how this can break the Fermata guarantees.

Unfortunately, since our `PauseTasks` can be delayed by long running JavaScript on the main thread, we can no longer bound the difference between the OS realtime clock and the available explicit clocks. We do still guarantee that all explicit clocks are only ever behind realtime.

While we experimented with a number of different grain settings, the settings providing very high privacy guarantees (100s of milliseconds) have severe usability impact. We believe that a clean Fermata implementation may not incur such a strong usability impact at similar grain settings.

6.2 Effectiveness

Effectiveness is measured as the available resolution for a given clock. In the ideal case, all clocks in Fuzzyfox should be degraded provide a resolution no less than g . We measure the observed properties of the clocks described in section 3 between Firefox and Fuzzyfox. We set the explicit time granularity (g) to 100ms and the average `PauseTask` interval (t_a) to 50ms for these tests. We chose $g = 100ms$ because a large g value most clearly illustrates the difference between Fuzzyfox and Firefox. See section 6.3 for an evaluation of the impact of high g values on performance.

The following figures show scatter plots for several

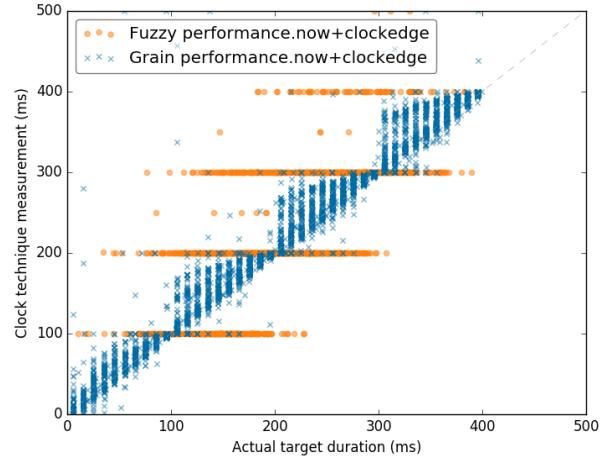

Figure 12: `performance.now` measurements with clock-edge on Fuzzyfox (existing) and Firefox (exitless, 100ms grain)

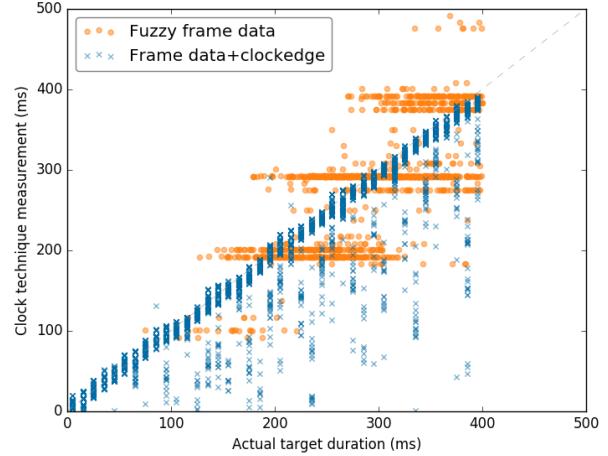

Figure 13: Frame data clock measurements on Firefox and Fuzzyfox

clock techniques as they operate in Firefox and in Fuzzyfox. In each, a perfectly accurate clock would follow the dashed grey line on $x = y$. Note that these figures show actual duration and clock technique duration, rather than target duration and error as in section 3.3. This is due to Fuzzyfox being unable to dependably schedule targets less than g (100ms) in duration. Thus, while the same testing code was used in Fuzzyfox and in Firefox, the actual durations of events are much longer in Fuzzyfox. Finally, there are no exitless clocks that we know of in Fuzzyfox to test, which would have been a closer comparison.

6.2.1 `performance.now`

Since time no longer moves forward during JavaScript execution, `performance.now` is now an existing

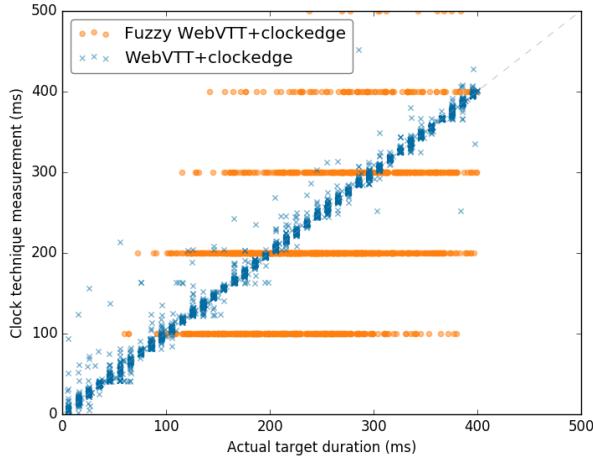

Figure 14: WebVTT clock measurements on Firefox and Fuzzyfox

clock. Figure 12 shows the results of using the clock-edge technique on `performance.now` for both Fuzzyfox and Firefox with a grain set to 100ms. Notably, clock-edge no longer improves the accuracy of the measurements! This demonstrates that the Fuzzyfox model successfully degrades explicit clocks.

6.2.2 Video frame data

Unexpectedly, Fuzzyfox transforms the video frame data clock from exitless to exiting. This is probably because the frame extracted for canvas is determined using the current explicit clock values (`TimeStamp`). Since time does not move forward during JavaScript execution, frame data is now an exiting clock. In general, we expect that run-to-completion violations (and by extension most exitless clocks) would not be properly degraded by Fuzzyfox. Figure 13 shows the exiting frame data clock on Fuzzyfox and Firefox.

6.2.3 WebSpeech API

Fuzzyfox degrades the WebSpeech API only because the `elapsedTime` field is drawn using the explicit clocks in Fuzzyfox. The starting and stopping of the speech is still synchronous, so it is possible some other piece of information passed back by the speech synthesis provider could provide a more accurate clock. WebSpeech should not be considered properly isolated by Fuzzyfox. Only if the *starting* and *stopping* of speech synthesis were queued like other events would Fuzzyfox correctly handle WebSpeech.

6.2.4 `setTimeout`

As `setTimeout` events are fired from the timer thread based on the degraded explicit clocks, they are no longer able to fire more often than the explicit time grain g of 100ms.

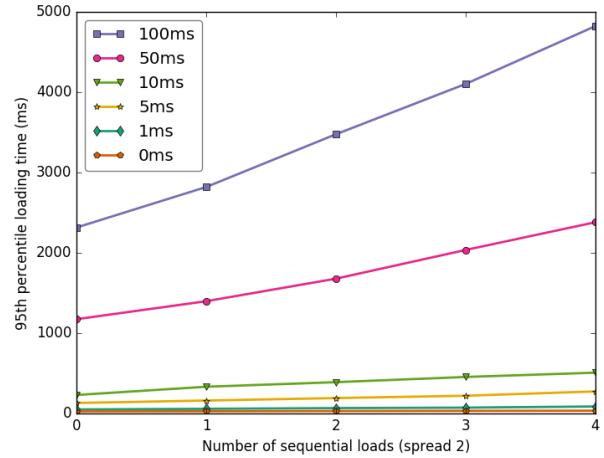

Figure 15: Page load times with variable depth for all Fuzzyfox configurations at a spread of 2

```
var njs=document.createElement('script')
njs.setAttribute('type','text/javascript')
njs.setAttribute('src','layer2.js')
document.getElementsByTagName('head')[0].appendChild(njs)
```

Figure 16: Iterative page load JavaScript

6.2.5 CSS Animations

As with `setTimeout`, CSS animation events are fired from the timer thread based on the degraded explicit clocks. Thus, they too are not able to be used as a clock of finer grain than the explicit time grain g .

6.2.6 XMLHttpRequests

XMLHttpRequests are properly degraded by Fuzzyfox. Since the callbacks for `onprogress` are queued on the main event queue and then gated by `PauseTask`, they are no longer timely when processed.

6.2.7 WebVTT subtitles

We examined the WebVTT subtitle implicit exiting clock in detail, as it performed among the best with the clock-edge technique on vanilla Firefox. Figure 14 shows the results for the same WebVTT clock techniques as described in section 3.2.2 on both Fuzzyfox and Firefox. Note that the clockedge code provided no benefits to the Fuzzyfox case.

6.3 Performance

Performance impact is difficult to measure, as most performance tools for browsers rely on accurate time measurements via JavaScript.

We performed a series of page load time tests, which show predictable results. We measure the impact of both *depth* of page loads and the *spread* of initial requests.

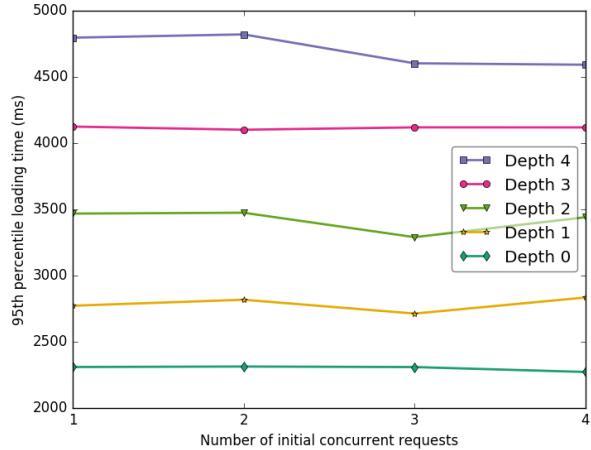

Figure 17: Page load times with variable spread and depth for $g = 100ms$

Our testing setup consisted of 20 test pages and 5 different fuzzyfox/Firefox configurations. The depth of the test pages represents how many sequential requests are made. Each request consists of inserting a script file of the form in figure 16. Each one has the loaded script be the next “layer” down, with layer 0 being an empty script. Thus, a test page that is 3 deep makes 4 sequential requests: `page.html`, `layer2.js`, `layer1.js`, `layer0.js`. Spread is achieved by the base `page.html` performing several duplicate initial requests to the top layer. Thus, a spread of 2 and a depth of 2 results in requests for: `page.html`, `layer1.js`, `layer1.js`, `layer0.js`, `layer0.js`. After the final page load completes, the total time from initial page navigation until completion is stored, and this process is repeated 1000 times per page test. We generate 20 test pages by combining up to 5 layers of depth with a spread from 1 to 5. We served the test pages via a basic nginx configuration running on the same host as the browser.

Figures 15 and 17 show two different views of some of the results, with the 95th percentile of load times being shown for $g = 100ms$. As expected, increasing the spread for a given depth (as shown in figure 17) results in almost no change to load times. All other browser configurations (see figure 18 for $g = 5ms$) had nearly identical results, with differing y-intercepts based on g . This occurs because outgoing HTTP requests in Fuzzyfox are batched, so queuing multiple requests at once does not incur any g -scaled penalties. However, as figure 15 shows, increasing the depth incurs a linear overhead with the slope and intercept scaled by the value of g . The worst case for Fuzzyfox are pages that do large numbers of sequential loads, each requiring JavaScript to run before the next load can be queued. Unfortunately, many modern webpages end up performing repeated loads of

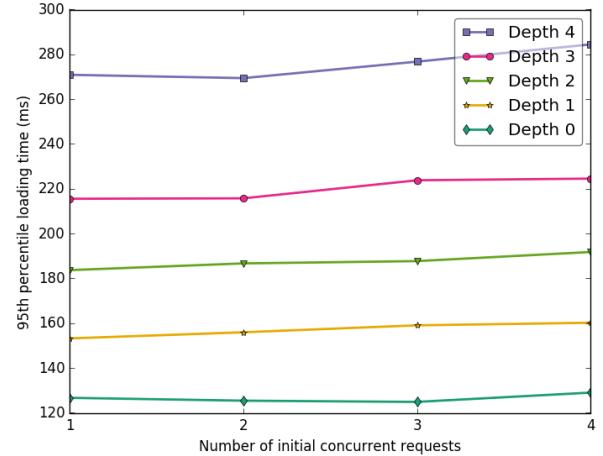

Figure 18: Page load times with variable spread and depth for $g = 5ms$

various libraries and partial content. One potential solution would be more widespread use of HTTP2’s Server Push which would alleviate the repeated g scaled penalties for resource requests.

JavaScript engine tests, such as JetStream, reported identical scores of 181 for both Firefox and Fuzzyfox.⁶ Fuzzyfox predictably records a maximum FPS equal to the average `PauseTask` fire rate or 20 FPS for $g = 100ms$, as compared to 60 FPS in the Firefox case.

6.3.1 Tor Browser

We also ran our page load tests on vanilla Tor Browser⁷. Rather than access the pages over the localhost interface, they are accessed over the Tor network. No other changes to the test setup were made. Due to the major changes in routing, the load times we observed are far more variable than in the Firefox or Fuzzyfox case and show no significant trends on the whole. If we compare the range of page load times between Fuzzyfox ($g = 100ms$) and Tor Browser in figures 19 and 20, we see that Tor Browser imposes a significantly *higher* overhead most of the time in both initial page load and in page load completion. Other spread levels show similar behavior. As in previous figures we show the 95th percentile load completion times but we additionally show the range from the minimum completion (`onload` fires) time as a shaded region.

6.3.2 Real world page loads

Table 3 shows a rough macro-benchmark of real-world page load times for Firefox, Fuzzyfox (various grains), and Tor Browser. In each case, the same Google search results page was loaded. These tests were manually performed and the reported page load time comes from the Firefox developer tools. Each load requested between

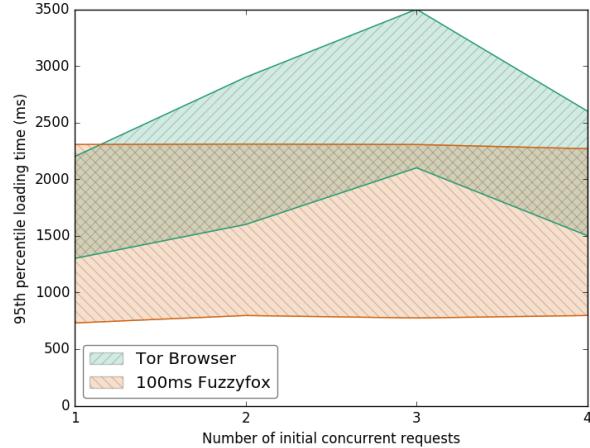

Figure 19: Range of page load completion times with variable depth at a spread of 0 for Tor Browser and Fuzzyfox $g = 100ms$

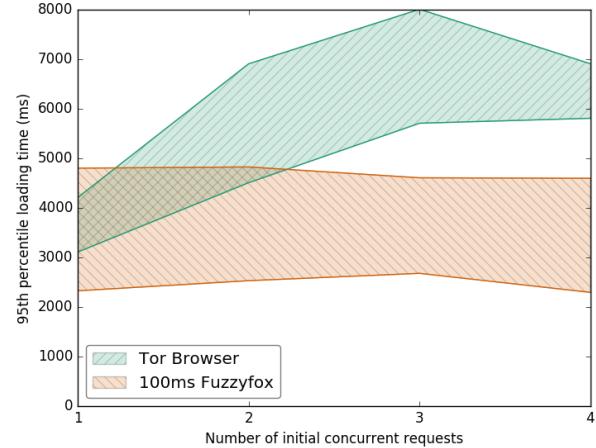

Figure 20: Range of page load completion times with variable depth at a spread of 4 for Tor Browser and Fuzzyfox $g = 100ms$

Browser or Grain(ms)	Reported load time(s)	
	Reload	Force Reload
Firefox	0.82	0.86
0.5	0.84	0.79
1	0.85	0.85
5	0.94	0.94
10	1.03	1.04
50	2.09	1.71
100	2.86	2.60
Tor	3.78	7.18

Table 3: Average page load times for https://www.google.com/?gws_rd=ssl#q=test+search with 10 reloads and 10 force reloads (no caching) on Firefox, Fuzzyfox, and Tor Browser

9 and 12 resources. The “force reload” column corresponds to a cache-less reload of the page, whereas the “reload” column indicates the load time with caching allowed. Minor differences between the reload and force reload results for a given browser are not statistically significant as we only have 10 samples.

While a larger study of more real-world pages would be valuable, such a study is larger in scope than this paper can cover. To perform such a measurement, we would need to individually determine a “load complete” point for each test page and re-instrument Fuzzyfox to enable measurements at these exact points. Google search results were chosen specifically because they do not continue to load resources indefinitely as many major websites do. (Ex: nytimes.com, youtube.com, etc.) We therefore leave a more detailed real-world page load time and user experience impact study to future work.

These metrics are incomplete, as they do not measure

interactivity of the pages, which can suffer in the Fuzzyfox case more than in Tor Browser. We leave further analysis of various performance impacts to future work.

While higher g settings cause significant page load time increases, these overheads are acceptable to some privacy conscious users and developers as demonstrated by Tor Browser. We do not have metrics for the impact of using both Tor Browser and our Fuzzyfox patch set, but we expect the overheads to be additive in the worst case. One option for integration with Tor Browser specifically would be to tune the value of g based on the setting of the “security slider” [20].

In light of these metrics, a g setting of $g \leq 5ms$ is likely tolerable for average use cases, while higher settings (up to and including $g = 100ms$) would likely be tolerated by users of Tor Browser. Ideally the clock fuzzing and other features as appropriate will be deployed in Firefox, and can be configured for a higher g in Tor Browser. If a more complete version of Fermata is developed, it will be worthwhile to run user studies before deploying g settings.

7 Related work

Popek and Kline [21] were the first to observe that the presence of clocks opens covert channels. They suggested that virtual machines be presented only with virtual clocks, not “a real time measure.” Lipner [16] responded that keeping virtual machines from correlating virtual time to real time is a “difficult problem,” since time is “the one system-wide resource [...] that can be observed in at least a coarse way by every user and every program.” Lipner suggested “randomizing the relation of virtual and real time” to add noise to the channel. Lipner also reported private communication from Saltzer

that timing channels had been demonstrated in Multics by mid-1975.

Digital’s VAX VMM Security Kernel project(initiated in 1981 and canceled in 1990 before its evaluation at the A1 level could be completed [12]) was the first system to attempt to randomize the relationship of virtual and real time. The VAX VMM Security Kernel team published three important papers describing their system. The first, by Karger et al. [11, 12], gave an overview of the system. The second, by Wray [28], presented a theory of time (“[w]e view the passage of time as being characterized by a sequence of events which can be distinguished one from another by an observer”) and of timing channels and is the source for our view, in this paper, of timing channels as arising from the comparison of a reference clock with a modulated clock. Wray noted that a process that increments a variable in a loop can be used as a clock. The third, by Hu [9, 10], described the VAX VMM’s fuzzy time system and is the inspiration for our paper. (A 2012 retrospective [15], though not the contemporaneous papers, reveals that the fuzzy time idea was developed in collaboration with the National Security Agency’s Robert Morris.) We describe many of the details of the fuzzy time system elsewhere in the paper. The 1992 journal version [9] of Hu’s paper gives a more complete security analysis than does the 1991 conference version [10]. In particular, it notes that fuzzy time would be defeated if the VM could devote a processor thread to incrementing a counter in memory shared with its other processor threads. This attack did not affect the Vax VMM Security Kernel, since it limited virtual machines to a single processor and did not support shared memory; it would apply to browsers if the proposed Shared Memory and Atomics specification [8] is implemented.

Several followup papers examined the security of fuzzy time. Trostle [25] observed that if scheduler time quanta coincide with upticks and if the scheduler employs a simple FIFO policy, then the scheduler can be used as a covert channel with 50 bps channel capacity. To send a bit, a high process either takes its entire time quantum or yields the processor; low processes try to send messages to each other in each time quantum. Which and how many messages arrived reveals the high process’ bit. Gray showed attacks on fuzzy time that exploit bus contention [7] and calculated a channel capacity for shared buses under fuzzy time under the assumption (satisfied in the case of the VAX VMM Security Kernel) that a low receiver can immediately notify the high sender when it receives an uptick [5]. A later tech report combines both papers by Gray [6].

Martin et al. [17] translated fuzzy time to the microarchitectural setting, proposing and evaluating a new microarchitecture in which execution is divided into variable-length “epochs.” The `rdtsc` instruction delays

execution until the next epoch and returns a cycle count randomly chosen from the last epoch. Because their focus is microarchitectural timing channels, Martin et al. argue that other sources of time, such as interrupt delivery, are inherently too coarse grained to need fuzzing. Martin et al. observe that simply rounding `rdtsc` to some granularity would be susceptible to clock-edge effects.

The success of infrastructure-as-a-service cloud computing brought with it the risk of cross-VM side channels [22]. Aviram et al. [2] proposed to close timing channels in cloud computing by enforcing deterministic execution and experimented with compiling a Linux kernel and userland not to use high-resolution timers like `rdtsc`, observing a drop in throughput. Vattikonda et al. [26] showed that it is possible to virtualize `rdtsc` for Xen guests, reducing its resolution (but allowing clock-edge attacks). Ford [4] proposed timing information flow control, or TIFC, “an extension of DIFC for reasoning about [...] the propagation of sensitive information into, out of, or within a software system via timing channels,” and proposed two mechanisms for implementing TIFC: deterministic execution and “pacing queues,” which are an extension of the VAX VMM Security Kernel’s interrupt queue mechanism.

Li et al. [13, 14] describe StopWatch, a virtual machine manager designed to defeat timing side channel attacks. In StopWatch, clocks are virtualized to “a deterministic function of the VM’s instructions executed so far”; multiple replicas of each VM are run in lockstep, and I/O timing for all of them is determined by the (virtual) time observed by the median replica.

Finally, Wu et Al. [29] present Deterland, a hypervisor that runs legacy operating systems deterministically. Deterland splits time into ticks and allows I/O only on tick boundaries. As in StopWatch, virtual time in Deterland is a function of the number of instructions executed.

8 Conclusions and future work

Restricting or removing timing side channels is a complex task. Simple degradation of available explicit clocks is an insufficient solution, allowing clock-edge techniques and implicit clocks to obtain additional timing information.

By drawing upon the lessons learned from trusted operating systems literature, we believe that browsers can be architected to mitigate all possible timing side channels. We propose Fermata as a design goal for such a verifiably resistant browser. Our Fuzzyfox patches to Firefox show that a Fermata-like design can intelligently make tradeoffs between performance and security, while not breaking the current interactions with JavaScript. Fuzzyfox empirically degrades clocks in a way that is

not susceptible to clock-edge techniques, protecting timing information.

Fuzzyfox requires a number of engineering improvements before it is ready to deploy to users, but it has proved that the fuzzy time concept can be applied to browsers. Notably, more experiments with setting channel bandwidth and exposing such settings to users need to be performed. Additionally, Fuzzyfox does not hook inbound network events, which a cooperating server could use to derive the duration of events in Fuzzyfox. Other interfaces (WebSockets, WebAudio, other media APIs) should be investigated for behavior that would break the Fuzzyfox design. We expect that with these changes Fuzzyfox could be adapted for use in projects like Tor Browser and protect real users against timing attacks.

Abstract

Numerous surveys have shown that Web users are concerned about the loss of privacy associated with online tracking. Alarmingly, these surveys also reveal that people are also unaware of the amount of data sharing that occurs between ad exchanges, and thus underestimate the privacy risks associated with online tracking.

In reality, the modern ad ecosystem is fueled by a flow of user data between trackers and ad exchanges. Although recent work has shown that ad exchanges routinely perform *cookie matching* with other exchanges, these studies are based on brittle heuristics that cannot detect all forms of information sharing, especially under adversarial conditions.

In this study, we develop a methodology that is able to detect client- and server-side flows of information between arbitrary ad exchanges. Our key insight is to leverage *retargeted ads* as a tool for identifying information flows. Intuitively, our methodology works because it relies on the *semantics* of how exchanges serve ads, rather than focusing on specific cookie matching *mechanisms*. Using crawled data on 35,448 ad impressions, we show that our methodology can successfully categorize four different kinds of information sharing behavior between ad exchanges, including cases where existing heuristic methods fail.

We conclude with a discussion of how our findings and methodologies can be leveraged to give users more control over what kind of ads they see and how their information is shared between ad exchanges.

1 Introduction

People have complicated feelings with respect to online behavioral advertising. While surveys have shown that some users prefer relevant, targeted ads to random, untargeted ads [60, 14], this preference has caveats. For example, users are uncomfortable with ads that are tar-

geted based on sensitive Personally Identifiable Information (PII) [44, 4] or specific kinds of browsing history (*e.g.*, visiting medical websites) [41]. Furthermore, some users are universally opposed to online tracking, regardless of circumstance [46, 60, 14].

One particular concern held by users is their “digital footprint” [33, 65, 58], *i.e.*, which first- and third-parties are able to track their browsing history? Large-scale web crawls have repeatedly shown that trackers are ubiquitous [24, 19], with DoubleClick alone being able to observe visitors on 40% of websites in the Alexa Top-100K [11]. These results paint a picture of a balkanized web, where trackers divide up the space and compete for the ability to collect data and serve targeted ads.

However, this picture of the privacy landscape is at odds with the current reality of the ad ecosystem. Specifically, ad exchanges routinely perform *cookie matching* with each other, to synchronize unique identifiers and share user data [2, 54, 21]. Cookie matching is a precondition for ad exchanges to participate in *Real Time Bidding* (RTB) auctions, which have become the dominant mechanism for buying and selling advertising inventory from publishers. Problematically, Hoofnagle *et al.* report that users naïvely believe that privacy policies prevent companies from sharing user data with third-parties, which is not always the case [32].

Despite user concerns about their digital footprint, we currently lack the tools to fully understand how information is being shared between ad exchanges. Prior empirical work on cookie matching has relied on heuristics that look for specific strings in HTTP messages to identify flows between ad networks [2, 54, 21]. However, these heuristics are brittle in the face of obfuscation: for example, DoubleClick cryptographically hashes their cookies before sending them to other ad networks [1]. More fundamentally, analysis of *client-side* HTTP messages are insufficient to detect *server-side* information flows between ad networks.

In this study, we develop a methodology that is able to detect client- and server-side flows of information between arbitrary ad exchanges that serve *retargeted ads*. Retargeted ads are the most specific form of behavioral ads, where a user is targeted with ads related to the exact products she has previously browsed (see § 2.2 for definition). For example, Bob visits nike.com and browses for running shoes but decides not to purchase them. Bob later visits cnn.com and sees an ad for the exact same running shoes from Nike.

Our key insight is to leverage retargeted ads as a mechanism for identifying information flows. This is possible because the strict conditions that must be met for a retarget to be served allow us to infer the precise flow of tracking information that facilitated the serving of the ad. Intuitively, our methodology works because it relies on the *semantics* of how exchanges serve ads, rather than focusing on specific cookie matching *mechanisms*.

To demonstrate the efficacy of our methodology, we conduct extensive experiments on real data. We train 90 *personas* by visiting popular e-commerce sites, and then crawl major publishers to gather retargeted ads [9, 12]. Our crawler is an instrumented version of Chromium that records the *inclusion chain* for every resource it encounters [5], including 35,448 chains associated with 5,102 unique retargeted ads. We use carefully designed pattern matching rules to categorize each of these chains, which reveal 1) the pair of ad exchanges that shared information in order to serve the retarget, and 2) the mechanism used to share the data (*e.g.*, cookie matching).

In summary, we make the following contributions:

- We present a novel methodology for identifying information flows between ad networks that is content- and ad exchange-agnostic. Our methodology allows to identify four different categories of information sharing between ad exchanges, of which cookie matching is one.
- Using crawled data, we show that the heuristic methods used by prior work to analyze cookie matching are unable to identify 31% of ad exchange pairs that share data.
- Although it is known that Google’s privacy policy allows it to share data between its services [26], we provide the first empirical evidence that Google uses this capability to serve retargeted ads.
- Using graph analysis, we show how our data can be used to automatically infer the roles played by different ad exchanges (*e.g.*, Supply-Side and Demand-Side Platforms). These results expand upon prior work [25] and facilitate a more nuanced understanding of the online ad ecosystem.

Ultimately, we view our methodology as a stepping stone towards more balanced privacy protection tools for

users, that also enable publishers to earn revenue. Surveys have shown that users are not necessarily opposed to online ads: some users are just opposed to tracking [46, 60, 14], while others simply desire more nuanced control over their digital footprint [4, 41]. However, existing tools (*e.g.*, browser extensions) cannot distinguish between targeted and untargeted ads, thus leaving users with no alternative but to block all ads. Conversely, our results open up the possibility of building in-browser tools that just block cookie matching, which will effectively prevent most targeted ads from RTB auctions, while still allowing untargeted ads to be served.

Open Source. As a service to the community, we have open sourced all the data from this project. This includes over 7K labeled behaviorally targeted and retargeted ads, as well as the inclusion chains and full HTTP traces associated with these ads. The data is available at:

<http://personalization.ccs.neu.edu/>

2 Background and Definitions

In this section, we set the stage for our study by providing background about the online display ad industry, as well as defining key terminology. We focus on techniques and terms related to Real Time Bidding and retargeted ads, since they are the focus of our study.

2.1 Online Display Advertising

Online display advertising is fundamentally a matching problem. On one side are *publishers* (*e.g.*, news websites, blogs, *etc.*) who produce content, and earn revenue by displaying ads to users. On the other side are advertisers who want to display ads to particular users (*e.g.*, based on demographics or market segments). Unfortunately, the online user population is fragmented across hundreds of thousands of publishers, making it difficult for advertisers to reach desired customers.

Ad networks bridge this gap by aggregating *inventory* from publishers (*i.e.*, space for displaying ads) and filling it with ads from advertisers. Ad networks make it possible for advertisers to reach a broad swath of users, while also guaranteeing a steady stream of revenue for publishers. Inventory is typically sold using a Cost per Mille (CPM) model, where advertisers purchase blocks of 1000 *impressions* (views of ads), or a Cost per Click (CPC) model, where the advertiser pays a small fee each time their ad is clicked by a user.

Ad Exchanges and Auctions. Over time, ad networks are being supplanted by *ad exchanges* that rely on an auction-based model. In Real-time Bidding (RTB) exchanges, advertisers bid on individual impressions, in real-time; the winner of the auction is permitted to serve

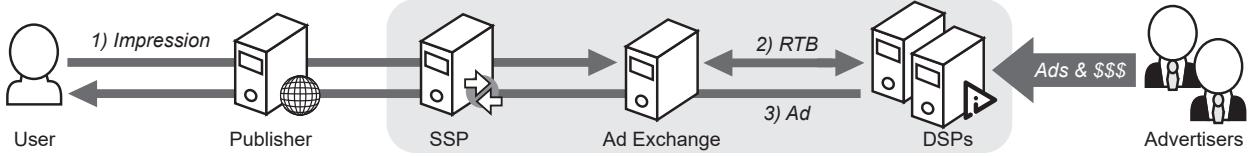

Figure 1: The display advertising ecosystem. Impressions and tracking data flow left-to-right, while revenue and ads flow right-to-left.

an ad to the user. Google’s DoubleClick is the largest ad exchange, and it supports RTB.

As shown in Figure 1, there is a distinction between Supply-side Platforms (*SSPs*) and Demand-side Platforms (*DSPs*) with respect to ad auctions. *SSPs* work with publishers to manage their relationships with multiple ad exchanges, typically to maximize revenue. For example, OpenX is an *SSP*. In contrast, *DSPs* work with advertisers to assess the value of each impression and optimize bid prices. MediaMath is an example of a *DSP*. To make matters more complicated, many companies offer products that cross categories; for example, Rubicon Project offers *SSP*, ad exchange, and *DSP* products. We direct interested readers to [45] for more discussion of the modern online advertising ecosystem.

2.2 Targeted Advertising

Initially, the online display ad industry focused on generic brand ads (*e.g.*, “Enjoy Coca-Cola!”) or *contextual ads* (*e.g.*, an ad for Microsoft on StackOverflow). However, the industry quickly evolved towards *behavioral targeted ads* that are served to specific users based on their browsing history, interests, and demographics.

Tracking. To serve targeted ads, ad exchanges and advertisers must collect data about online users by tracking their actions. Publishers embed JavaScript or invisible “tracking pixels” that are hosted by tracking companies into their web pages, thus any user who visits the publisher also receives third-party cookies from the tracker (we discuss other tracking mechanisms in § 3). Numerous studies have shown that trackers are pervasive across the Web [38, 36, 55, 11], which allows ad-

vertisers to collect users’ browsing history. All major ad exchanges, like DoubleClick and Rubicon, perform user tracking, but there are also companies like BlueKai that just specialize in tracking.

Cookie Matching. During an RTB ad auction, *DSPs* submit bids on an impression. The amount that a *DSP* bids on a given impression is intrinsically linked to the amount of information they have about that user. For example, a *DSP* is unlikely to bid highly for user u whom they have never observed before, whereas a *DSP* may bid heavily for user v who they have recently observed browsing high-value websites (*e.g.*, the baby site TheBump.com).

However, the Same Origin Policy (SOP) hinders the ability of *DSPs* to identify users in ad auctions. As shown in Figure 1, requests are first sent to an *SSP* which forwards the impression to an exchange (or holds the auction itself). At this point, the *SSP*’s cookies are known, but not the *DSPs*. This leads to a catch-22 situation: a *DSP* cannot read its cookies until it contacts the user, but it cannot contact the user without first bidding and winning the auction.

To circumvent SOP restrictions, ad exchanges and advertisers engage in *cookie matching* (sometimes called *cookie syncing*). *Cookie matching* is illustrated in Figure 2: the user’s browser first contacts ad exchange s .com, which returns an HTTP redirect to its partner d .com. s reads its own cookie, and includes it as a parameter in the redirect to d . d now has a mapping from its cookie to s ’s. In the future, if d participates in an auction held by s , it will be able to identify matched users using s ’s cookie. Note that some ad exchanges (including DoubleClick) send cryptographically hashed cookies to their partners, which prevents the ad network’s true cookies from leaking to third-parties.

Retargeted Ads. In this study, we focus on *retargeted ads*, which are the most specific type of targeted display ads. Two conditions must be met for a *DSP* to serve a retargeted ad to a user u : 1) the *DSP* must know that u browsed a specific product on a specific e-commerce site, and 2) the *DSP* must be able to uniquely identify u during an auction. If these conditions are met, the *DSP* can serve u a highly personalized ad reminding them to purchase the product from the retailer. Cookie

Figure 2: *SSP* s matches their cookie to *DSP* d using an HTTP redirect.

matching is crucial for ad retargeting, since it enables DSPs to meet requirement (2).

3 Related Work

Next, we briefly survey related work on online advertising. We begin by looking at more general studies of the advertising and tracking ecosystem, and conclude with a more focused examination of studies on cookie matching and retargeting. Although existing studies on cookie matching demonstrate that this practice is widespread and that the privacy implications are alarming, these works have significant methodological shortcomings that motivate us to develop new techniques in this work.

3.1 Measuring the Ad Ecosystem

Numerous studies have measured and broadly characterized the online advertising ecosystem. Guha *et al.* were the first to systematically measure online ads, and their carefully controlled methodology has been very influential on subsequent studies (including this one) [27]. Barford *et al.* take a much broader look at the *adscape* to determine who the major ad networks are, what fraction of ads are targeted, and what user characteristics drive targeting [9]. Carrascosa *et al.* take an even finer grained look at targeted ads by training *personas* that embody specific interest profiles (*e.g.*, cooking, sports), and find that advertisers routinely target users based on sensitive attributes (*e.g.*, religion) [12]. Rodriguez *et al.* measure the ad ecosystem on mobile devices [61], while Zarras *et al.* analyzed malicious ad campaigns and the ad networks that serve them [66].

Note that **none** of these studies examine retargeted ads; Carrascosa *et al.* specifically excluded retargets from their analysis [12].

Trackers and Tracking Mechanisms. To facilitate ad targeting, participants in the ad ecosystem must extensively track users. Krishnamurthy *et al.* have been cataloging the spread of trackers and assessing the ensuing privacy implications for years [38, 36, 37]. Roesner *et al.* develop a comprehensive taxonomy of different tracking mechanisms that store state in users' browsers (*e.g.*, cookies, HTML5 LocalStorage, and Flash LSOs), as well as strategies to block them [55]. Gill *et al.* use large web browsing traces to model the revenue earned by different trackers (or *aggregators* in their terminology), and found that revenues are skewed towards the largest trackers (primarily Google) [24]. More recently, Cahn *et al.* performed a broad survey of cookie characteristics across the Web, and found that less than 1% of trackers can aggregate information across 75% of websites in the Alexa Top-10K [11]. Falahrastegar *et al.* ex-

pand on these results by comparing trackers across geographic regions [20], while Li *et al.* show that most tracking cookies can be automatically detected using simple machine learning methods [42].

Note that **none** of these studies examine cookie matching, or information sharing between ad exchanges.

Although users can try to evade trackers by clearing their cookies or using private/incognito browsing modes, companies have fought back using techniques like *Evercookies* and *fingerprinting*. Evercookies store the tracker's state in many places within the browser (*e.g.*, FlashLSOs, etags, *etc.*), thus facilitating regeneration of tracking identifiers even if users delete their cookies [34, 57, 6, 47]. Fingerprinting involves generating a unique ID for a user based on the characteristics of their browser [18, 48, 50], browsing history [53], and computer (*e.g.*, the HTML5 canvas [49]). Several studies have found trackers in-the-wild that use fingerprinting techniques [3, 52, 35]; Nikiforakis *et al.* propose to stop fingerprinting by carefully and intentionally adding more entropy to users' browsers [51].

User Profiles. Several studies specifically focus on tracking data collected by Google, since their trackers are more pervasive than any others on the Web [24, 11]. Alarming, two studies have found that Google's Ad Preferences Manager, which is supposed to allow users to see and adjust how they are being targeted for ads, actually hides sensitive information from users [64, 16]. This finding is troubling given that several studies rely on data from the Ad Preferences Manager as their source of ground-truth [27, 13, 9]. To combat this lack of transparency, Lecuyer *et al.* have built systems that rely on controlled experiments and statistical analysis to infer the profiles that Google constructs about users [39, 40]. Castelluccia *et al.* go further by showing that adversaries can infer users' profiles by passively observing the targeted ads they are shown by Google [13].

3.2 Cookie Matching and Retargeting

Although ad exchanges have been transitioning to RTB auctions since the mid-2000s, only three empirical studies have examined the cookie matching that enables these services. Acar *et al.* found that hundreds of domains passed unique identifiers to each other while crawling websites in the Alexa Top-3K [2]. Olejnik *et al.* noticed that ad auctions were leaking the winning bid prices for impressions, thus enabling a fascinating behind-the-scenes look at RTB auctions [54]. In addition to examining the monetary aspects of auctions, Olejnik *et al.* found 125 ad exchanges using cookie matching. Finally, Falahrastegar *et al.* examine the clusters of domains that all share unique, matched cookies using crowdsourced browsing data [21]. Additionally, Ghosh *et al.* use game

theory to model the incentives for ad exchanges to match cookies with their competitors, but they provide no empirical measurements of cookie matching [23].

Several studies examine retargeted ads, which are directly facilitated by cookie matching and RTB. Liu *et al.* identify and measure retargeted ads served by DoubleClick by relying on unique AdSense tags that are embedded in ad URLs [43]. Olejnik *et al.* crawled specific e-commerce sites in order to elicit retargeted ads from those retailers, and observe that retargeted ads can cost advertisers over \$1 per impression (an enormous sum, considering contextual ads sell for <\$0.01) [54].

Limitations. The prior work on cookie matching demonstrates that this practice is widespread. However, these studies also have significant methodological limitations, which prevent them from observing all forms of information sharing between ad exchanges. Specifically:

1. All three studies identify cookie matching by locating unique user IDs that are transmitted to multiple third-party domains [2, 54, 21]. Unfortunately, this will miss cases where exchanges send permuted or obfuscated IDs to their partners. Indeed, DoubleClick is known to do this [1].
2. The two studies that have examined the behavior of DoubleClick have done so by relying on specific cookie keys and URL parameters to detect cookie matching and retargeting [54, 43]. Again, these methods are not robust to obfuscation or encryption that hide the content of HTTP messages.
3. Existing studies cannot determine the precise information flows between ad exchanges, *i.e.*, which parties are sending or receiving information [2]. This limitation stems from analysis techniques that rely entirely on analyzing HTTP headers. For example, a script from t1.com embedded in pub.com may share cookies with t2.com using dynamic AJAX, but the referrer appears to be pub.com, thus potentially hiding t1’s role as the source of the flow.

In general, these limitations stem from a reliance on analyzing specific *mechanisms* for cookie matching. In this study, one of our primary goals is to develop a methodology for detecting cookie matching that is agnostic to the underlying matching mechanism, and instead relies on the fundamental *semantics* of ad exchanges.

4 Methodology

In this study, our primary goal is to develop a methodology for detecting flows of user data between arbitrary ad exchanges. This includes client-side flows (*i.e.*, cookie matching), as well as server-side flows.

In this section, we discuss the methods and data we use to meet this goal. First, we briefly sketch our high-level approach, and discuss key enabling insights. Second, we introduce the instrumented version of Chromium that we use during our crawls. Third, we explain how we designed and trained shopper *personas* that view products on the web, and finally we detail how we collected ads using the trained personas.

4.1 Insights and Approach

Although prior work has examined information flow between ad exchanges, these studies are limited to specific types of cookie matching that follow well-defined patterns (see § 3.2). To study arbitrary information flows in a mechanism-agnostic way, we need a fundamentally different methodology.

We solve this problem by relying on a key insight: in most cases, if a user is served a retargeted ad, this proves that ad exchanges shared information about the user (see § 6.1.1). To understand this insight, consider that two preconditions must be met for user u to be served a retarget ad for *shop* by DSP d . *First*, either d directly observed u visiting *shop*, or d must be told this information by SSP s . If this condition is not met, then d would not pay the premium price necessary to serve u a retarget. *Second*, if the retarget was served from an ad auction, SSP s and d must be sharing information about u . If this condition is not met, then d would have no way of identifying u as the source of the impression (see § 2.2).

In this study, we leverage this observation to reliably infer information flows between SSPs and DSPs, regardless of whether the flow occurs client- or server-side. The high-level methodology is quite intuitive: have a clean browser visit specific e-commerce sites, then crawl publishers and gather ads. If we observe retargeted ads, we know that ad exchanges tracking the user on the *shopper-side* are sharing information with exchanges serving ads on the *publisher-side*. Specifically, our methodology uses the following steps:

- § 4.2: We use an instrumented version of Chromium to record *inclusion chains* for all resources encountered during our crawls [5]. These chains record the precise origins of all resource requests, even when the requests are generated dynamically by JavaScript or Flash. We use these chains in § 6 to categorize information flows between ad exchanges.
- § 4.3: To elicit retargeted ads from ad exchanges, we design *personas* (to borrow terminology from [9] and [12]) that visit specific e-commerce sites. These sites are carefully chosen to cover different types of products, and include a wide variety of common trackers.

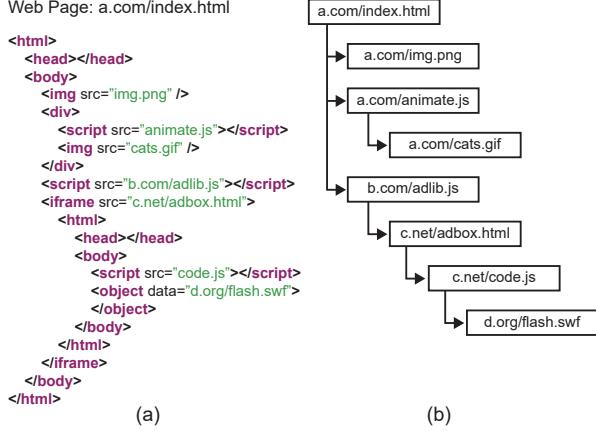

Figure 3: (a) DOM Tree, and (b) Inclusion Tree.

- § 4.4: To collect ads, our personas crawl 150 publishers from the Alexa Top-1K.
- § 5: We leverage well-known filtering techniques and crowdsourcing to identify retargeted ads from our corpus of 571,636 unique crawled images.

4.2 Instrumenting Chromium

Before we can begin crawling, we first need a browser that is capable of recording detailed information about the provenance of third-party resource inclusions in webpages. Recall that prior work on cookie matching was unable to determine which ad exchanges were syncing cookies in many cases because the analysis relied solely on the contents of HTTP requests [2, 21] (see § 3.2). The fundamental problem is that HTTP requests, and even the DOM tree itself, do not reveal the true sources of resource inclusions in the presence of dynamic code (JavaScript, Flash, etc.) from third-parties.

To understand this problem, consider the example DOM tree for a.com/index.html in Figure 3(a). Based on the DOM, we might conclude that the chain $a \rightarrow c \rightarrow d$ captures the sequence of inclusions leading from the root of the page to the Flash object from d.org.

However, direct use of a webpage’s DOM is misleading because the DOM does not reliably record the inclusion relationships between resources in a page. This is due to the ability of JavaScript to manipulate the DOM at run-time, *i.e.*, by adding new inclusions dynamically. As such, while the DOM is a faithful syntactic description of a webpage *at a given point in time*, it cannot be relied upon to extract relationships between included resources. Furthermore, analysis of HTTP request headers does not solve this problem, since the Referer is set to the first-party domain even when inclusions are dynamically added by third-party scripts.

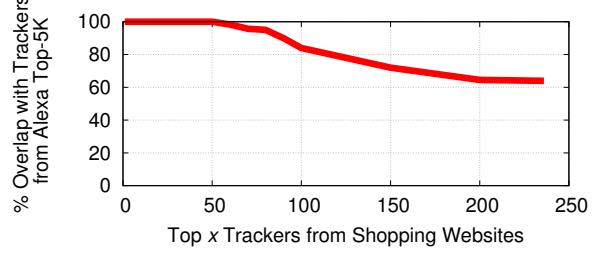

Figure 4: Overlap between frequent trackers on e-commerce sites and Alexa Top-5K sites.

To solve this issue, we make use of a heavily instrumented version of Chromium that produces *inclusion trees* directly from Chromium’s resource loading code [5]. Inclusion trees capture the semantic inclusion structure of resources in a webpage (*i.e.*, which objects cause other objects to be loaded), unlike DOM trees which only capture syntactic structures. Our instrumented Chromium accurately captures relationships between elements, regardless of where they are located (*e.g.*, within a single page or across frames) or how the relevant code executes (*e.g.*, via an inline `<script>`, `eval()`, or an event handler). We direct interested readers to [5] for more detailed information about inclusion trees, and the technical details of how the Chromium binary is instrumented.

Figure 3(b) shows the inclusion tree corresponding to the DOM tree in Figure 3(a). From the inclusion tree, we can see that the true *inclusion chain* leading to the Flash object is $a \rightarrow b \rightarrow c \rightarrow c \rightarrow d$, since the IFrame and the Flash are dynamically included by JavaScript from b.com and c.net, respectively.

Using inclusion chains, we can precisely analyze the provenance of third-party resources included in webpages. In § 6, we use this capability to distinguish client-side flows of information between ad exchanges (*i.e.*, cookie matching) from server-side flows.

4.3 Creating Shopper Personas

Now that we have a robust crawling tool, the next step in our methodology is designing shopper personas. Each persona visits products on specific e-commerce sites, in hope of seeing retargeted ads when we crawl publishers.

Since we do not know *a priori* which e-commerce sites are conducting retargeted ad campaigns, our personas must cover a wide variety of sites. To facilitate this, we leverage the hierarchical categorization of e-commerce sites maintained by Alexa¹. Although Alexa’s hierarchy

¹<http://www.alexa.com/topsites/category/Top/Shopping>

has 847 total categories, there is significant overlap between categories. We manually selected 90 categories to use for our personas that have minimal overlap, as well as cover major e-commerce sites (*e.g.*, Amazon and Walmart) and shopping categories (*e.g.*, sports and jewelry).

For each persona, we included the top 10 e-commerce sites in the corresponding Alexa category. In total, the personas cover 738 unique websites. Furthermore, we manually selected 10 product URLs on each of these websites. Thus, each persona visits 100 products URLs.

Sanity Checking. The final step in designing our personas is ensuring that the e-commerce sites are embedded with a representative set of trackers. If they are not, we will not be able to collect targeted ads.

Figure 4 plots the overlap between the trackers we observe on the Alexa Top-5K websites, compared to the top x trackers (*i.e.*, most frequent) we observe on the e-commerce sites. We see that 84% of the top 100 e-commerce trackers are also present in the trackers on Alexa Top-5K sites². These results demonstrate that our shopping personas will be seen by the vast majority of major trackers when they visit our 738 e-commerce sites.

4.4 Collecting Ads

In addition to selecting e-commerce sites for our personas, we must also select publishers to crawl for ads. We manually select 150 publishers by examining the Alexa Top-1K websites and filtering out those which do not display ads, are non-English, are pornographic, or require logging-in to view content (*e.g.*, Facebook). We randomly selected 15 URLs on each publisher to crawl.

At this point, we are ready to crawl ads. We initialized 91 copies of our instrumented Chromium binary: 90 corresponding to our shopper personas, and one which serves as a control. During each *round* of crawling, the personas visit their associated e-commerce sites, then visit the 2,250 publisher URLs (150 publishers * 15 pages per publisher). The control *only* visits the publisher URLs, *i.e.*, it does not browse e-commerce sites, and therefore should never be served retargeted ads. The crawlers are executed in tandem, so they visit the publishers URLs in the same order at the same times. We hard-coded a 1 minute delay between subsequent page loads to avoid overloading any servers, and to allow time for the crawler to automatically scroll to the bottom of each page. Each round takes 40 hours to complete.

We conducted nine rounds of crawling between December 4 to 19, 2015. We stopped after 9 rounds because we observed that we only gathered 4% new images during the ninth round. The crawlers recorded inclusion

²We separately crawled the resources included by the Alexa Top-5K websites in January 2015. For each website, we visited 6 pages and recorded all the requested resources.

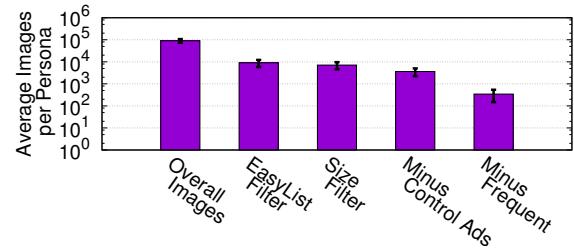

Figure 5: Average number of images per persona, with standard deviation error bars.

trees, HTTP request and response headers, cookies, and images from all pages. At no point did our crawlers click on ads, since this can be construed as click-fraud (*i.e.*, advertisers often have to pay each time their ads are clicked, and thus automated clicks drain their advertising budget). All crawls were done from *Northeastern University’s IP addresses in Boston*.

5 Image Labeling

Using the methodology in § 4.4, we collected 571,636 unique images in total. However, only a small subset are retargeted ads, which are our focus. In this section, we discuss the steps we used to filter down our image set and isolate retargeted ads, beginning with standard filters used by prior work [9, 42], and ending with crowd-sourced image labeling.

5.1 Basic Filtering

Prior work has used a number of techniques to identify ad images from crawled data. First, we leverage the *EasyList* filter³ provided by *AdBlockPlus* to detect images that are likely to be ads [9, 42]. In our case, we look at the inclusion chain for each image, and filter out those in which none of the URLs in the chain are a hit against EasyList. This reduces the set to 93,726 unique images.

Next, we filter out all images with dimensions $< 50 \times 50$ pixels. These images are too small to be ads; most are 1×1 tracking pixels.

Our final filter relies on a unique property of retargeted ads: they should only appear to personas that visit a specific e-commerce site. In other words, any ad that was shown to our control account (which visits no e-commerce sites) is either untargeted or contextually targeted, and can be discarded. Furthermore, any ad shown to >1 persona may be behaviorally targeted, but it cannot be a retarget, and is therefore filtered out⁴.

³<https://easylist-downloads.adblockplus.org/easylist.txt>

⁴Several of our personas have retailers in common, which we account for when filtering ads.

Figure 5 shows the average number of images remaining per persona after applying each filter. After applying all four filters, we are left with 31,850 ad images.

5.2 Identifying Targeted & Retargeted Ads

At this point, we do not know which of the ad images are retargets. Prior work has identified retargets by looking for specific URL parameters associated with them, however this technique is only able to identify a subset of retargets served by DoubleClick [43]. Since our goal is to be mechanism and ad exchange agnostic, we must use a more generalizable method to identify retargets.

Crowdsourcing. Given the large number of ads in our corpus, we decided to crowdsource labels from workers on Amazon Mechanical Turk (AMT). We constructed Human Intelligence Tasks (HITs) that ask workers to label 30 ads, 27 of which are unlabeled, and 3 of which are known to be retargeted ads and serve as controls (we manually identified 1,016 retargets from our corpus of 31,850 to serve as these controls).

Figure 6(a) shows a screenshot of our HIT. On the right is an ad image, and on the left we ask the worker two questions:

1. Does the image belong to one of the following categories (with “None of the above” being one option)?
2. Does the image say it came from one of the following websites (with “No” being one option)?

The purpose of question (1) is to isolate behavioral and retargeted ads from contextual and untargeted ads (*e.g.*, Figure 6(c), which was served to our *Music* persona). The list for question (1) is populated with the shopping categories associated with the persona that crawled the ad. For example, as shown in Figure 6(a), the category list includes “shopping_jewelry_diamonds” for ads shown to our *Diamond Jewelry* persona. In most cases, this list contains exactly one entry, although there are rare cases where up to 3 categories are in the list.

If the worker does not select “None” for question (1), then they are shown question (2). Question (2) is designed to separate retargets from behavioral targeted ads. The list of websites for question (2) is populated with the e-commerce sites visited by the persona that crawled the ad. For example, in Figure 6(a), the ad clearly says “Adiamor”, and one of the sites visited by the persona is adiamor.com; thus, this image is likely to be a retarget.

Quality Control. We apply four widely used techniques to maintain and validate the quality of our crowdsourced image labels [63, 29, 56]. *First*, we restrict our HITs to workers that have completed ≥ 50 HITs and have an approval rating $\geq 95\%$. *Second*, we restrict our HITs to workers living in the US, since our ads were collected

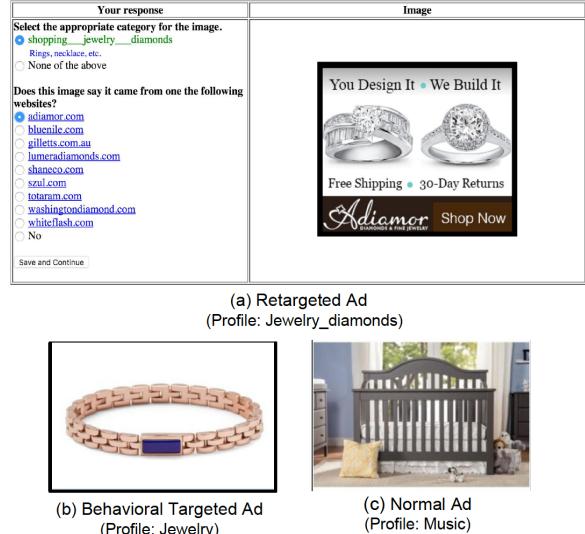

Figure 6: Screenshot of our AMT HIT, and examples of different types of ads.

from US websites. *Third*, we reject a HIT if the worker mislabels ≥ 2 of the control images (*i.e.*, known retargeted ads); this prevents workers from being able to simply answer “None” to all questions. We resubmitted rejected HITs for completion by another worker. Overall, the workers correctly labeled 87% of the control images. *Fourth* and finally, we obtain two labels on each unlabeled image by different workers. For 92.4% of images both labels match, so we accept them. We manually labeled the divergent images ourselves to break the tie.

Finding More Retargets. The workers from AMT successfully identified 1,359 retargeted ads. However, it is possible that they failed to identify some retargets, *i.e.*, there are false negatives. This may occur in cases like Figure 6(b): it is not clear if this ad was served as a behavioral target based on the persona’s interest in jewelry, or as a retarget for a specific jeweler.

To mitigate this issue, we manually examined all 7,563 images that were labeled as behavioral ads by the workers. In addition to the images themselves, we also looked at the inclusion chains for each image. In many cases, the URLs reveal that specific e-commerce sites visited by our personas hosted the images, indicating that the ads are retargets. For example, Figure 6(b) is actually part of a retargeted ad from fossil.com. Our manual analysis uncovered an additional 3,743 retargeted ads.

These results suggest that the number of false negatives from our crowdsourcing task could be dramatically reduced by showing the URLs associated with each ad image to the workers. However, note that adding this information to the HIT will change the dynamics of the

task: false negatives may go down but the effort (and therefore the cost) of each HIT will go up. This stems from the additional time it will take each worker to review the ad URLs for relevant keywords.

In § 6.2, we compare the datasets labeled by the workers and by the authors. Interestingly, although our dataset contains a greater *magnitude* of retargeted ads versus the worker’s dataset, it does not improve *diversity*, *i.e.*, the smaller dataset identifies 96% of the top 25 most frequent ad networks in the larger dataset. These networks are responsible for the vast majority of retargeted ads and inclusion chains in our dataset.

Final Results. Overall, we submitted 1,142 HITs to AMT. We paid \$0.18 per HIT, for a total of \$415. We did not collect any personal information from workers. In total, we and workers from AMT labeled 31,850 images, of which 7,563 are behavioral targeted ads and 5,102 are retargeted ads. These retargets advertise 281 distinct e-commerce websites (38% of all e-commerce sites).

5.3 Limitations

With any labeling task of this size and complexity, it is possible that there are false positives and negatives. Unfortunately, we cannot bound these quantities, since we do not have ground-truth information about known retargeted ad campaigns, nor is there a reliable mechanism to automatically detect retargets (*e.g.*, based on special URL parameters, *etc.*).

In practice, the effect of false positives is that we will erroneously classify pairs of ad exchanges as sharing information. We take measures to mitigate false positives by running a control crawl and removing images which appear in multiple personas (see § 5.1), but false positives can still occur. However, as we show in § 6, the results of our classifier are extremely consistent, suggesting that there are few false positives in our dataset.

False negatives have the opposite effect: we may miss pairs of ad exchanges that are sharing information. Fortunately, the practical impact of false negatives is low, since we only need to correctly identify a single retargeted ad to infer that a given pair of ad exchanges are sharing information.

6 Analysis

In this section, we use the 5,102 retargeted ads uncovered in § 5, coupled with their associated inclusion chains (see § 4.2), to analyze the information flows between ad exchanges. Specifically, we seek to answer two fundamental questions: *who* is sharing user data, and *how* does the sharing take place (*e.g.*, client-side via cookie matching, or server-side)?

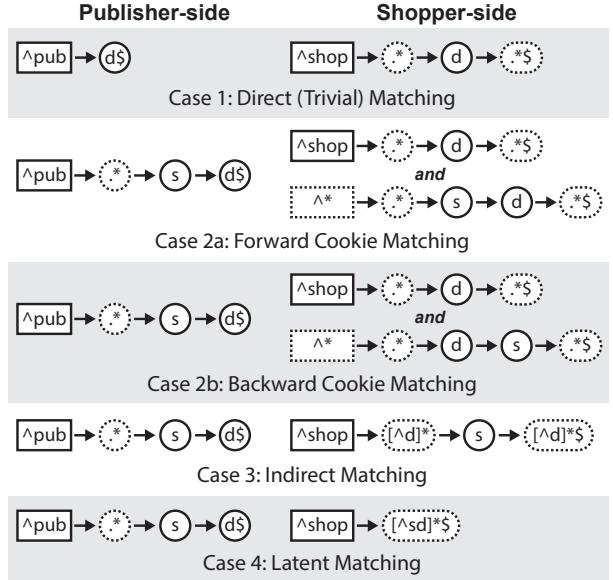

Figure 7: Regex-like rules we use to identify different types of ad exchange interactions. *shop* and *pub* refer to chains that begin at an e-commerce site or publisher, respectively. *d* is the DSP that serves a retarget; *s* is the predecessor to *d* in the publisher-side chain, and is most likely an SSP holding an auction. Dot star (.) matches any domains zero or more times.

We begin by *categorizing* all of the retargeted ads and their associated inclusion chains into one of four classes, which correspond to different mechanisms for sharing user data. Next, we examine specific pairs of ad exchanges that share data, and compare our detection approach to those used in prior work to identify cookie matching [43, 2, 54, 21]. We find that prior work may be missing 31% of collaborating exchanges. Finally, we construct a graph that captures ad exchanges and the relationships between them, and use it to reveal nuanced characteristics about the roles that different exchanges play in the ad ecosystem.

6.1 Information Flow Categorization

We begin our analysis by answering two basic questions: *for a given retargeted ad, was user information shared between ad exchanges, and if so, how?* To answer these questions, we categorize the 35,448 *publisher-side* inclusion chains corresponding to the 5,102 retargeted ads in our data. Note that 1) we observe some retargeted ads multiple times, resulting in multiple chains, and 2) the chains for a given unique ad may not be identical.

We place publisher-side chains into one of four categories, each of which corresponds to a specific information sharing mechanism (or lack thereof). To determine

the category of a given chain, we match it against carefully designed, regular expression-like rules. Figure 7 shows the pattern matching rules that we use to identify chains in each category. These rules are mutually exclusive, *i.e.*, a chain will match one or none of them.

Terminology. Before we explain each classification in detail, we first introduce shared terminology that will be used throughout this section. Each retargeted ad was served to our persona via a *publisher-side* chain. *pub* is the domain of the publisher at the root of the chain, while *d* is the domain at the end of the chain that served the ad. Typically, *d* is a DSP. If the retarget was served via an auction, then an SSP *s* must immediately precede *d* in the publisher-side chain.

Each retarget advertises a particular e-commerce site. *shop* is the domain of the e-commerce site corresponding to a particular retargeted ad. To categorize a given publisher-side chain, we must also consider the corresponding *shopper-side* chains rooted at *shop*.

6.1.1 Categorization Rules

Case 1: Direct Matches. The first chain type that we define are *direct matches*. Direct matches are the simplest type of chains that can be used to serve a retargeted ad. As shown in Figure 7, for us to categorize a publisher-side chain as a direct match, it must be exactly length two, with a direct resource inclusion request from *pub* to *d*. *d* receives any cookies they have stored on the persona inside this request, and thus it is trivial for *d* to identify our persona.

On the shopper-side, the only requirement is that *d* observed our persona browsing *shop*. If *d* does not observe our persona at *shop*, then *d* would not serve the persona a retargeted ad for *shop*. *d* is able to set a cookie on our persona, allowing *d* to re-identify the persona in future.

We refer to direct matching chains as “trivial” because it is obvious how *d* is able to track our persona and serve a retargeted ad for *shop*. Furthermore, in these cases no user information needs to be shared between ad exchanges, since there are no ad auctions being held on the publisher-side.

Case 2: Cookie Matching. The second chain type that we define are *cookie matches*. As the name implies, chains in this category correspond to instances where an auction is held on the publisher-side, and we observe direct resource inclusion requests between the SSP and DSP, implying that they are matching cookies.

As shown in Figure 7, for us to categorize a publisher-side chain as cookie matching, *s* and *d* must be adjacent at the end of the chain. On the shopper-side, *d* must observe the persona at *shop*. Lastly, we must observe a request from *s* to *d* or from *d* to *s* in some chain before

the retargeted ad is served. These requests capture the moment when the two ad exchanges match their cookies. Note that *s* → *d* or *d* → *s* can occur in a publisher- or shopper-side chain; in practice, it often occurs in a chain rooted at *shop*, thus fulfilling both requirements at once.

For the purposes of our analysis, we distinguish between *forward* (*s* → *d*) and *backward* (*d* → *s*) cookie matches. Figure 2 shows an example of a forward cookie match. As we will see, many pairs of ad exchanges engage in both forward and backward matching to maximize their opportunities for data sharing. To our knowledge, no prior work examines the distinction between forward and backward cookie matching.

Case 3: Indirect Matching. The third chain type we define are *indirect matches*. Indirect matching occurs when an SSP sends meta-data about a user to a DSP, to help them determine if they should bid on an impression. With respect to retargeted ads, the SSP tells the DSPs about the browsing history of the user, thus enabling the DSPs to serve retargets for specific retailers, even if the DSP never directly observed the user browsing the retailer (hence the name, *indirect*). Note that no cookie matching is necessary in this case for DSPs to serve retargeted ads.

As shown in Figure 7, the crucial difference between cookie matching chains and indirect chains is that *d* *never* observes our persona at *shop*; only *s* observes our persona at *shop*. Thus, by inductive reasoning, we must conclude that *s* shares information about our persona with *d*, otherwise *d* would never serve the persona a retarget for *shop*.

Case 4: Latent Matching. The fourth and final chain type that we define are *latent matches*. As shown in Figure 7, the defining characteristic of latent chains is that neither *s* nor *d* observe our persona at *shop*. This begs the question: how do *s* and *d* know to serve a retargeted ad for *shop* if they never observe our persona at *shop*? The most reasonable explanation is that some other ad exchange *x* that is present in the shopper-side chains shares this information with *d* behind-the-scenes.

We hypothesize that the simplest way for ad exchanges to implement latent matching is by having *x* and *d* share the same unique identifiers for users. Although *x* and *d* are different domains, and are thus prevented by the SOP from reading each others’ cookies, both ad exchanges may use the same deterministic algorithm for generating user IDs (*e.g.*, by relying on IP addresses or browser fingerprints). However, as we will show, these synchronized identifiers are not necessarily visible from the client-side (*i.e.*, the values of cookies set by *x* and *d* may be obfuscated), which prevents trivial identification of latent cookie matching.

Type	Unclustered Chains	%	Clustered Chains	%
Direct	1770	5%	8449	24%
Forward Cookie Match	24575	69%	25873	73%
Backward Cookie Match	19388	55%	24994	70%
Indirect Match	2492	7%	178	1%
Latent Match	5362	15%	343	1%
No Match	775	2%	183	1%

Table 1: Results of categorizing publisher-side chains, before and after clustering domains.

Note: Although we do not expect to see cases 3 and 4, they can still occur. We explain in § 6.1.2 that indirect and latent matching is mostly performed by domains belonging to the same company. The remaining few instances of these cases are probably mislabeled behaviorally targeted ads.

6.1.2 Categorization Results

We applied the rules in Figure 7 to all 35,448 publisher-side chains in our dataset twice. First, we categorized the raw, unmodified chains; then we *clustered* domains that belong to the same companies, and categorized the chains again. For example, Google owns youtube.com, doubleclick.com, and 2mdn.net; in the clustered experiments, we replace all instances of these domains with google.com. Appendix A.1 lists all clustered domains.

Table 1 presents the results of our categorization. The first thing we observe is that cookie matching is the most frequent classification by a large margin. This conforms to our expectations, given that RTB is widespread in today’s ad ecosystem, and major exchanges like DoubleClick support it [17]. Note that, for a given (s, d) pair in a publisher-side chain, we may observe $s \rightarrow d$ and $d \rightarrow s$ requests in our data, *i.e.*, the pair engages in forward and backward cookie matching. This explains why the percentages in Table 1 do not add up to 100%.

The next interesting feature that we observe in Table 1 is that indirect and latent matches are relatively rare (7% and 15%, respectively). Again, this is expected, since these types of matching are more exotic and require a greater degree of collaboration between ad exchanges to implement. Furthermore, the percentage of indirect and latent matches drops to 1% when we cluster domains. To understand why this occurs, consider the following real-world example chains:

Publisher-side: $pub \rightarrow rubicon \rightarrow googlesyndication$

Shopper-side: $shop \rightarrow doubleclick$

According to the rules in Figure 7, this appears to be a latent match, since Rubicon and Google Syndication do not observe our persona on the shopper-side. However, after clustering the Google domains, this will be clas-

sified as cookie matching (assuming that there exists at least one other request from Rubicon to Google).

The above example is extremely common in our dataset: 731 indirect chains become cookie matching chains after we cluster the Google domains *alone*. Importantly, this finding provides strong evidence that Google does in fact use latent matching to share user tracking data between its various domains. Although this is allowed in Google’s terms of service as of 2014 [26], our results provide direct evidence of this data sharing with respect to serving targeted ads. In the vast majority of these cases, Google Syndication is the DSP, suggesting that on the server-side, it ingests tracking data and user identifiers from all other Google services (*e.g.*, DoubleClick and Google Tag Manager).

Of the remaining 1% of chains that are still classified as indirect or latent after clustering, the majority appear to be false positives. In most of these cases, we observe s and d doing cookie matching in other instances, and it seems unlikely that s and d would also utilize indirect and latent mechanisms. These ads are probably mislabeled behaviorally targeted ads.

The final takeaway from Table 1 is that the number of uncategorized chains that do not match any of our rules is extremely low (1-2%). These publisher-side chains are likely to be false positives, *i.e.*, ads that are not actually retargeted. These results suggest that our image labeling approach is very robust, since the vast majority of chains are properly classified as direct or cookie matches.

6.2 Cookie Matching

The results from the previous section confirm that cookie matching is ubiquitous on today’s Web, and that this information sharing fuels highly targeted advertisements. Furthermore, our classification results demonstrate that we can detect cookie matching without relying on semantic information about cookie matching mechanisms.

In this section, we take a closer look at the pairs of ad exchanges that we observe matching cookies. We seek to answer two questions: *first*, which pairs match most frequently, and what is the directionality of these relationships? *Second*, what fraction of cookie matching relationships will be missed by the heuristic detection approaches used by prior work [43, 2, 54, 21]?

Who Is Cookie Matching? Table 2 shows the top 25 most frequent pairs of domains that we observe matching cookies. The arrows indicate the direction of matching (forward, backward, or both). “Ads” is the number of unique retargets served by the pair, while “Chains” is the total number of associated publisher-side chains. We present both quantities as observed in our complete dataset (containing 5,102 retargets), as well as the subset

Participant 1	Participant 2	All Data		AMT Only		Heuristics
		Chains	Ads	Chains	Ads

Table 2: Top 25 cookie matching partners in our dataset. The arrow signifies whether we observe forward matches (\rightarrow), backward matches (\leftarrow), or both (\leftrightarrow). The heuristics for detecting cookie matching are: *DC* (match using DoubleClick URL parameters), *E* (string match for exact cookie values), *US* (URLs that include parameters like “usersync”), and - (no identifiable mechanisms). Note that the HTTP request formats used for forward and backward matches between a given pair of exchanges may vary.

that was identified solely by the AMT workers (containing 1,359 retargets).

We observe that cookie matching frequency is heavily skewed towards several heavy-hitters. In aggregate, Google’s domains are most common, which makes sense given that Google is the largest ad exchange on the Web today. The second most common is Criteo; this result also makes sense, given that Criteo specializes in retargeted advertising [15]. These observations remain broadly true across the AMT and complete datasets: although the relative proportion of ads and chains from less-frequent exchange pairs differs somewhat between the two datasets, the heavy-hitters do not change. Furthermore, we also see that the vast majority of exchange pairs are identified in both datasets.

Interestingly, we observe a great deal of heterogeneity with respect to the directionality of cookie matching. Some boutique exchanges, like Adacado, only ingest cookies from other exchanges. Others, like Criteo, are omnivorous, sending or receiving data from any and all willing partners. These results suggest that some participants are more wary about releasing their user identifiers to other exchanges.

Comparison to Prior Work. We observe many of the same participants matching cookies as prior work, in-

cluding DoubleClick, Rubicon, AppNexus, OpenX, MediaMath, and myThings [2, 54, 21]. Prior work identifies some additional ad exchanges that we do not (*e.g.*, Turn); this is due to our exclusive focus on participants involved in retargeted advertising.

However, we also observe participants (*e.g.*, Adacado and AdRoll) that prior work does not. This may be because prior work identifies cookie matching using heuristics to pick out specific features in HTTP requests [43, 2, 54, 21]. In contrast, our categorization approach is content and mechanism agnostic.

To investigate the efficacy of heuristic detection methods, we applied three of them to our dataset. Specifically, for each pair (s, d) of exchanges that we categorize as cookie matching, we apply the following tests to the HTTP headers of requests between s and d or vice-versa:

1. We look for specific keys that are known to be used by DoubleClick and other Google domains for cookie matching (*e.g.*, “google_nid” [54]).
2. We look for cases where unique cookie values set by one participant are included in requests sent to the other participant⁵.

⁵To reduce false positives, we only consider cookie values that have length > 10 and < 100 .

	Domain	Degree			Position p in Chains (%)			# of Shopper Websites	# of Ads

Table 3: Overall statistics about the connectivity, position, and frequency of ad domains in our dataset.

- We look for keys with revealing names like “user-sync” that frequently appear in requests between participants in our data.

As shown in the “Heuristics” column in Table 2, in the majority of cases, heuristics are able to identify cookie matching between the participants. Interestingly, we observe that the mechanisms used by some pairs (*e.g.*, Criteo and DoubleClick) change depending on the directionality of the cookie match, revealing that the two sides have different cookie matching APIs.

However, for 31% of our cookie matching partners, the heuristics are unable to detect signs of cookie matching. We hypothesize that this is due to obfuscation techniques employed by specific ad exchanges. In total, there are 4.1% cookie matching chains that would be completely missed by heuristic tests. This finding highlights the limitations of prior work, and bolsters the case for our mechanism-agnostic classification methodology.

6.3 The Retargeting Ecosystem

In this last section, we take a step back and examine the broader ecosystem for retargeted ads that is revealed by our dataset. To facilitate this analysis, we construct a graph by taking the union of all of our publisher-side chains. In this graph, each node is a domain (either a publisher or an ad exchange), and edges correspond to resource inclusion relationships between the domains. Our graph formulation differs from prior work in that edges denote actual information flows, as opposed to simple co-occurrences of trackers on a given domain [25].

Table 3 presents statistics on the top ad-related domains in our dataset. The “Degree” column shows the in- and out-degree of nodes, while “Position” looks at the relative location of nodes within chains. p_2 is the second position in the chain, corresponding to the first ad network after the publisher; p_n is the DSP that serves the retarget in a chain of length n ; p_{n-1} is the second to last position, corresponding to the final SSP before the DSP. Note that a domain may appear in a chain multiple times, so the sum of the p_i percentages may be $>100\%$. The last two columns count the number of unique e-commerce sites that embed resources from a given domain, and the unique number of ads served by the domain.

Based on the data in Table 3, we can roughly cluster the ad domains into two groups, corresponding to SSPs and DSPs. DSPs have low or zero out-degree since they often appear at position p_n , *i.e.*, they serve an ad and terminate the chain. Criteo is the largest source of retargeted ads in our dataset by an order of magnitude. This is not surprising, given that Criteo was identified as the largest retargeter in the US and UK in 2014 [15].

In contrast, SSPs tend to have in/out degree ratios closer to 1, since they facilitate the exchange of ads between multiple publishers, DSPs, and even other SSPs. Some SSPs, like Atwola, work more closely with publishers and thus appear more frequently at p_2 , while others, like Mathtag, cater to other SSPs and thus appear almost exclusively at p_{n-1} . Most of the SSPs we observe also function as DSPs (*i.e.*, they serve some retargeted ads), but there are “pure” SSPs like Casale Media and OpenX that do not serve ads. Lastly, Table 3 reveals that

SSPs tend to do more user tracking than DSPs, by getting embedded in more e-commerce sites (with Criteo being the notable exception).

Google is an interesting case study because its different domains have clearly delineated purposes. `googletagservices` is Google’s in-house SSP, which funnels impressions directly from publishers to Google’s DSPs: `2mdn`, `googlesyndication`, and `doubleclick`. In contrast, `googleadservices` is also an SSP, but it holds auctions with third-party participants (*e.g.*, Criteo). `googlesyndication` and `doubleclick` function as both SSPs and DSPs, sometimes holding auctions, and sometimes winning auctions held by others to serve ads. Google Syndication is the second most frequent source of retargeted ads in our dataset behind Criteo.

7 Concluding Discussion

In this study, we develop a novel, principled methodology for detecting flows of tracking information between ad exchanges. The key insight behind our approach is that we re-purpose retargeted ads as a detection mechanism, since their presence reveals information flows between ad exchanges. Our methodology is content-agnostic, and thus we are able to identify flows even if they occur on the server-side. This is a significant improvement over prior work, which relies on heuristics to detect cookie matching [2, 54, 21]. As we show in § 6, these heuristics fail to detect 31% of matching pairs today, and they are likely to fail more in the future as ad networks adopt content obfuscation techniques.

Implications for Users. Ultimately, our goal is not just to measure information flows between ad exchanges, but to facilitate the development of systems that balance user privacy against the revenue needs of publishers.

Currently, users are faced with unsatisfactory choices when deciding if and how to block ads and tracking. Whitelisting approaches like NoScript are effective at protecting privacy, but are too complicated for most users, and deprive publishers of revenue. Blocking third-party cookies is ineffective against first-party trackers (*e.g.*, Facebook). AdBlockPlus’ controversial “Acceptable Ads” program is poorly governed and leaves users vulnerable to unscrupulous ad networks [62]. DNT is DOA [8]. Although researchers have proposed privacy preserving ad exchanges, these systems have yet to see widespread adoption [22, 28, 7].

We believe that data about information flows between ad exchanges potentially opens up a new middle ground in ad blocking. One possibility is to develop an automated system that uses the methodology developed in this paper to continuously crawl ads, identify cookie matching flows, and construct rules that match these

flows. Users could then install a browser extension that blocks flows matching these rules. The advantage of this extension is that it would offer improved privacy protection relative to existing systems (*e.g.*, Ghostery and Disconnect), while also allowing advertising (as opposed to traditional ad blockers). However, the open challenge with this system design would be making it cost effective, since it would still rely on crowdsourced labor.

Another possibility is using our data as ground-truth for a sophisticated blocker that relies on client-side Information Flow Control (IFC). There exist many promising, lightweight approaches to implementing JavaScript IFC in the browser [30, 10, 59, 31]. However, IFC alone is not enough to block cookie matching flows: as we have shown, ad networks obfuscate data, making it impossible to separate benign from “leaky” flows in general. Instead, we can use information gathered using our methodology as ground-truth to mark data in specific incoming flows, and rely on IFC to enforce restrictions that prevent outgoing flows from containing the marked data.

A Appendix

A.1 Clustered Domains

We clustered the following domains together when classifying publisher-side chains in § 6.1.2.

Google: google-analytics, googleapis, google, doubleclick, gstatic, googlesyndication, googleusercontent, googleleadservices, googletagmanager, googletagservices, googlecommerce, youtube, yimg, youtube-mp3, googlevideo, 2mdn

OpenX: openxenterprise, openx, servedbyopenx

Affinity: affinitymatrix, affinity

Ebay: ebay, ebaystatic

Yahoo: yahoo, yimg

Mythings: mythingsmedia, mythings

Amazon: cloudfront, amazonaws, amazon-adsystem, images-amazon

Tellapart: tellapart, tellaparts

Virtual U: Defeating Face Liveness Detection by Building Virtual Models From Your Public Photos

Yi Xu, True Price, Jan-Michael Frahm, Fabian Monroe

Abstract

In this paper, we introduce a novel approach to bypass modern face authentication systems. More specifically, by leveraging a handful of pictures of the target user taken from social media, we show how to create realistic, textured, 3D facial models that undermine the security of widely used face authentication solutions. Our framework makes use of virtual reality (VR) systems, incorporating along the way the ability to perform animations (*e.g.*, raising an eyebrow or smiling) of the facial model, in order to trick liveness detectors into believing that the 3D model is a real human face. The synthetic face of the user is displayed on the screen of the VR device, and as the device rotates and translates in the real world, the 3D face moves accordingly. To an observing face authentication system, the depth and motion cues of the display match what would be expected for a human face.

We argue that such VR-based spoofing attacks constitute a fundamentally new class of attacks that point to a serious weaknesses in camera-based authentication systems: Unless they incorporate other sources of verifiable data, systems relying on color image data and camera motion are prone to attacks via virtual realism. To demonstrate the practical nature of this threat, we conduct thorough experiments using an end-to-end implementation of our approach and show how it undermines the security of several face authentication solutions that include both motion-based and liveness detectors.

1 Introduction

Over the past few years, face authentication systems have become increasingly popular as an enhanced security feature in both mobile devices and desktop computers. As the underlying computer vision algorithms have matured, many application designers and nascent specialist vendors have jumped in and started to offer solutions for mobile devices with varying degrees of security and usability. Other more well-known players, like Apple and

Google, are poised to enter the market with their own solutions, having already acquired several facial recognition software companies¹. While the market is segmented based on the type of technology offered (*e.g.*, 2D facial recognition, 3D recognition, and facial analytics/face biometric authentication), Gartner research estimates that the overall market will grow to over \$6.5 billion in 2018 (compared to roughly \$2 billion today) [13].

With this push to market, improving the accuracy of face recognition technologies remains an active area of research in academia and industry. Google’s FaceNet system, which achieved near-perfect accuracy on the Labeled Faces in the Wild dataset [47], exemplifies one such effort. Additionally, recent advances with deep learning algorithms [38, 53] show much promise in strengthening the robustness of the face identification and authentication techniques used today. Indeed, state-of-the-art face identification systems can now outperform their human counterparts [36], and this high accuracy is one of the driving factors behind the increased use of face recognition systems.

However, even given the high accuracy of modern face recognition technologies, their application in face authentication systems has left much to be desired. For instance, at the Black Hat security conference in 2009, Duc and Minh [10] demonstrated the weaknesses of popular face authentication systems from commodity vendors like Lenovo, Asus, and Toshiba. Amusingly, Duc and Minh [10] were able to reliably bypass face-locked computers simply by presenting the software with photographs and fake pictures of faces. Essentially, the security of these systems rested solely on the problem of face detection, rather than face authentication. This widely publicized event led to subsequent integration of more robust face authentication protocols. One prominent example is Android OS, which augmented its face authen-

¹See, for example, “Apple Acquires Face Recognition, Expression Analysis firm, Emotient”, TechTimes, Jan, 2016; “Google Acquires Facial Recognition Software Company PittPar,” WSJ, 2011.

tication approach in 2012 to require users to blink while authenticating (*i.e.*, as a countermeasure to still-image spoofing attacks). Unfortunately, this approach was also shown to provide little protection, and can be easily bypassed by presenting the system with two alternating images — one with the user’s eyes open, and one with her eyes closed.² These attacks underscore the fact that face authentication systems require robust security features beyond mere recognition in order to foil spoofing attacks.

Loosely speaking, three types of such spoofing attacks have been used in the past, to varying degrees of success: (*i*) still-image-based spoofing, (*ii*) video-based spoofing, and (*iii*) 3D-mask-based spoofing. As the name suggests, still-image-based spoofing attacks present one or more still images of the user to the authentication camera; each image is either printed on paper or shown with a digitized display. Video-based spoofing, on the other hand, presents a pre-recorded video of the victim’s moving face in an attempt to trick the system into falsely recognizing motion as an indication of liveness. The 3D-mask-based approach, wherein 3D-printed facial masks are used, was recently explored by Erdogmus and Marcel [11].

As is the typical case in the field of computer security, the cleverness of skilled, motivated adversaries drove system designers to incorporate defensive techniques in the biometric solutions they develop. This cat-and-mouse game continues to play out in the realm of face authentication systems, and the current recommendation calls for the use of well-designed face liveness detection schemes (that attempt to distinguish a real user from a spoofed one). Indeed, most modern systems now require more active participation compared to simple blink detection, often asking the user to rotate her head or raise an eyebrow during login. Motion-based techniques that check, for example, that the input captured during login exhibits sufficient 3D behavior, are also an active area of research in face authentication.

One such example is the recent work of Li et al. [34] that appeared in CCS’2015. In that work, the use of liveness detection was proposed as a solution to thwarting video-based attacks by checking the consistency of the recorded data with inertial sensors. Such a detection scheme relies on the fact that as a camera moves relative to a user’s stationary head, the facial features it detects will also move in a predictable way. Thus, a 2D video of the victim would have to be captured under the exact same camera motion in order to fool the system.

As mentioned in [34], 3D-printed facial reconstructions offer one option for defeating motion-based liveness detection schemes. In our view, a more realizable approach is to present the system with a 3D facial mesh in a virtual reality (VR) environment. Here, the motion

of the authenticating camera is tracked, and the VR system internally rotates and translates the mesh to match. In this fashion, the camera observes exactly the same movement of facial features as it would for a real face, fulfilling the requirements for liveness detection. Such an attack defeats color-image- and motion-based face authentication on a fundamental level because, with sufficient effort, a VR system can display an environment that is essentially indistinguishable from real-world input.

In this paper, we show that it is possible to undermine modern face authentication systems using one such attack. Moreover, we show that an accurate facial model can be built using *only* a handful of publicly accessible photos — collected, for example, from social network websites — of the victim. From a pragmatic point of view, we are confronted with two main challenges: *i*) the number of photos of the target may be limited, and *ii*) for each available photo, the illumination setting is unknown and the user’s pose and expression are not constrained. To overcome these challenges, we leverage robust, publicly available 3D face reconstruction methods from the field of computer vision, and adapt these techniques to fit our needs. Once a credible synthetic model of a user is obtained, we then employ entry-level virtual reality displays to defeat the state of the art in liveness detection.

The rest of the paper is laid out as follows: §2 provides background and related work related to face authentication, exploitation of users’ online photos, and 3D facial reconstruction. §3 outlines the steps we take to perform our VR-based attack. In §4, we evaluate the performance of our method on 5 commercial face authentication systems and, additionally, on a proposed state-of-the-art system for liveness detection. We suggest steps that could be taken to mitigate our attack in §5, and we address the implications of our successful attack strategy in §6.

2 Background and Related Work

Before delving into the details of our approach, we first present pertinent background information needed to understanding the remainder of this paper.

First, we note that given the three prominent classes of spoofing attacks mentioned earlier, it should be clear that while still-image-based attacks are the easiest to perform, they can be easily countered by detecting the 3D structure of the face. Video-based spoofing is more difficult to accomplish because facial videos of the target user may be harder to come by; moreover, such attacks can also be successfully defeated, for example, using the recently suggested techniques of Li et al. [34] (which we discuss in more detail later). 3D-mask-based approaches, on the other hand, are harder to counter. That said, building a 3D mask is arguably more time-consuming and also requires specialized equipment. Nevertheless, because

²<https://www.youtube.com/watch?v=zYxphDK6s3I>

of the threat this attack vector poses, much research has gone into detecting the textures of 3D masks [11].

2.1 Modern Defenses Against Spoofing

Just as new types of spoofing attacks have been introduced to fool face authentication systems, so too have more advanced methods for countering these attacks been developed. Nowadays, the most popular liveness detection techniques can be categorized as either texture-based approaches, motion-based approaches, or liveness assessment approaches. We discuss each in turn.

Texture-based approaches [11, 25, 37, 40, 54, 60] attempt to identify spoofing attacks based on the assumption that a spoofed face will have a distinctly different texture from a real face. Specifically, they assume that due to properties of its generation, a spoofed face (irrespective of whether it is printed on paper, shown on a display, or made as a 3D mask) will be different from a real face in terms of shape, detail, micro-textures, resolution, blurring, gamma correction, and shading. That is, these techniques rely on perceived limitations of image displays and printing techniques. However, with the advent of high-resolution displays (*e.g.*, 5K), the difference in visual quality between a spoofed image and a living face is hard to notice. Another limitation is that these techniques often require training on every possible spoofing material, which is not practical for real systems.

Motion-based approaches [3, 27, 29, 32, 57] detect spoofing attacks by using motion of the user’s head to infer 3D shape. Techniques such as optical flow and focal-length analysis are typically used. The basic assumption is that structures recovered from genuine faces usually contain sufficient 3D information, whereas structures from fake faces (photos) are usually planar in depth. For instance, the approach of Li et al. [34] checks the consistency of movement between the mobile device’s internal motion sensors and the observed change in head pose computed from the recorded video taken while the claimant attempts to authenticate herself to the device. Such 3D reasoning provides a formidable defense against both still-image and video-based attacks.

Lastly, liveness assessment techniques [19, 30, 31, 49] require the user to perform certain tasks during the authentication stage. For the systems we evaluated, the user is typically asked to follow certain guidelines during registration, and to perform a random series of actions (*e.g.*, eye movement, lip movement, and blinking) at login. The requested gestures help to defeat contemporary spoofing attacks.

Take-away: For real-world systems, liveness detection schemes are often combined with motion-based approaches to provide better security protection than either

can provide on their own. With these ensemble techniques, traditional spoofing attacks can be reliably detected. For that reason, the combination of motion-based systems and liveness detectors has gained traction and is now widely adopted in many commercial systems, including popular face authentication systems offered by companies like KeyLemon, Rohos, and Biomids. For the remainder of this paper, we consider this combination as the state of the art in defenses against spoofing attacks for face authentication systems.

2.2 Online Photos and Face Authentication

It should come as no surprise that personal photos from online social networks can compromise privacy. Major social network sites advise users to set privacy settings for the images they upload, but the vast majority of these photos are often accessible to the public or set to ‘friend-only’ viewing’ [14, 26, 35]. Users also do not have direct control over the accessibility of photos of themselves posted by other users, although they can remove (‘untag’) the association of such photos with their account.

A notable use of social network photos for online security is Facebook’s social authentication (SA) system [15], an extension of CAPTCHAs that seeks to bolster identity verification by requiring the user to identify photos of their friends. While this method does require more specific knowledge than general CAPTCHAs, Polakis et al. [42] demonstrated that facial recognition could be applied to a user’s public photos to discover their social relationships and solve 22% of SA tests automatically.

Given that one’s online photo presence is not entirely controlled by the user alone — but by their collective social circles — many avenues exist for an attacker to uncover the facial appearance of a user, even when the user makes private their own personal photos. In an effort to curb such easy access, work by Ilia et al. [17] has explored the automatic privatization of user data across a social network. This method uses face detection and photo tags to selectively blur the face of a user when the viewing party does not have permission to see the photo. In the future, such an approach may help decrease the public accessibility of users’ personal photos, but it is unlikely that an individual’s appearance can ever be completely obfuscated from attackers across all social media sites and image stores on the Internet.

Clearly, the availability of online user photos is a boon for an adversary tasked with the challenge of undermining face authentication systems. The most germane on this front is the work of Li et al. [33]. There, the authors proposed an attack that defeated commonly used face authentication systems by using photos of the target user gathered from online social networks. Li et al. [33] reported that 77% of the users in their test set were vul-

nerable to their proposed attack. However, their work is targeted at face recognition systems that *do not incorporate face liveness detection*. As noted in §2, in modern face authentication software, sophisticated liveness detection approaches are already in use, and these techniques thwart still-image spoofing attacks of the kind performed by Li et al. [33].

2.3 3D Facial Reconstruction

Constructing a 3D facial model from a small number of personal photos involves the application of powerful techniques from the field of computer vision. Fortunately, there exists a variety of reconstruction approaches that make this task less daunting than it may seem on first blush, and many techniques have been introduced for facial reconstruction from single images [4, 23, 24, 43], videos [20, 48, 51], and combinations of both [52]. For pedagogical reasons, we briefly review concepts that help the reader better understand our approach.

The most popular facial model reconstruction approaches can be categorized into three classes: shape from shading (SFS), structure from motion (SFM) combined with dense stereoscopic depth estimation, and statistical facial models. The SFS approach [24] uses a model of scene illumination and reflectance to recover face structure. Using this technique, a 3D facial model can be reconstructed from only a single input photo. SFS relies on the assumption that the brightness level and gradient of the face image reveals the 3D structure of the face. However, the constraints of the illumination model used in SFS require a relatively simple illumination setting and, therefore, cannot typically be applied to real-world photo samples, where the configuration of the light sources is unknown and often complicated.

As an alternative, the structure from motion approach [12] makes use of multiple photos to triangulate spatial positions of 3D points. It then leverages stereoscopic techniques across the different viewpoints to recover the complete 3D surface of the face. With this method, the reconstruction of a dense and accurate model often requires many consistent views of the surface from different angles; moreover, non-rigid variations (*e.g.*, facial expressions) in the images can easily cause SFM methods to fail. In our scenario, these requirements make such an approach less usable: for many individuals, only a limited number of images might be publicly available online, and the dynamic nature of the face makes it difficult to find multiple images having a consistent appearance (*i.e.*, the exact same facial expression).

Unlike SFS and SFM, statistical facial models [4, 43] seek to perform facial reconstruction on an image using a training set of existing facial models. The basis for this type of facial reconstruction is the 3D morphable model

(3DMM) of Blanz and Vetter [6, 7], which learns the principal variations of face shape and appearance that occur within a population, then fits these properties to images of a specific face. Training the morphable models can be performed either on a controlled set of images [8, 39] or from internet photo-collections [23]. The underlying variations fall on a continuum and capture both expression (*e.g.*, a frowning-to-smiling spectrum) and identity (*e.g.*, a skinny-to-heavy or a male-to-female spectrum). In 3DMM and its derivatives, both 3D shape and texture information are cast into a high-dimensional linear space, which can be analyzed with principal component analysis (PCA) [22]. By optimizing over the weights of different eigenvectors in PCA, any particular human face model can be approximated. Statistical facial models have shown to be very robust and only require a few photos for high-precision reconstruction. For instance, the approach of Baumberger et al. [4] achieves good reconstruction quality using only two images.

To make the process fully automatic, recent 3D facial reconstruction approaches have relied on a few facial landmark points instead of operating on the whole model. These landmarks can be accurately detected using the supervised descent method (SDM) [59] or deep convolutional networks [50]. By first identifying these 2D features in an image and then mapping them to points in 3D space, the entire 3D facial surface can be efficiently reconstructed with high accuracy. In this process, the main challenge is the localization of facial landmarks within the images, especially contour landmarks (along the cheekbones), which are half-occluded in non-frontal views; we introduce a new method for solving this problem when multiple input images are available.

The end result of 3D reconstruction is a untextured (*i.e.*, lacking skin color, eye color, etc.) facial surface. Texturing is then applied using source image(s), creating a realistic final face model. We next detail our process for building such a facial model from a user’s publicly available internet photos, and we outline how this model can be leveraged for a VR-based face authentication attack.

3 Our Approach

A high-level overview of our approach for creating a synthetic face model is shown in Figure 1. Given one or more photos of the target user, we first automatically extract the landmarks of the user’s face (stage ①). These landmarks capture the pose, shape, and expression of the user. Next, we estimate a 3D facial model for the user, optimizing the geometry to match the observed 2D landmarks (stage ②). Once we have recovered the shape of the user’s face, we use a single image to transfer texture information to the 3D mesh. Transferring the texture is non-trivial since parts of the face might be self-occluded

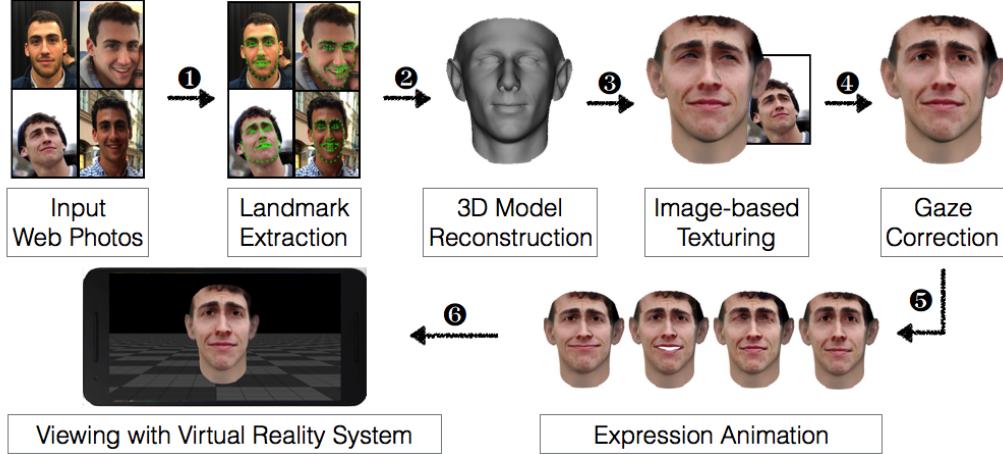

Figure 1: Overview of our proposed approach.

(e.g., when the photo is taken from the side). The texture of these occluded parts must be estimated in a manner that does not introduce too many artifacts (stage ③). Once the texture is filled, we have a realistic 3D model of the user’s face based on a single image.

However, despite its realism, the output of stage ③ is still not able to fool modern face authentication systems. The primary reason for this is that modern face authentication systems use the subject’s gaze direction as a strong feature, requiring the user to look at the camera in order to pass the system. Therefore, we must also automatically correct the direction of the user’s gaze on the textured mesh (stage ④). The adjusted model can then be deformed to produce animation for different facial expressions, such as smiling, blinking, and raising the eyebrows (stage ⑤). These expressions are often used as liveness clues in face authentication systems, and as such, we need to be able to automatically reproduce them on our 3D model. Finally, we output the textured 3D model into a virtual reality system (stage ⑥).

Using this framework, an adversary can bypass both the face recognition and liveness detection components of modern face authentication systems. In what follows, we discuss the approach we take to solve each of the various challenges that arise in our six-staged process.

3.1 Facial Landmark Extraction

Starting from multiple input photos of the user, our first task is to perform facial landmark extraction. Following the approach of Zhu et al. [63], we extract 68 2D facial landmarks in each image using the supervised descent method (SDM) [59]. SDM successfully identifies facial landmarks under relatively large pose differences (± 45 deg yaw, ± 90 deg roll, ± 30 deg pitch). We chose the technique of Zhu et al. [63] because it achieves a me-

dian alignment error of 2.7 pixels on well-known datasets [1] and outperforms other commonly used techniques (e.g., [5]) for landmark extraction.

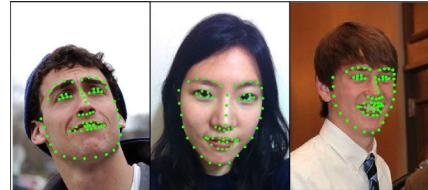

Figure 2: Examples of facial landmark extraction

For our needs, SDM works well on most online images, even those where the face is captured at a low resolution (e.g., 40×50 pixels). It does, however, fail on a handful of the online photos we collected (less than 5%) where the pose is beyond the tolerance level of the algorithm. If this occurs, we simply discard the image. In our experiments, the landmark extraction results are manually checked for correctness, although an automatic scoring system could potentially be devised for this task. Example landmark extractions are shown in Figure 2.

3.2 3D Model Reconstruction

The 68 extracted 3D point landmarks from each of the N input images provide us with a set of coordinates $s_{i,j} \in \mathbb{R}^2$, with $1 \leq i \leq 68, 1 \leq j \leq N$. The projection of the 3D points $S_{i,j} \in \mathbb{R}^3$ on the face onto the image coordinates $s_{i,j}$ follows what is called the “weak perspective projection” (WPP) model [16], computed as follows:

$$s_{i,j} = f_j P R_j (S_{i,j} + t_j), \quad (1)$$

where f_j is a uniform scaling factor; P is the projection matrix $\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$; R_j is a 3×3 rotation matrix defined by

the pitch, yaw, and roll, respectively, of the face relative to the camera; and $t_j \in \mathbb{R}^3$ is the translation of the face with respect to the camera. Among these parameters, only $s_{i,j}$ and P are known, and so we must estimate the others.

Fortunately, a large body of work exists on the shape statistics of human faces. Following Zhu et al. [63], we capture face characteristics using the 3D Morphable Model (3DMM) [39] with an expression extension proposed by Chu et al. [9]. This method characterizes variations in face shape for a population using principal component analysis (PCA), with each individual’s 68 3D point landmarks being concatenated into a single feature vector for the analysis. These variations can be split into two categories: constant factors related to an individual’s distinct appearance (identity), and non-constant factors related to expression. The identity axes capture characteristics such as face width, brow placement, or lip size, while the expression axes capture variations like smiling versus frowning. Example axes for variations in expression are shown in Figure 6.

More formally, for any given individual, the 3D coordinates $S_{i,j}$ on the face can be modeled as

$$S_{i,j} = \bar{S}_i + A_i^{id} \alpha_i^{id} + A_i^{exp} \alpha_j^{exp}, \quad (2)$$

where \bar{S}_i is the statistical average of $S_{i,j}$ among the individuals in the population, A_i^{id} is the set of principal axes of variation related to identity, and A_i^{exp} is the set of principal axes related to expression. α_i^{id} and α_j^{exp} are the identity and expression weight vectors, respectively, that determine *person-specific* facial characteristics and expression-specific facial appearance. We obtain \bar{S}_i and A_i^{id} using the 3D Morphable Model [39] and A_i^{exp} from Face Warehouse [8].

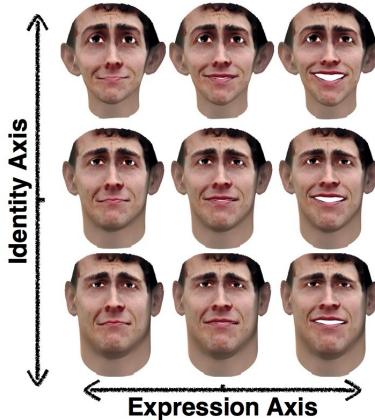

Figure 3: Illustration of identity axes (heavy-set to thin) and expression axes (pursed lips to open smile).

When combining Eqs. (1) and (2), we inevitably run into the so-called “correspondence problem.” That is,

given each identified facial landmark $s_{i,j}$ in the input image, we need to find the corresponding 3D point $S_{i',j}$ on the underlying face model. For landmarks such as the corners of the eyes and mouth, this correspondence is self-evident and consistent across images. However, for contour landmarks marking the edge of the face in an image, the associated 3D point on the user’s facial model is pose-dependent: When the user is directly facing the camera, their jawline and cheekbones are fully in view, and the observed 2D landmarks lie on the fiducial boundary on the user’s 3D facial model. When the user rotates their face left (or right), however, the previously observed 2D contour landmarks on the left (resp. right) side of the face shift out of view. As a result, the observed 2D landmarks on the edge of the face correspond to 3D points closer to the center of the face. This 3D point displacement must be taken into account when recovering the underlying facial model.

Qu et al. [44] deal with contour landmarks using constraints on surface normal direction, based on the observation that points on the edge of the face in the image will have surface normals perpendicular to the viewing direction. However, this approach is less robust because the normal direction cannot always be accurately estimated and, as such, requires careful parameter tuning. Zhu et al. [63] proposed a “landmark marching” scheme that iteratively estimates 3D head pose and 2D contour landmark position. While their approach is efficient and robust against different face angles and surface shapes, it can only handle a single image and cannot refine the reconstruction result using additional images.

Our solution to the correspondence problem is to model 3D point variance for each facial landmark using a pre-trained Gaussian distribution (see Appendix A). Unlike the approach of Zhu et al. [63] which is based on single image input, we solve for pose, perspective, expression, and neutral-expression parameters over *all* images jointly. From this, we obtain a neutral-expression model S_i of the user’s face. A typical reconstruction, S_i , is presented in Figure 4.

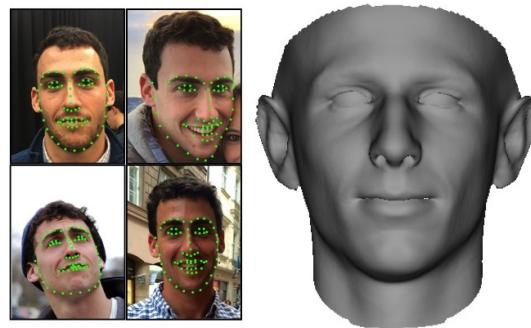

Figure 4: 3D facial model (right) built from facial landmarks extracted from 4 images (left).

3.3 Facial Texture Patching

Given the 3D facial model, the next step is to patch the model with realistic textures that can be recognized by the face authentication systems. Due to the appearance variation across social media photos, we have to achieve this by mapping the pixels in a *single* captured photo onto the 3D facial model, which avoids the challenges of mixing different illuminations of the face. However, this still leaves many of the regions without texture, and those untextured spots will be noticeable to modern face authentication systems. To fill these missing regions, the naïve approach is to utilize the vertical symmetry of the face and fill the missing texture regions with their symmetrical complements. However, doing so would lead to strong artifacts at the boundary of missing regions. A realistic textured model should be free of these artifacts.

To lessen the presence of these artifacts, one approach is to iteratively average the color of neighboring vertices as a color trend and then mix this trend with texture details [45]. However, such an approach over-simplifies the problem and fails to realistically model the illumination of facial surfaces. Instead, we follow the suggestion of Zhu et al. [63] and estimate facial illumination using spherical harmonics [61], then fill in texture details with Poisson editing [41]. In this way, the output model will appear to have a more natural illumination. Sadly, we cannot use their approach directly as it reconstructs a planar normalized face, instead of a 3D facial model, and so we must extend their technique to the 3D surface mesh.

The idea we implemented for improving our initial textured 3D model was as follows: Starting from the single photo chosen as the main texture source, we first estimate and subsequently remove the illumination conditions present in the photo. Next, we map the textured facial model onto a plane via a conformal mapping, then impute the unknown texture using 2D Poisson editing. We further extend their approach to three dimensions and perform Poisson editing directly on the surface of the facial model. Intuitively, the idea behind Poisson editing is to keep the detailed texture in the editing region while enforcing the texture’s smoothness across the boundary. This process is defined mathematically as

$$\Delta f = \Delta g, s.t. f|_{\partial\Omega} = f^0|_{\partial\Omega}, \quad (3)$$

where Ω is the editing region, f is the editing result, f^0 is the known original texture value, and g is the texture value in the editing region that is unknown and needs to be patched with its reflection complement. On a 3D surface mesh, every vertex is connected with 2 to 8 neighbors. Transforming Eq. 3 into discrete form, we have

$$|N_p|f_p - \sum_{q \in N_p \cap \Omega} f_q = \sum_{q \in N_p \cap \bar{\Omega}} f_q^0 + (\Delta g)_p, \quad (4)$$

where N_p is the neighborhood of point p on the mesh. Our enhancement is a natural extension of the Poisson editing method suggested in the seminal work of Pérez et al. [41], although no formulation was given for 3D. By solving Eq. 4 instead of projecting the texture onto a plane and solving Eq. 3, we obtain more realistic texture on the facial model, as shown in Figure 5.

Figure 5: Naïve symmetrical patching (left); Planar Poisson editing (middle); 3D Poisson editing (right).

3.4 Gaze Correction

We now have a realistic 3D facial model of the user. Yet, we found that models at stage ③ were unable to bypass most well-known face recognition systems. Digging deeper into the reasons why, we observed that most recognition systems rely heavily on gaze direction during authentication, *i.e.*, they fail-close if the user is not looking at the device. To address this, we introduce a simple, but effective, approach to correct the gaze direction of our synthetic model (Figure 1, Stage ④).

The idea is as follows. Since we have already reconstructed the texture of the facial model, we can synthesize the texture data in the eye region. These data contain the color information from the sclera, cornea, and pupil and form a three-dimensional distribution in the RGB color space. We estimate this color distribution with a 3D Gaussian function whose three principle components can be computed as (b_1, b_2, b_3) with weight $(\sigma_1, \sigma_2, \sigma_3)$, $\sigma_1 \geq \sigma_2 \geq \sigma_3 > 0$. We perform the same analysis for the eye region of the average face model obtained from 3DMM [39], whose eye is looking straight towards the camera, and we similarly obtain principle color components $(b_1^{std}, b_2^{std}, b_3^{std})$ with weight $(\sigma_1^{std}, \sigma_2^{std}, \sigma_3^{std})$, $\sigma_1^{std} \geq \sigma_2^{std} \geq \sigma_3^{std} > 0$. Then, we convert the eye texture from the average model into the eye texture of the user. For a texture pixel c in the eye region of average texture, we convert it to

$$c_{convert} = \sum_{i=1}^3 \frac{\sigma_i}{\sigma_i^{std}} (c' b_i^{std}) b_i. \quad (5)$$

In effect, we align the color distribution of the average eye texture with the color distribution of the user’s eye texture. By patching the eye region of the facial model with this converted average texture, we realistically capture the user’s eye appearance with forward gaze.

3.5 Adding Facial Animations

Some of the liveness detection methods that we test require that the user performs specific actions in order to unlock the system. To mimic these actions, we can simply animate our facial model using a pre-defined set of facial expressions (*e.g.*, from FaceWarehouse [8]). Recall that in deriving in Eq. 2, we have already computed the weight for the identity axis α_{std}^{id} , which captures the user-specific face structure in a neutral expression. We can adjust the expression of the model by substituting a specific, known expression weight vector α_{std}^{exp} into Eq. 2. By interpolating the model’s expression weight from 0 to α_{std}^{exp} , we are able to animate the 3D facial model to smile, laugh, blink, and raise the eyebrows (see Figure 6).

Figure 6: Animated expressions. From left to right: smiling, laughing, closing the eyes, and raising the eyebrows.

3.6 Leveraging Virtual Reality

While the previous steps were necessary to recover a realistic, animated model of a targeted user’s face, our driving insight is that virtual reality systems can be leveraged to display this model as if it were a real, three-dimensional face. This VR-based spoofing constitutes a fundamentally new class of attacks that exploit weaknesses in camera-based authentication systems.

In the VR system, the synthetic 3D face of the user is displayed on the screen of the VR device, and as the device rotates and translates in the real world, the 3D face moves accordingly. To an observing face authentication system, the depth and motion cues of the display exactly match what would be expected for a human face. Our experimental VR setup consists of custom 3D-rendering software displayed on a Nexus 5X smart phone. Given the ubiquity of smart phones in modern society, our implementation is practical and comes at no additional hardware cost to an attacker. In practice, any device with similar rendering capabilities and inertial sensors could be used.

On smart phones, accelerometers and gyroscopes work in tandem to provide the device with a sense of self-motion. An example use case is detecting when the device is rotated from a portrait view to a landscape view, and rotating the display, in response. However, these sensors are not able to recover absolute *translation* — that is, the device is unable to determine how its position has

changed in 3D space. This presents a challenge because without knowledge of how the device has moved in 3D space, we cannot move our 3D facial model in a realistic fashion. As a result, the observed 3D facial motion will not agree with the device’s inertial sensors, causing our method to fail on methods like that of Li et al. [34] that use such data for liveness detection.

Fortunately, it is possible to track the 3D position of a moving smart phone using its outward-facing camera with structure from motion (see §2.3). Using the camera’s video stream as input, the method works by tracking points in the surrounding environment (*e.g.*, the corners of tables) and then estimating their position in 3D space. At the same time, the 3D position of the camera is recovered relative to the tracked points, thus inferring the camera’s change in 3D position. Several computer vision approaches have been recently introduced to solve this problem accurately and in real time on mobile devices [28, 46, 55, 56]. In our experiments, we make use of a printed marker³ placed on a wall in front of the camera, rather than tracking arbitrary objects in the surrounding scene; however, the end result is the same. By incorporating this module into our proof of concept, the perspective of the viewed model due to camera translation can be simulated with high consistency and low latency.⁴

An example setup for our attack is shown in Figure 7. The VR system consists of a Nexus 5X unit using its outward-facing camera to track a printed marker in the environment. On the Nexus 5X screen, the system displays a 3D facial model whose perspective is always consistent with the spatial position and orientation of the authenticating device. The authenticating camera views the facial model on the VR display, and it is successfully duped into believing it is viewing the real face of the user.

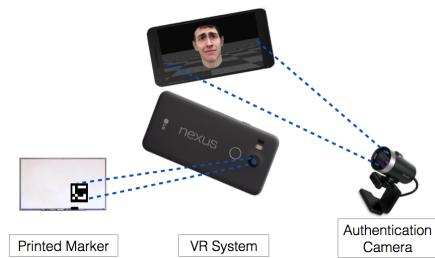

Figure 7: Example setup using virtual reality to mimic 3D structure from motion. The authentication system observes a virtual display of a user’s 3D facial model that rotates and translates as the device moves. To recover the 3D translation of the VR device, an outward-facing camera is used to track a marker in the surrounding environment.

³See Goggle Paper at <http://gogllepaper.com>

⁴Specialized VR systems such as the Oculus Rift could be used to further improve the precision and latency of camera tracking. Such advanced, yet easily obtainable, hardware has the potential to deliver even more sophisticated VR attacks compared to what is presented here.

4 Evaluation

We now demonstrate that our proposed spoofing method constitutes a significant security threat to modern face authentication systems. Using real social media photos from consenting users, we successfully broke five commercial authentication systems with a practical, end-to-end implementation of our approach. To better understand the threat, we further systematically run lab experiments to test the capabilities and limitations of our proposed method. Moreover, we successfully test our proposed approach with the latest motion-based liveness detection approach by Li et al. [34], which is not yet available in commercial systems.

Participants

We recruited 20 volunteers for our tests of commercial face authentication systems. The volunteers were recruited by word of mouth and span graduate students and faculty in two separate research labs. Consultation with our IRB departmental liaison revealed that no application was needed. There was no compensation for participating in the lab study. The ages of the participants range between 24 and 44 years, and the sample consists of 6 females and 14 males. The participants come from a variety of ethnic backgrounds (as stated by the volunteers): 6 are of Asian descent, 4 are Indian, 1 is African-American, 1 is Hispanic, and 8 are Caucasian. With their consent, we collected public photos from the users' Facebook and Google+ social media pages; we also collected any photos we could find of the users on personal or community web pages, as well as via image search on the web. The smallest number of photos we collected for an individual was 3, and the largest number was 27. The average number of photos was 15, with a standard deviation of approximately 6 photos. No private information about the subjects was recorded beside storage of the photographs they consented too. Any images of subjects displayed in this paper was done with the consent of that particular volunteer.

For our experiments, we manually extracted the region around user's face in each image. An adversary could also perform this action automatically using tag information on social media sites, when available. One interesting aspect of social media photos is they may capture significant physical changes of users over time. For instance, one of our participants lost 20 pounds in the last 6 months, and our reconstruction had to utilize images from before and after this change. Two other users had frequent changes in facial hair styles – beards, moustaches, and clean-shaven – all of which we used for our reconstruction. Another user had only uploaded 2 photos to social media in the past 3 years. These varieties all

present challenges for our framework, both for initially reconstructing the user's face and for creating a likeness that matches their current appearance.

Industry-leading Solutions

We tested our approach on five advanced commercial face authentication systems: KeyLemon⁵, Mobius⁶, True Key [18], BioID [21], and 1U App⁷. Table 1 summarizes the training data required by each system when learning a user's facial appearance, as well as the approximate number of users for each system, when available. All systems incorporate some degree of liveness detection into their authentication protocol. KeyLemon and the 1U App require users to perform an action such as blinking, smiling, rotating the head, and raising the eyebrows. In addition, the 1U App requests these actions in a random fashion, making it more resilient to video-based attacks. BioID, Mobius and True Key are motion-based systems and detect 3D facial structure as the user turns their head. It is also possible that these five systems employ other advanced liveness detection approaches, such as texture-based detection schemes, but such information has not been made available to the public.

Methodology

System	Training Method	# Installs
KeyLemon ³	Single video	~100,000
Mobius ²	10 still images	18 reviews
True Key ¹	Single video	50,000-100,000
BioID ²	4 videos	unknown
1U App ¹	1 still image	50-100

Table 1: Summary of the face authentication systems evaluated. The second column lists how each system acquires training data for learning a user's face, and the third column shows the number approximate number of installations or reviews each system has received according to (1) the Google Play Store, (2) the iTunes store, or (3) softpedia.com. BioID is a relatively new app and does not yet have customer reviews on iTunes.

All participants were registered with the 5 face authentication systems under indoor illumination. The average length of time spent by each of the volunteers to register across all systems was 20 minutes. As a control, we first verified that all systems were able to correctly identify the users in the same environment. Next, before testing our method using textures obtained via social media, we evaluated whether our system could spoof the recognition systems using photos taken in this environment. We

⁵<http://www.keylemon.com>

⁶<http://www.biomids.com>

⁷<http://www.1uapps.com>

thus captured one front-view photo for each user under the same indoor illumination and then created their 3D facial model with our proposed approach. We found that these 3D facial models were able to spoof each of the 5 candidate systems with a 100% success rate, which is shown in the second column of Table 2

Following this, we reconstructed each user’s 3D facial model using the images collected from public online sources. As a reminder, any source image can be used as the main image when texturing the model. Since not all textures will successfully spoof the recognition systems, we created textured reconstructions from all source images and iteratively presented them to the system (in order of what we believed to be the best reconstruction, followed by the second best, and so on) until either authentication succeeded or all reconstructions had been tested.

Findings

We summarize the spoofing success rate for each system in Table 2. Except for the 1U system, all facial recognition systems were successfully spoofed for the majority of participants when using social media photos, and all systems were spoofed using indoor, frontal view photos. Out of our 20 participants, there were only 2 individuals for whom none of the systems was spoofed via the social-media-based attack.

Looking into the social media photos we collected of our participants, we observe a few trends among our results. First, we note that moderate- to high-resolution photos lend substantial realism to the textured models. In particular, photos taken by professional photographers (*e.g.*, wedding photos or family portraits) lead to high-quality facial texturing. Such photos are prime targets for facial reconstruction because they are often posted by other users and made publicly available. Second, we note that group photos provide consistent frontal views of individuals, albeit with lower resolution. In cases where high-resolution photos are not available, such frontal views can be used to accurately recover a user’s 3D facial structure. These photos are easily accessible via friends of users, as well. Third, we note that the least spoofable users were not those who necessarily had a low number of personal photos, but rather users who had few forward-facing photos and/or no photos with sufficiently high resolution. From this observation, it seems that creating a realistic texture for user recognition is the primary factor in determining whether a face authentication method will be fooled by our approach. Only a small number of photos are necessary in order to defeat facial recognition systems.

We found that our failure to spoof the 1U App, as well as our lower performance on BioID, using social media photos was directly related to the poor usability of

	Indoor	Social Media	
	Spoof %	Spoof %	Avg. # Tries
KeyLemon	100%	85%	1.6
Mobius	100%	80%	1.5
True Key	100%	70%	1.3
BioID	100%	55%	1.7
1U App	100%	0%	—

Table 2: Success rate for 5 face authentication systems using a model built from (second column) an image of the user taken in an indoor environment and (third and fourth columns) images obtained on users’ social media accounts. The fourth column shows the average number of attempts needed before successfully spoofing the target user.

those systems. Specifically, we found the systems have a very high false rejection rate when live users attempt to authenticate themselves in different illumination conditions. To test this, we had 5 participants register their faces indoors on the 4 mobile systems.⁸ We then had each user attempt to log in to each system 10 times indoors and 10 times outdoors on a sunny day, and we counted the number of accepted logins in each environment for each system. True Key and Mobius, which we found were easier to defeat, correctly authenticated the users 98% and 100% of the time for indoor logins, respectively, and 96% and 100% of the time for outdoor logins. Meanwhile, the indoor/outdoor login rates of BioID and the 1U App were 50%/14% and 96%/48%, respectively. The high false rejection rates under outdoor illumination show that the two systems have substantial difficulty with their authentication when the user’s environment changes. Our impression is that 1U’s single-image user registration simply lacks the training data necessary to accommodate to different illumination settings. BioID is very sensitive to a variety of factors including head rotation and illumination, which leads to many false rejections. (Possibly realizing this, the makers of BioID therefore grant the user 3 trials per login attempt.) Even so, as evidenced by the second column in Table 2, our method still handily defeats the liveness detection modules of these systems given images of the user in the original illumination conditions, which suggests that all the systems we tested are vulnerable to our VR-based attack.

Our findings also suggest that our approach is able to successfully handle significant changes in facial expression, illumination, and for the most part, physical characteristics such as weight and facial hair. Moreover, the approach appears to generalize to users regardless of gender or ethnicity. Given that it has shown to work on a varied collection of real-world data, we believe that the at-

⁸As it is a desktop application, KeyLemon was excluded.

tack presented herein represents a realistic security threat model that could be exploited in the present day.

Next, to gain a deeper understanding of the realism of this threat, we take a closer look at what conditions are necessary for our method to bypass the various face authentication systems we tested. We also consider what main factors contribute to the failure cases of our method.

4.1 Evaluating System Robustness

To further understand the limitations of the proposed spoofing system, we test its robustness against resolution and viewing angle, which are two important factors for the social media photos users upload. Specifically, we answer the question: what is the minimum resolution and maximum head rotation allowed in an uploaded photo before it becomes unusable for spoofing attacks like ours? We further explore how low-resolution frontal images can be used to improve our success rates when high-resolution side-view images are not available.

4.1.1 Blurry, Grainy Pictures Still Say A Lot

To assess our ability to spoof face authentication systems when provided only low-resolution images of a user’s face, we texture the 3D facial models of our sample users using an indoor, frontal view photo. This photo is then downsampled at various resolutions such that the distance between the user’s chin and forehead ranges between 20 and 50 pixels. Then, we attempt to spoof the True Key, BioId, and KeyLemon systems with facial models textured using the down-sampled photos.⁹ If we are successful at a certain resolution, that implies that that resolution leaks the user’s identity information to our spoofing system. The spoofing success rate for various image resolutions is shown in Figure 8.

The result indicates that our approach robustly spoofs face authentication systems when the height of the face in the image is at least 50 pixels. If the resolution of an uploaded photo is less than 30 pixels, the photo is likely of too low-resolution to reliably encode useful features for identifying the user. In our sample set, 88% of users had more than 6 online photos with a chin-to-forehead distance greater than 100 pixels, which easily satisfies the resolution requirement of our proposed spoofing system.

4.1.2 A Little to the Left, a Little to the Right

To identify the robustness of the proposed system against head rotation, we first evaluate the maximum yaw angle allowed for our system to spoof baseline systems using a

⁹We skip analysis of Mobius because its detection method is similar to True Key, and our method did not perform as well on True Key. We also do not investigate the robustness of our method in the 1U system because of our inability to spoof this system using online photos.

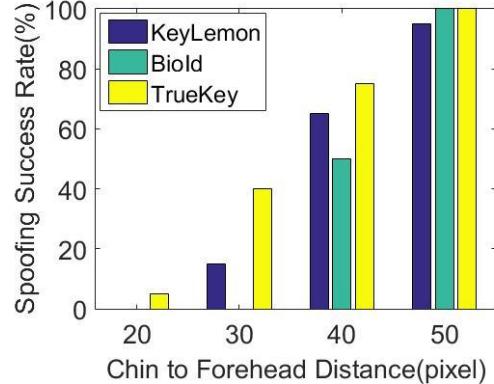

Figure 8: Spoofing success rate with texture taken from photos of different resolution.

single image. For all 20 sample users, we collect multiple indoor photos with yaw angle varying from 5 degrees (approximately frontal view) to 40 degrees (significantly rotated view). We then perform 3D reconstruction for each image, for each user, on the same three face authentication systems. The spoofing success rate for a single input image as a function of head rotation is illustrated in Figure 9 (left). It can be seen that the proposed method successfully spoofs all the baseline systems when the input image has a largely frontal view. As yaw angle increases, it becomes more difficult to infer the user’s frontal view from the image, leading to a decreased spoofing success rate.

4.1.3 For Want of a Selfie

The results of Figure 9 (left) indicate that our success rate falls dramatically if given only a single image with a yaw angle larger than 20 degrees. However, we argue that these high-resolution side-angle views can serve as base images for facial texturing if additional low-resolution frontal views of the user are available. We test this hypothesis by taking, for each user, the rotated images from the previous section along with 1 or 2 low-resolution frontal view photos (chin-to-forehead distance of 30 pixels). We then reconstruct each user’s facial model and use it to spoof our baseline systems. Alone, the provided low-resolution images provide insufficient texture for spoofing, and the higher-resolution side view does not provide adequate facial structure. As shown in Figure 9 (right), by *using the low-resolution front views to guide 3D reconstruction and then using the side view for texturing*, the spoofing success rate for large-angle head rotation increases substantially. From a practical standpoint, low-resolution frontal views are relatively easy to obtain, since they can often be found in publicly posted group photos.

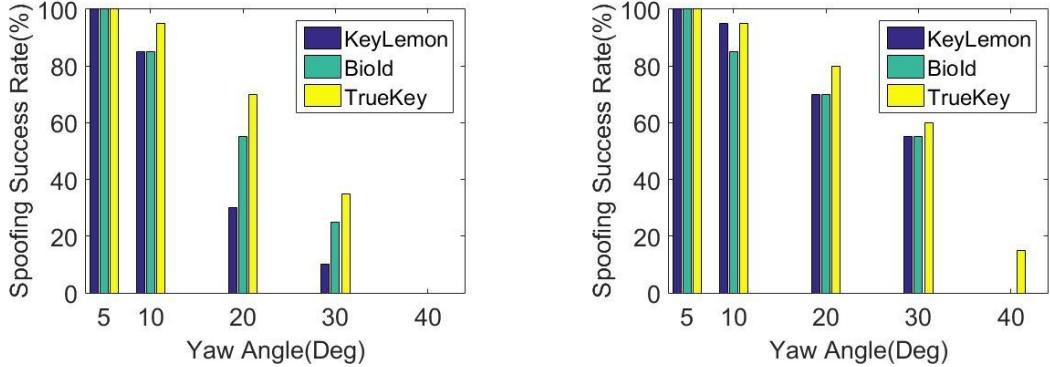

Figure 9: Spoofing success rate with different yaw angles. Left: Using only a single image at the specified angle. Right: Supplementing the single image with low-resolution frontal views, which aid in 3D reconstruction.

4.2 Seeing Your Face Is Enough

Our approach not only defeats existing commercial systems having liveness detection — it fundamentally undermines the process of liveness detection based on color images, entirely. To illustrate this, we use our method to attack the recently proposed authentication approach of Li et al. [34], which obtains a high rate of success in guarding against video-based spoofing attacks. This system adds another layer to motion-based liveness detection by requiring that the movement of the face in the captured video be consistent with the data obtained from the motion sensor of the device. Fortunately, as discussed in §3, the data consistency requirement is automatically satisfied with our virtual reality spoofing system because the 3D model rotates in tandem with the camera motion.

Central to Li et al. [34]’s approach is to build a classifier that evaluates the consistency of captured video and motion sensor data. In turn, the learned classifier is used to distinguish real faces from spoofed ones. Since their code and training samples have not been made public, we implemented our own version of Li et al. [34]’s liveness detection system and trained a classifier with our own training data. We refer the reader to [34] for a full overview of the method.

Following the methodology of [34], we capture video samples (and inertial sensor data) of ~ 4 seconds from the front-facing camera of a mobile phone. In each sample, the phone is held at a distance of 40cm from the subject and moved back-and-forth 20cm to the left and right. We capture 40 samples of real subjects moving the phone in front of their face, 40 samples where a pre-recorded video of a user is presented to the camera, and 30 samples where the camera is presented with a 3D reconstruction of a user in our VR environment. For training, we use a binary logistic regression classifier trained on 20 samples from each class, with the other samples used for testing. Due to the relatively small size of our

training sets, we repeat our classification experiments 4 times, with random train/test splits in each trial, and we report the average performance over all four trials.

Training Data	Real	Video	VR
Real+Video	19.50 / 20	0.25 / 20	9.75 / 10
Real+Video+VR	14.00 / 20	0.00 / 20	5.00 / 10
Real+VR	14.75 / 20	—	5.00 / 10

Table 3: Number of testing samples classified as real users. Values in the first column represent true positive rates, and the second and third columns represent false positives. Each row shows the classification results after training on the classes in the first column. The results were averaged over four trials.

The results of our experiments are shown in Table 3. For each class (real user data, video spoof data, and VR data), we report the average number (over 4 trials) of test samples classified as real user data. We experiment with three different training configurations, which are listed in the first column of the table. The first row shows the results when using real user data as positive samples and video spoof data as negative samples. In this case, it can easily be seen that the real-versus-video identification is almost perfect, matching the results of [34]. However, our VR-based attack is able to spoof this training configuration nearly 100% of the time. The second and third rows of Table 3 show the classification performance when VR spoof data is included in the training data. In both cases, our approach defeats the liveness detector in 50% of trials, and the real user data is correctly identified as such less than 75% of the time.

All three training configurations clearly point to the fact that our VR system presents motion features that are close to real user data. Even if the liveness detector of [34] is specifically trained to look for our VR-based attack, 1 out of every 2 attacks will still succeed, with the false rejection rate also increasing. Any system using

this detector will need to require multiple log-in attempts to account for the decreased recall rate; allowing multiple log-in attempts, however, allows our method more opportunities to succeed. Overall, the results indicate that the proposed VR-based attack successfully spoofs Li et al. [34]’s approach, which is to our knowledge the state of the art in motion-based liveness detection.

5 Defense in Depth

While current facial authentication systems succumb to our VR-based attack, several features could be added to these systems to confound our approach. Here, we detail three such features, namely random projection of light patterns, detection of minor skin tone fluctuations related to pulse, and the use of illuminated infrared (IR) sensors. Of these, the first two could still be bypassed with additional adversary effort, while the third presents a significantly different hardware configuration that would require non-trivial alterations to our method.

Light Projection The principle of using light projection for liveness detection is simple: Using an outward-facing light source (*e.g.*, the flashlight commonly included on camera-equipped mobile phones), flash light on the user’s face at random intervals. If the observed change in illumination does not match the random pattern, then face authentication fails. The simplicity of this approach makes it appealing and easily implementable; however, an adversary could modify our proposed approach to detect the random flashes of light and, with low latency, subsequently add rendered light to the VR scene. Random projections of structured light [62], *i.e.*, checkerboard patterns and lines, would increase the difficulty of such an attack, as the 3D-rendering system must be able to quickly and accurately render the projected illumination patterns on a model. However, structured light projection requires specialized hardware that typically is not found on smart phones and similar devices, which decreases the feasibility of this mitigation.

Pulse Detection Recent computer vision research [2, 58] has explored the prospect of video magnification, which transforms micro-scale fluctuations over time into strong visual changes. One such application is the detection of human pulse from a standard video of a human face. The method detects small, periodic color changes related to pulse in the region of the face and then amplifies this effect such that the face appears to undergo strong changes in brightness and hue. This amplification could be used as an additional method for liveness detection by requiring that the observed face have a detectable pulse. Similar ideas have been applied to fingerprint systems that check for blood flow using light emitted from

beneath a prism. Of course, an attacker using our proposed approach could simply add subtle color variation to the 3D model to approximate this effect. Nevertheless, such a method would provide another layer of defense against spoofed facial models.

Infrared Illumination Microsoft released Windows Hello as a more personal way to sign into Windows 10 devices with just a look or a touch. The new interface supports biometric authentication that includes face, iris, or fingerprint authentication. The platform includes Intel’s RealSense IR-based, rather than a color-based, facial authentication method. In principle, their approach works in the same way as contemporary face authentication methods, but instead uses an IR camera to capture a video of the user’s face. The attack presented in this paper would fail to bypass this approach because typical VR displays are not built to project IR light; however, specialized IR display hardware could potentially be used to overcome this limitation.

One limiting factor that may make IR-based techniques less common (especially on mobile devices) is the requirement for additional hardware to support this enhanced form of face authentication. Indeed, as of this writing, only a handful of personal computers support Windows Hello.¹⁰ Nevertheless, the use of infrared illumination offers intriguing possibilities for the future.

Takeaway In our opinion, it is highly unlikely that robust facial authentication systems will be able to operate using solely web/mobile camera input. Given the widespread nature of high-resolution personal online photos, today’s adversaries have a goldmine of information at their disposal for synthetically creating fake face data. Moreover, even if a system is able to robustly detect a certain type of attack – be it using a paper printout, a 3D-printed mask, or our proposed method – generalizing to all possible attacks will increase the possibility of false rejections and therefore limit the overall usability of the system. The strongest facial authentication systems will need to incorporate non-public imagery of the user that cannot be easily printed or reconstructed (*e.g.*, a skin heat map from special IR sensors).

6 Discussion

Our work outlines several important lessons for both the present state and the future state of security, particularly as it relates to face authentication systems. First, our exploitation of social media photos to perform facial reconstruction underscores the notion that online privacy of one’s appearance is tantamount to online privacy of other personal information, such as age and location.

¹⁰See “[PC platforms that support Windows Hello](#)” for more info.

The ability of an adversary to recover an individual’s facial characteristics through online photos is an immediate and very serious threat, albeit one that clearly cannot be completely neutralized in the age of social media. Therefore, it is prudent that face recognition tools become increasingly robust against such threats in order to remain a viable security option in the future.

At a minimum, it is imperative that face authentication systems be able to reject synthetic faces with low-resolution textures, as we show in our evaluations. Of more concern, however, is the increasing threat of virtual reality, as well as computer vision, as an adversarial tool. It appears to us that the designers of face authentication systems have assumed a rather weak adversarial model wherein attackers may have limited technical skills and be limited to inexpensive materials. This practice is risky, at best. Unfortunately, VR itself is quickly becoming commonplace, cheap, and easy-to-use. Moreover, VR visualizations are increasingly *convincing*, making it easier and easier to create realistic 3D environments that can be used to fool visual security systems. As such, it is our belief that authentication mechanisms of the future must aggressively anticipate and adapt to the rapid developments in the virtual and online realms.

Appendix

A Multi-Image Facial Model Estimation

In §3.2, we outline how to associate 2D facial landmarks with corresponding 3D points on an underlying facial model. Contour landmarks pose a substantial difficulty for this 2D-to-3D correspondence problem because the associated set of 3D points for these features is pose-dependent. Zhu et al. [63] compensate for this phenomenon by modeling contour landmarks with parallel curved line segments and iteratively optimizing head orientation and 2D-to-3D correspondence. For a specific head orientation R_j , the corresponding landmark points on the 3D model are found using an explicit function based on rotation angle:

$$\begin{aligned} s_{i,j} &= f_j PR_j(S_{i',j} + t_j) \\ S_{i',j} &= \bar{S}_{i'} + A_{i'}^{id} \alpha^{id} + A_{i'}^{exp} \alpha_j^{exp} \\ i' &= land(i, R_j), \end{aligned} \quad (6)$$

where $land(i, R_j)$ is the pre-calculated mapping function that computes the position of landmarks i on the 3D model when the orientation is R_j . Ideally, the first equation in Eq. (6) should hold for all the landmark points in all the images. However, this is not the case due to the alignment error introduced by landmark extraction. Generally, contour landmarks introduce more error than

corner landmarks, and this approach actually leads to inferior results when multiple input images are used.

Therefore, different from Zhu et al. [63], we compute the 3D facial model with Maximum a Posteriori (MAP) estimation. We assume the alignment error of each 3D landmark independently follows a Gaussian distribution. Then, the most probable parameters $\theta := (\{f_j\}, \{R_j\}, \{t_j\}, \{\alpha_j^{exp}\}, \alpha^{id})$ can be estimated by minimizing the cost function

$$\begin{aligned} \theta = \operatorname{argmax}_{\theta} \{ &\sum_{i=1}^{68} \sum_{j=1}^N \frac{1}{(\sigma_i^s)^2} \|s_{i,j} - f_j PR_j(S_{i',j} + t_j)\|^2 + \\ &\sum_{j=1}^N (\alpha_j^{exp})' \Sigma_{exp}^{-1} \alpha_j^{exp} + (\alpha^{id})' \Sigma_{id}^{-1} \alpha^{id} \}. \end{aligned} \quad (7)$$

Here, $S_{i',j}$ is computed using Eq. (6). Σ_{id} and Σ_{exp} are covariance matrices of α^{id} and α_j^{exp} , which can be obtained from the pre-existing face model. $(\sigma_i^s)^2$ is the variance of alignment error of the i -th landmark and is obtained from a separate training set consisting 20 images with hand-labeled landmarks. Eq. (7) can be computed efficiently, leading to the estimated identity weight α^{id} , with which we can compute the neutral-expression model $S_i (= \bar{S}_{i'} + A_{i'}^{id} \alpha^{id})$.

Abstract

Voice interfaces are becoming more ubiquitous and are now the primary input method for many devices. We explore in this paper how they can be attacked with *hidden voice commands* that are unintelligible to human listeners but which are interpreted as commands by devices.

We evaluate these attacks under two different threat models. In the black-box model, an attacker uses the speech recognition system as an opaque oracle. We show that the adversary can produce difficult to understand commands that are effective against existing systems in the black-box model. Under the white-box model, the attacker has full knowledge of the internals of the speech recognition system and uses it to create attack commands that we demonstrate through user testing are not understandable by humans.

We then evaluate several defenses, including notifying the user when a voice command is accepted; a verbal challenge-response protocol; and a machine learning approach that can detect our attacks with 99.8% accuracy.

1 Introduction

Voice interfaces to computer systems are becoming ubiquitous, driven in part by their ease of use and in part by decreases in the size of modern mobile and wearable devices that make physical interaction difficult. Many devices have adopted an always-on model in which they continuously listen for possible voice input. While voice interfaces allow for increased accessibility and potentially easier human-computer interaction, they are at the same time susceptible to attacks: Voice is a broadcast channel open to any attacker that is able to create sound within the vicinity of a device. This introduces an opportunity for attackers to try to issue unauthorized voice commands to these devices.

An attacker may issue voice commands to any device that is within speaker range. However, naïve attacks will be conspicuous: a device owner who overhears such a

command may recognize it as an unwanted command and cancel it, or otherwise take action. This motivates the question we study in this paper: can an attacker create *hidden voice commands*, i.e., commands that will be executed by the device but which won't be understood (or perhaps even noticed) by the human user?

The severity of a hidden voice command depends upon what commands the targeted device will accept. Depending upon the device, attacks could lead to information leakage (e.g., posting the user's location on Twitter), cause denial of service (e.g., activating airplane mode), or serve as a stepping stone for further attacks (e.g., opening a web page hosting drive-by malware). Hidden voice commands may also be broadcast from a loudspeaker at an event or embedded in a trending YouTube video, compounding the reach of a single attack.

Vaidya et al. [41] showed that hidden voice commands are possible—attackers can generate commands that are recognized by mobile devices but are considered as noise by humans. Building on their work, we show more powerful attacks and then introduce and analyze a number of candidate defenses.

The contributions of this paper include the following:

- We show that hidden voice commands can be constructed even with very little knowledge about the speech recognition system. We provide a general attack procedure for generating commands that are likely to work with any modern voice recognition system. We show that our attacks work against Google Now's speech recognition system and that they improve significantly on previous work [41].
- We show that adversaries with significant knowledge of the speech recognition system can construct hidden voice commands that humans cannot understand at all.
- Finally, we propose, analyze, and evaluate a suite of detection and mitigation strategies that limit the effects of the above attacks.

Audio files for the hidden voice commands and a video demonstration of the attack are available at <http://hiddenvoicecommands.com>.

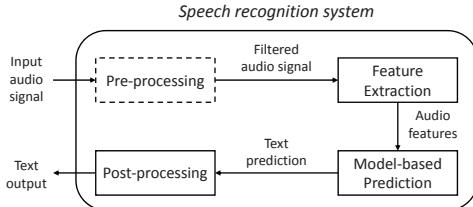

Figure 1: Overview of a typical speech recognition system.

2 Background and Related Work

To set the stage for the attacks that we present in §3 and §4, we briefly review how speech recognition works.

Figure 1 presents a high-level overview of a typical speech recognition procedure, which consists of the following four steps: pre-processing, feature extraction, model-based prediction, and post-processing. Pre-processing performs initial speech/non-speech identification by filtering out frequencies that are beyond the range of a human voice and eliminating time periods where the signal energy falls below a particular threshold. This step only does rudimentary filtering, but still allows non-speech signals to pass through the filter if they pass the energy-level and frequency checks.

The second step, feature extraction, splits the filtered audio signal into short (usually around 20 ms) frames and extracts features from each frame. The feature extraction algorithm used in speech recognition is almost always the Mel-frequency cepstral (MFC) transform [20, 42]. We describe the MFC transform in detail in Appendix A, but at a high level it can be thought of as a transformation that extracts the dominant frequencies from the input.

The model-based prediction step takes as input the extracted features, and matches them against an existing model built offline to generate text predictions. The technique used in this step can vary widely: some systems use Hidden Markov Models, while many recent systems have begun to use recurrent neural networks (RNNs).

Finally, a post-processing step ranks the text predictions by employing additional sources of information, such as grammar rules or locality of words.

Related work. Unauthorized voice commands have been studied by Diao et al. [12] and Jang et al. [21] who demonstrate that malicious apps can inject synthetic audio or play commands to control smartphones. Unlike in this paper, these attacks use non-hidden channels that are understandable by a human listener.

Similar to our work, Kasmi and Lopes Esteves [23] consider the problem of *covert* audio commands. There, the authors inject voice commands by transmitting FM signals that are received by a headset. In our work, we do not require the device to have an FM antenna (which is not often present) and we obfuscate the voice com-

mand so that it is not human-recognizable. Schlegel et al. [36] show that malicious apps can eavesdrop and record phone calls to extract sensitive information. Our work differs in that it exploits targeted devices’ existing functionality (i.e., speech recognition) and does not require the installation of malicious apps.

Earlier work by Vaidya et al. [41] introduces obfuscated voice commands that are accepted by voice interfaces. Our work significantly extends their black-box approach by (i) evaluating the effectiveness of their attacks under realistic scenarios, (ii) introducing more effective “white-box” attacks that leverage knowledge of the speech recognition system to produce machine-understandable speech that is almost never recognized by humans, (iii) formalizing the method of creating hidden voice commands, and (iv) proposing and evaluating defenses.

Image recognition systems have been shown to be vulnerable to attacks where slight modifications to only a few pixels can change the resulting classification dramatically [17, 19, 25, 38]. Our work has two key differences. First, feature extraction for speech recognition is significantly more complex than for images; this is one of the main hurdles for our work. Second, attacks on image recognition have focused on the case where the adversary is allowed to directly modify the electronic image. In contrast, our attacks work “over the air”; that is, we create audio that when played and recorded is recognized as speech. The analogous attack on image recognition systems would be to create a physical object which appears benign, but when photographed, is classified incorrectly. As far as we know, no one has demonstrated such an attack on image recognition systems.

More generally, our attacks can be framed as an evasion attack against machine learning classifiers: if f is a classifier and A is a set of acceptable inputs, given a desired class y , the goal is to find an input $x \in A$ such that $f(x) = y$. In our context, f is the speech recognition system, A is a set of audio inputs that a human would not recognize as speech, and y is the text of the desired command. Attacks on machine learning have been studied extensively in other contexts [1, 4, 5, 10, 13, 22, 31, 40]; In particular, Fawzi et al. [14] develop a rigorous framework to analyze the vulnerability of various types of classifiers to adversarial perturbation of inputs. They demonstrate that a minimal set of adversarial changes to input data is enough to fool most classifiers into misclassifying the input. Our work is different in two key respects: (i) the above caveats for image recognition systems still apply, and moreover, (ii) their work does not necessarily aim to create inputs that are misclassified into a particular category; but rather that it is just misclassified. On the other hand, we aim to craft inputs that are recognized as potentially sensitive commands.

Finally, Fredrikson et al. [15] attempt to invert machine learning models to learn private and potentially sensitive data in the training corpus. They formulate their task as an optimization problem, similar to our white-box approach, but they (i) test their approach primarily on image recognition models, which, as noted above, are easier to fool, and (ii) do not aim to generate adversarial inputs, but rather only extract information about individual data points.

3 Black-box Attacks

We first show that under a weak set of assumptions an attacker with no internal knowledge of a voice recognition system can generate hidden voice commands that are difficult for human listeners to understand. We refer to these as *obfuscated commands*, in contrast to unmodified and understandable *normal commands*.

These attacks were first proposed by Vaidya et al. [41]. This section improves upon the efficacy and practicality of their attacks and analysis by (i) carrying out and testing the performance of the attacks under more practical settings, (ii) considering the effects of background noise, and (iii) running the experiments against Google’s improved speech recognition service [34].

3.1 Threat model & attacker assumptions

In this black-box model the adversary does not know the specific algorithms used by the speech recognition system. We assume that the system extracts acoustic information through some transform function such as an MFC, perhaps after performing some pre-processing such as identifying segments containing human speech or removing noise. MFCs are commonly used in current-generation speech recognition systems [20, 42], making our results widely applicable, but not limited to such systems.

We treat the speech recognition system as an oracle to which the adversary can pose transcription tasks. The adversary can thus learn how a particular obfuscated audio signal is interpreted. We do not assume that a particular transcription is guaranteed to be consistent in the future. This allows us to consider speech recognition systems that apply randomized algorithms as well as to account for transient effects such as background noise and environmental interference.

Conceptually, this model allows the adversary to iteratively develop obfuscated commands that are increasingly difficult for humans to recognize while ensuring, with some probability, that they will be correctly interpreted by a machine. This trial-and-error process occurs in advance of any attack and is invisible to the victim.

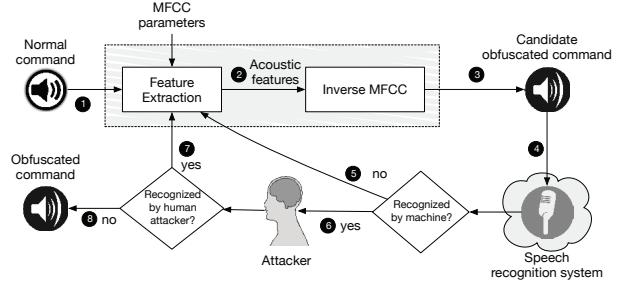

Figure 2: Adversary’s workflow for producing an obfuscated audio command from a normal command.

3.2 Overview of approach

We rerun the black-box attack proposed by Vaidya et al. [41] as shown in Figure 2. The attacker’s goal is to produce an obfuscated command that is accepted by the victim’s speech recognition system but is indecipherable by a human listener.

The attacker first produces a normal command that it wants executed on the targeted device. To thwart individual recognition the attacker may use a text-to-speech engine, which we found is generally correctly transcribed. This command is then provided as input (Figure 2, step ①) to an *audio mangler*, shown as the grey box in the figure. The audio mangler performs an MFC with a starting set of parameters on the input audio, and then performs an inverse MFC (step ②) that additionally adds noise to the output. By performing the MFC and then inverting the obtained acoustic features back into an audio sample, the attacker is in essence attempting to remove all audio features that are not used in the speech recognition system but which a human listener might use for comprehension.

Since the attacker does not know the MFC features used by the speech recognition system, experimentation is required. First, the attacker provides the *candidate obfuscated audio* that results from the MFC→inverse-MFC process (step ③) to the speech recognition system (step ④). If the command is not recognized then the attacker must update the MFC parameters to ensure that the result of the MFC→inverse-MFC transformation will yield higher fidelity audio (step ⑤).

If the candidate obfuscated audio is interpreted correctly (step ⑥), then the human attacker tests if it is human understandable. This step is clearly subjective and, worse, is subject to *priming* effects [28] since the attacker already knows the correct transcription. The attacker may solicit outside opinions by crowdsourcing. If the obfuscated audio is too easily understood by humans the attacker discards the candidate and generates new candidates by adjusting the MFC parameters to produce lower fidelity audio (step ⑦). Otherwise, the can-

Table 1: MFC parameters tuned to produce obfuscated audio.

Parameter	Description
wintime	time for which the signal is considered constant
hoptime	time step between adjacent windows
numcep	number of cepstral coefficients
nbands	no. of warped spectral bands for aggregating energy levels

didate obfuscated audio command—which is recognized by machines but not by humans—is used to conduct the actual attack (step ⑧).

3.3 Experimental setup

We obtained the audio mangling program used by Vaidya et al. [41]. Conforming to their approach, we also manually tune four MFC parameters to mangle and test audio using the workflow described in §3.2 to determine the ranges for human and machine perception of voice commands. The list of modified MFC parameters is presented in Table 1.

Our voice commands consisted of the phrases “OK google”, “call 911”, and “turn on airplane mode”. These commands were chosen to represent a variety of potential attacks against personal digital assistants. Voice commands were played using Harmon Kardon speakers, model number HK695-01,13, in a conference room measuring approximately 12 by 6 meters, 2.5 meters tall. Speakers were on a table approximately three meters from the phones. The room contained office furniture and projection equipment. We measured a background noise level (P_{noise}) of approximately 53 dB.

We tested the commands against two smart phones, a Samsung Galaxy S4 running Android 4.4.2 and Apple iPhone 6 running iOS 9.1 with Google Now app version 9.0.60246. Google’s recently updated [34] default speech recognition system was used to interpret the commands. In the absence of injected ambient background noise, our sound level meter positioned next to the smartphones measured the median intensity of the voice commands to be approximately 88 dB.

We also projected various background noise samples collected from SoundBible [9], recorded from a casino, classroom, shopping mall, and an event during which applause occurred. We varied the volume of these background noises—thus artificially adjusting the signal-to-noise ratio—and played them through eight overhead JBL in-ceiling speakers. We placed a Kinobo “Akiro” table mic next to our test devices and recorded all audio commands that we played to the devices for use in later experiments, described below.

3.4 Evaluation

Attack range. We found that the phone’s speech recognition system failed to identify speech when the speaker was located more than 3.5 meters away or when the perceived SNR was less than 5 dB. We conjecture that the speech recognition system is designed to discard far away noises, and that sound attenuation further limits the attacker’s possible range. While the attacker’s locality is clearly a limitation of this approach, there are many attack vectors that allow the attacker to launch attacks within a few meters of the targeted device, such as obfuscated audio commands embedded in streaming videos, overhead speakers in offices, elevators, or other enclosed spaces, and propagation from other nearby phones.

Machine understanding. Table 2 shows a side-by-side comparison of human and machine understanding, for both normal and obfuscated commands.

The “machine” columns indicate the percentage of trials in which a command is correctly interpreted by the phone, averaged over the various background noises. Here, our sound meter measured the signal’s median audio level at 88 dB and the background noise at 73 dB, corresponding to a signal-to-noise ratio of 15 dB.

Across all three commands, the phones correctly interpreted the normal versions 85% of the time. This accuracy decreased to 60% for obfuscated commands.

We also evaluate how the amplitude of background noise affects machine understanding of the commands. Figure 3 shows the percentage of voice commands that are correctly interpreted by the phones (“success rate”) as a function of the SNR (in dB) using the Mall background noise. Note that a higher SNR denotes more favorable conditions for speech recognition. Generally, Google’s speech recognition engine correctly transcribes the voice commands and activates the phone. The accuracy is higher for normal commands than obfuscated commands, with accuracy improving as SNR increases. In all cases, the speech recognition system is able to perfectly understand and activate the phone functionality in at least some configurations—that is, all of our obfuscated audio commands work at least *some* of the time. With little background noise, the obfuscated commands work extremely well and are often correctly transcribed at least 80% of the time. Appendix B shows detailed results for additional background noises.

Human understanding. To test human understanding of the obfuscated voice commands, we conducted a study on Amazon Mechanical Turk¹, a service that pays

¹**Note on ethics:** Before conducting our Amazon Mechanical Turk experiments, we submitted an online application to our institution’s IRB. The IRB responded by stating that we were exempt from IRB. Irrespective of our IRB, we believe our experiments fall well within the

Table 2: Black-box attack results. The “machine” columns report the percentage of commands that were correctly interpreted by the tested smartphones. The percentage of commands that were correctly understood by humans (Amazon Turk workers) is shown under the “human” columns. For the latter, the authors assessed whether the Turk workers correctly understood the commands.

	Ok Google		Turn on airplane mode		Call 911	
	Machine	Human	Machine	Human	Machine	Human
Normal	90% (36/40)	89% (356/400)	75% (30/40)	69% (315/456)	90% (36/40)	87% (283/324)
Obfuscated	95% (38/40)	22% (86/376)	45% (18/40)	24% (109/444)	40% (16/40)	94% (246/260)

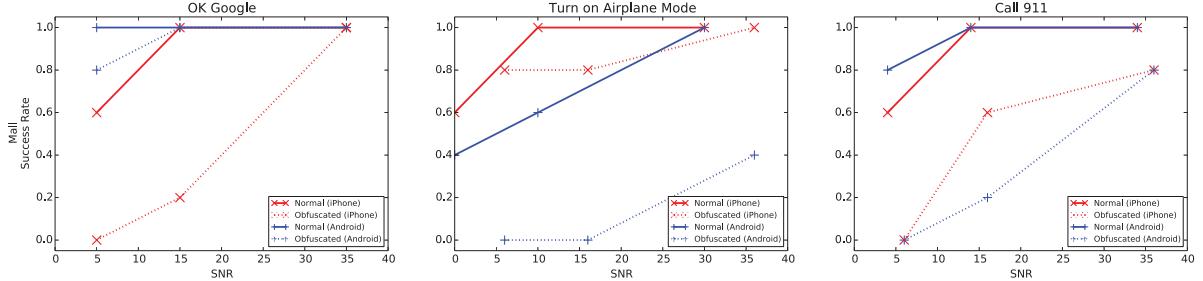

Figure 3: Machine understanding of normal and obfuscated variants of “OK Google”, “Turn on Airplane Mode”, and “Call 911” voice commands under Mall background noise. Each graph shows the measured average success rate (the fraction of correct transcripts) on the y-axis as a function of the signal-to-noise ratio.

human workers to complete online tasks called Human Intelligence Tasks (HITs). Each HIT asks a user to transcribe several audio samples, and presents the following instructions: ‘‘We are conducting an academic study that explores the limits of how well humans can understand obfuscated audio of human speech. The audio files for this task may have been algorithmically modified and may be difficult to understand. Please supply your best guess to what is being said in the recordings.’’

We constructed the online tasks to minimize priming effects—no worker was presented with both the normal and obfuscated variants of the same command. Due to this structuring, the number of completed tasks varies among the commands as reflected in Table 2 under the “human” columns.

We additionally required that workers be over 18 years of age, citizens of the United States, and non-employees of our institution. Mechanical Turk workers were paid \$1.80 for completing a HIT, and awarded an additional \$0.20 for each correct transcription. We could not prevent the workers from replaying the audio samples multiple times on their computers and the workers were incentivized to do so, thus our results could be considered conservative: if the attacks were mounted in practice, device owners might only be able to hear an attack once.

basic principles of ethical research. With respect in particular to beneficence, the Mechanical Turk workers benefited from their involvement (by being compensated). The costs/risks were extremely low: workers were fully informed of their task and no subterfuge occurred. No personal information—either personally identifiable or otherwise—was collected and the audio samples consisted solely of innocuous speech that is very unlikely to offend (e.g., commands such as “OK Google”).

To assess how well the Turk workers understood normal and obfuscated commands, four of the authors compared the workers’ transcriptions to the correct transcriptions (e.g., “OK Google”) and evaluated *whether both had the same meaning*. Our goal was not to assess whether the workers correctly heard the obfuscated command, but more conservatively, whether their perception conformed with the command’s meaning. For example, the transcript “activate airplane functionality” indicates a failed attack even though the transcription differs significantly from the baseline of “turn on airplane mode”.

Values shown under the “human” columns in Table 2 indicate the fraction of total transcriptions for which the survey takers believed that the Turk worker understood the command. Each pair of authors had an agreement of over 95% in their responses, the discrepancies being mainly due to about 5% of responses in which one survey taker believed they matched but the others did not. The survey takers were presented only with the actual phrase and transcribed text, and were blind to whether or not the phrase was an obfuscated command or not.

Turk workers were fairly adept (although not perfect) at transcribing normal audio commands: across all commands, we assessed 81% of the Turkers’ transcripts to convey the same meaning as the actual command.

The workers’ ability to understand obfuscated audio was considerably less: only about 41% of obfuscated commands were labeled as having the same meaning as the actual command. An interesting result is that the black-box attack performed far better for some commands than others. For the “Ok Google” command, we

decreased human transcription accuracy fourfold without any loss in machine understanding.

“Call 911” shows an anomaly: human understanding increases for obfuscated commands. This is due to a tricky part of the black-box attack workflow: the attacker must manage priming effects when choosing an obfuscated command. In this case, we believed the “call 911” candidate command to be unintelligible; these results show we were wrong. A better approach would have been to repeat several rounds of crowdsourcing to identify a candidate that was not understandable; any attacker could do this. It is also possible that among our US reviewers, “call 911” is a common phrase and that they were primed to recognize it outside our study.

Objective measures of human understanding: The analysis above is based on the authors’ assessment of Turk workers’ transcripts. In Appendix C, we present a more objective analysis using the Levenshtein edit distance between the true transcript and the Turkers’ transcripts, with phonemes as the underlying alphabet.

We posit that our (admittedly subjective) assessment is more conservative, as it directly addresses human *understanding* and considers attacks to fail if a human understands the meaning of a command; in contrast, comparing phonemes measures something slightly different—whether a human is able to reconstruct the *sounds* of an obfuscated command—and does not directly capture understanding. Regardless, the phoneme-based results from Appendix C largely agree with those presented above.

4 White-box Attacks

We next consider an attacker who has knowledge of the underlying voice recognition system. To demonstrate this attack, we construct hidden voice commands that are accepted by the open-source CMU Sphinx speech recognition system [24]. CMU Sphinx is used for speech recognition by a number of apps and platforms², making it likely that these whitebox attacks are also practical against these applications.

4.1 Overview of CMU Sphinx

CMU Sphinx uses the Mel-Frequency Cepstrum (MFC) transformation to reduce the audio input to a smaller dimensional space. It then uses a Gaussian Mixture Model (GMM) to compute the probabilities that any given piece of audio corresponds to a given phoneme. Finally, using a Hidden Markov Model (HMM), Sphinx converts the phoneme probabilities to words.

²Systems that use CMU Sphinx speech recognition include the Jasper open-source personal digital assistant and Gnome Desktop voice commands. The Sphinx Project maintains a list of software that uses Sphinx at <http://cmusphinx.sourceforge.net/wiki/sphinxinaction>.

The purpose of the MFC transformation is to take a high-dimensional input space—raw audio samples—and reduce its dimensionality to something which a machine learning algorithm can better handle. This is done in two steps. First, the audio is split into overlapping frames.

Once the audio has been split into frames, we run the MFC transformation on each frame. The Mel-Frequency Cepstrum Coefficients (MFCC) are the 13-dimensional values returned by the MFC transform.

After the MFC is computed, Sphinx performs two further steps. First, Sphinx maintains a running average of each of the 13 coordinates and subtracts off the mean from the current terms. This normalizes for effects such as changes in amplitude or shifts in pitch.

Second, Sphinx numerically estimates the first and second derivatives of this sequence to create a 39-dimensional vector containing the original 13-dimensional vector, the 13-dimensional first-derivative vector, and the 13-dimensional-second derivative vector.

Note on terminology: For ease of exposition and clarity, in the remainder of this section, we call the output of the MFCC function *13-vectors*, and refer to the output after taking derivatives as *39-vectors*.

The Hidden Markov Model. The Sphinx HMM acts on the sequence of 39-vectors from the MFCC. States in the HMM correspond to phonemes, and each 39-vector is assigned a probability of arising from a given phoneme by a Gaussian model, described next. The Sphinx HMM is, in practice, much more intricate: we give the complete description in Appendix A.

The Gaussian Mixture Model. Each HMM state yields some distribution on the 39-vectors that could be emitted while in that state. Sphinx uses a GMM to represent this distribution. The GMMs in Sphinx are a mixture of eight Gaussians, each over \mathbb{R}^{39} . Each Gaussian has a mean and standard deviation over every dimension. The probability of a 39-vector v is the sum of the probabilities from each of the 8 Gaussians, divided by 8. For most cases we can approximate the sum with a maximization, as the Gaussians typically have little overlap.

4.2 Threat model

We assume the attacker has complete knowledge of the algorithms used in the system and can interact with them at will while creating an attack. We also assume the attacker knows the parameters used in each algorithm.³

We use knowledge of the coefficients for each Gaussian in the GMM, including the mean and standard deviation for each dimension and the importance of each

³Papernot et al. [32] demonstrated that it is often possible to transform a white-box attack into a black-box attack by using the black-box as an oracle and reconstructing the model and using the reconstructed parameters.

Gaussian. We also use knowledge of the dictionary file in order to turn words into phonemes. An attacker could reconstruct this file without much effort.

4.3 Simple approach

Given this additional information, a first possible attack would be to use the additional information about exactly what the MFCC coefficients are to re-mount the the previous black-box attack.

Instead of using the MFCC inversion process described in §3.2, this time we implement it using gradient descent—a generic optimization approach for finding a good solution over a given space—an approach which can be generalized to arbitrary objective functions.

Gradient descent attempts to find the minimum (or maximum) value of an objective function over a multi-dimensional space by starting from an initial point and traveling in the direction which reduces the objective most quickly. Formally, given a smooth function f , gradient descent picks an initial point x_0 and then repeatedly improves on it by setting $x_{i+1} = x_i + \epsilon \cdot \nabla f(x_0)$ (for some small ϵ) until we have a solution which is “good enough”.

We define the objective function $f(x) = (\text{MFCC}(x) - y)^2 \cdot z$, where x is the input frame, y is the target MFCC vector, and z is the relative importance of each dimension. Setting $z = (1, 1, \dots, 1)$ takes the L^2 norm as the objective.

Gradient descent is not guaranteed to find the global optimal value. For many problems it finds only a *local* optimum. Indeed, in our experiments we have found that gradient descent only finds local optima, but this turns out to be sufficient for our purposes.

We perform gradient descent search one frame at a time, working our way from the first frame to the last. For the first frame, we allow gradient descent to pick any 410 samples. For subsequent frames, we fix the first 250 samples as the last 250 of the preceding frame, and run gradient descent to find the best 160 samples for the rest of the frame.

As it turns out, when we implement this attack, our results are no better than the previous black-box-only attack. Below we describe our improvements to make attacks completely unrecognizable.

4.4 Improved attack

To construct hidden voice commands that are more difficult for humans to understand, we introduce two refinements. First, rather than targeting a specific sequence of MFCC vectors, we start with the target phrase we wish to produce, derive a sequence of phonemes and thus a sequence of HMM states, and attempt to find an input that matches that sequence of HMM states. This provides

more freedom by allowing the attack to create an input that yields the same sequence of phonemes but generates a different sequence of MFCC vectors.

Second, to make the attacks difficult to understand, we use as few frames per phoneme as possible. In normal human speech, each phoneme might last for a dozen frames or so. We try to generate synthetic speech that uses only four frames per phoneme (a minimum of three is possible—one for each HMM state). The intuition is that the HMM is relatively insensitive to the number of times each HMM state is repeated, but humans are sensitive to it. If Sphinx does not recognize the phrase at the end of this process, we use more frames per phoneme.

For each target HMM state, we pick one Gaussian from that state’s GMM. This gives us a sequence of target Gaussians, each with a mean and standard deviation.

Recall that the MFC transformation as we defined it returns a 13-dimensional vector. However, there is a second step which takes sequential derivatives of 13-vectors to produce 39-vectors. The second step of our attack is to pick these 13-vectors so that after we take the derivatives, we maximize the likelihood score the GMM assigns to the resulting 39-vector. Formally, we wish to find a sequence y_i of 39-dimensional vectors, and x_i of 13-dimensional vectors, satisfying the derivative relation

$$y_i = (x_i, x_{i+2} - x_{i-2}, (x_{i+3} - x_{i-1}) - (x_{i+1} - x_{i-3}))$$

and maximizing the likelihood score

$$\prod_i \exp \left\{ \sum_{j=1}^{39} \frac{\alpha_i^j - (y_i^j - \mu_i^j)^2}{\sigma_i^j} \right\}$$

where μ_i , σ_i , and α_i are the mean, standard deviation, and importance vectors respectively.

We can solve this problem exactly by using the least-squares method. We maximize the *log-likelihood*,

$$\log \prod_i \exp \left\{ \sum_j \frac{-\alpha_i^j + (y_i^j - \mu_i^j)^2}{\sigma_i^j} \right\} = \sum_i \sum_j \frac{-\alpha_i^j + (y_i^j - \mu_i^j)^2}{\sigma_i^j}$$

The log-likelihood is a sum of squares, so maximizing it is a least-squares problem: we have a linear relationship between the x and y values, and the error is a squared difference.

In practice we cannot solve the full least squares problem all at once. The Viterbi algorithm only keeps track of the 100 best paths for each prefix of the input, so if the global optimal path had a prefix that was the 101st most likely path, it would be discarded. Therefore, we work one frame at a time and use the least squares approach to find the next best frame.

This gives us three benefits: First, it ensures that at every point in time, the next frame is the best possible given what we have done so far. Second, it allows us to

try all eight possible Gaussians in the GMM to pick the one which provides the highest score. Third, it makes our approach more resilient to failures of gradient descent. Sometimes gradient descent cannot hit the 13-vector suggested by this method exactly. When this happens, the error score for subsequent frames is based on the actual 13-vector obtained by gradient descent.

Complete description. We first define two subroutines to help specify our attack more precisely. $\text{LSTDERRIV}(f, \bar{g}, g)$ accepts a sequence of 13-vectors f that have already been reached by previous iterations of search, the desired 39-vector sequence \bar{g} , and one new 39-vector g ; it uses least squares to compute the next 13-vector which should be targeted along with the least-squares error score. Specifically:

1. Define A as the $39k \times 13(6+k)$ dimensional matrix which computes the derivative of a sequence of $6+k$ 13-vectors and returns the k resulting 39-vectors.
2. Define b as the $39k$ dimensional vector corresponding to the concatenation of the $k-1$ 39-vectors in \bar{g} and the single 39-vector g .
3. Split A in two pieces, with A_L being the left $13k$ columns, and A_R being the right 6×13 columns.
4. Define \bar{f} as the concatenation of the 13-vectors in f .
5. Define $\bar{b} = b - A_L \cdot \bar{f}$.
6. Using least squares, find the best approximate solution \hat{x} to the system of equations $A_R \cdot \hat{x} = \bar{b}$.
7. Return $(|(A_R \cdot \hat{x}) - \bar{b}|, \hat{x})$

$\text{GRADDESC}(s, t)$ accepts the previous frame $s \in \mathbb{R}^{410}$ and a target 13-vector t , and returns a frame $\hat{s} \in \mathbb{R}^{410}$ such that \hat{s} matches s in the 250 entries where they overlap and $\text{MFCC}(\hat{s})$ is as close to t as possible. More precisely, it looks for a 160-dimensional vector x that minimizes $f(x) = \|\text{MFCC}(s_{160..410}||x) - s\|_2$, where $||$ is concatenation, and returns $s_{160..410}||x$. We use the Newton Conjugate-Gradient algorithm for gradient descent and compute the derivative symbolically for efficiency.

Our full algorithm works as follows:

1. In the following, f will represent a sequence of chosen 13-vectors (initially empty), \bar{g} a sequence of target 39-vectors, s the audio samples to return, and i the iteration number (initially 0).
2. Given the target phrase, pick HMM states h_i such that each state corresponds to a portion of a phoneme of a word in the phrase.
3. Let g_i^j be the 39-vector corresponding to the mean of the j^{th} Gaussian of the GMM for this HMM state. One of these will be the target vector we will try to invert.
4. For each j , solve the least squares problem $(s_j, d_j) = \text{LSTDERRIV}(f, \bar{g}, g_i^j)$ and set $\hat{j} = \arg \min_j s_j$ and $\bar{d} = d_{\hat{j}}$ to obtain a sequence of 13-vectors \bar{d}_0 to \bar{d}_{i+6} . Let \bar{d}_i be the “target 13-vector”

5. Append the 39-vector corresponding to t to \bar{g} .
6. Use gradient descent to get $\hat{s} = \text{GRADDESC}(s, t)$. Let $s := \hat{s}$. Append $\text{MFCC}(s)$ to f .
7. Repeat for the next i from step 3 until all states are completed.

4.5 Playing over the air

The previous attacks work well when we feed the audio file directly into Sphinx. However, Sphinx could not correctly transcribe recordings made by playing the audio using speakers. We developed three approaches to solve this complication:

Make the audio easier to play over speaker. Gradient descent often generates audio with very large spikes. It’s physically impossible for the speaker membrane to move quickly enough to accurately reproduce these spikes. We modified gradient descent to penalize waveforms that a speaker cannot reproduce. In particular, we add a penalty for large second derivatives in the signal, with the hope that gradient descent finds solutions that do not include such large spikes.

Predict the MFCC of played audio. Even with this penalty, the audio is still not perfectly playable over a speaker. When we compared the waveform of the played audio and recorded audio, they had significant differences. To address this, we built a model to predict the MFCC when a file is played through a speaker and recorded. Recall that the MFCC transformation essentially computes the function $C \log(B \|Ax\|^2)$.

By playing and recording many audio signals, we learned new matrices \hat{A} , \hat{B} , \hat{C} so that for each played frame x and recorded frame y , $C \log(B \|Ay\|^2)$ is close to $\hat{C} \log(\hat{B} \|\hat{A}x\|^2)$. We computed \hat{A} , \hat{B} , \hat{C} by solving a least-squares problem. This was still not enough for correct audio recognition, but it did point us in a promising direction.

Play the audio during gradient descent. The ideas above are not enough for recognition of recorded audio. To see what is going on here, we compare the MFCC of the played audio (after recording it) and the initial audio (before playing it). We found the correlation to be very high ($r = .97$ for the important coefficients).

Based on this observation, we augment our algorithm to include an outer iteration of gradient descent. Given a target MFCC we first run our previous gradient descent algorithm to find a sound sequence which (before playing over the speaker) reaches the target MFCC. Then, we play and record it over the speaker. We obtain from this the actual MFCC. We then adjust the target MFCC by the difference between what was received and what is desired.

We implemented this approach. Figure 4 plots the L^2

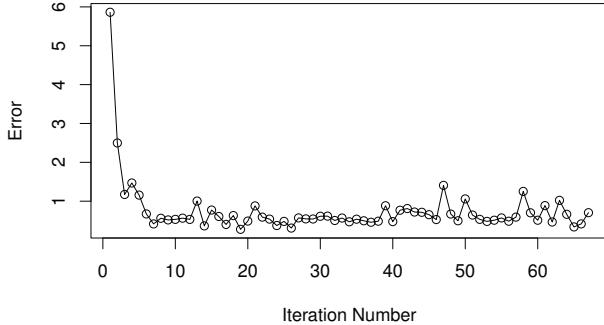

Figure 4: Incorporating actually playing the audio over the speakers into the gradient descent significantly reduces the error. The plot is of the L^2 norm of the error of from the target feature vector to the actually recorded feature vector, over time.

error (the difference between the target MFCC and what is actually recorded during each iteration of our algorithm) over time. By repeating this procedure 50 times and taking the frame with the minimum noise, we obtain an audio file that is correctly recognized by Sphinx after being played over the speaker.

Since we perform 50 iterations of the inner gradient descent per frame, and each iteration takes 30 seconds, our approach takes nearly 30 hours to find a valid attack sample. In practice, sometimes this process can take even longer; since we are recording audio, if the microphone picks up too much background noise, we must discard the recorded sample and try again. We have built in an error-detection system to mitigate these effects.

This might seem like a high cost to generate one attack sample. However, once generated, we can reuse the obfuscated audio on that speaker forever. Even though the setup cost is high, it must only be performed once; thereafter the same audio file can be used repeatedly.

4.6 Evaluation

Machine comprehension. For the former, we apply the above techniques and generate three audio commands: “okay google, take a picture”, “okay google, text 12345”, and “okay google, browse to evil.com”. The speech recognition system is an instance of CMU Sphinx version 4-1.0beta6.

We determined the minimum number of frames per phoneme that is sufficient to allow Sphinx to recognize the command. Some words are more difficult to create correctly than others, and thus require more frames per phoneme. Detailed results can be found in Appendix E. When we modify the lengths of the phonemes to account for this data, *over 90% of generated phrases are correctly recognized by Sphinx*.

To evaluate our attack playing over a microphone, we equipped our computer with an external Blue Snowball

Table 3: White-box attack results. Percentages show successful comprehension of Normal and Obfuscated version of voice commands for humans and machines. Our white-box attack constructs the obfuscated attack without a starting normal attack; we only evaluate the machine understanding of the obfuscated commands.

	Human Understanding	Machine Understanding
Normal	74% (230/310)	–
Obfuscated	0% (1/377)	82% (82/100)

microphone. Obfuscated audio commands are played from an Altec Lansing ASC45.1 speaker located 0.5 meters from the microphone. All of our evaluated phrases were commands recorded from the microphone. We trained our MFCC vector predictor with one minute (16 million samples) of audio played over this speaker in a large room to minimize echoes. The room was isolated, and thus we encountered nearly no background noise. The attack took 32 hours to generate the command for “okay google, take a picture”, but required no human intervention, using the same number of frames chosen from the previous attack for a total of 101 frames.

Once the file was generated, we played the command over the speaker 100 times. Sphinx was able to recognize it in 82 of the instances. This is to be expected—for a given audio played multiple times, there is a very high (99%+) correlation between the recorded MFCC values.

Human comprehension. As with our black-box attack, we evaluate our obfuscated commands with the same Amazon Mechanical Turk study. Workers were blind to how the obfuscated audio was generated. As a baseline, we asked workers to transcribe a phrase spoken by a human naturally. The results show that our white-box attack is significantly better than the black-box attack. No worker was able to transcribe more than half of the words in the phrase correctly, and 75% of workers transcriptions shared no words in common with the actual phrase.

Four of the authors independently evaluated 377 transcriptions of attack commands generated by our white-box attack and compared them with correct transcriptions to answer whether both transcriptions had the same meaning. The four authors agreed on over 95% of instances. Table 3 contains the results, showing that normal commands were correctly transcribed by workers 74% of the time, but obfuscated commands were almost never transcribed correctly. A comparison using phoneme-level edit distance yields similar results; see Appendix C.2.

While these results indicate that obfuscated commands generated using our white-box attack are very difficult to understand, we conducted a second study to determine

if users actually thought the audio was human speech or just noise. Specifically, we created audio samples of a human speaking a phrase, followed by an obfuscated (different) phrase, and finally a human speaking a third different phrase. In this study we were interested in seeing if the worker would try to transcribe the obfuscated speech at all, or leave it out entirely.

Transcription accuracy was 80% for the first and last commands given by a human speaking. Only 24% of users attempted to transcribe the obfuscated speech. This study clearly demonstrates that when given a choice about what they viewed as speech and not-speech, the majority of workers believed our audio was not speech.

5 Defenses

We are unaware of any device or system that currently defends against obfuscated voice commands. In this section, we explore potential defenses for hidden voice commands across three dimensions: *defenses that notify*, *defenses that challenge*, and *defenses that detect and prohibit*. The defenses described below are not intended to be exhaustive; they represent a first examination of potential defenses against this new threat.

5.1 Defenses that notify

As a first-line of defense we consider defenses that alert the user when the device interprets voice commands, though these will only be effective when the device operator is present and notification is useful (e.g., when it is possible to undo any performed action).

The “Beep”, the “Buzz” and the “Lightshow”. These defenses are very simple: when the device receives a voice command, it notifies the user, e.g., by beeping. The goal is to make the user aware a voice command was accepted. There are two main potential issues with “the Beep”: (i) attackers may be able to mask the beep, or (ii) users may become accustomed to their device’s beep and begin to ignore it. To mask the beep, the attacker might play a loud noise concurrent with the beep. This may not be physically possible depending on the attacker’s speakers and may not be sufficiently stealthy depending on the environment as the noise require can be startling.

A more subtle attack technique is to attempt to mask the beep via noise cancellation. If the beep were a single-frequency sine wave an attacker might be able to cause the user to hear nothing by playing an identical frequency sine wave that is out of phase by exactly half a wavelength. We evaluated the efficacy of this attack by constructing a mathematical model that dramatically oversimplifies the attacker’s job and shows that even this simplified “anti-beep” attack is nearly impossible. We

present a more detailed evaluation of beep cancellation in Appendix D.

Some devices might inform the user when they interpret voice commands by vibrating (“the buzz”) or by flashing LED indicators (“the lightshow”). These notifications also assume that the user will understand and heed such warnings and will not grow accustomed to them. To differentiate these alerts from other vibration and LED alerts the device could employ different pulsing patterns for each message type. A benefit of such notification techniques is that they have low overhead: voice commands are relatively rare and hence generating a momentary tone, vibration, or flashing light consumes little power and is arguably non-intrusive.

Unfortunately, users notoriously ignore security warning messages, as is demonstrated by numerous studies of the (in)effectiveness of warning messages in deployed systems [35, 37, 44]. There is unfortunately little reason to believe that most users would recognize and not quickly become acclimated to voice command notifications. Still, given the low cost of deploying a notification system, it may be worth considering *in combination* with some of the other defenses described below.

5.2 Defenses that challenge

There are many ways in which a device may seek confirmation from the user before executing a voice command. Devices with a screen might present a confirmation dialogue, though this limits the utility of the voice interface. We therefore consider defenses in which the user must vocally confirm interpreted voice commands. Presenting an audio challenge has the advantage of requiring the user’s attention, and thus may prevent all hidden voice commands from affected the device assuming the user will not confirm an unintended command. A consistent verbal confirmation command, however, offers little protection from hidden voice commands: the attacker also provide the response in an obfuscated manner. If the attacker can monitor any random challenge provided by the device, it might also be spoofed. To be effective, the confirmation must be easily produced by the human operator and be difficult to forge by an adversary.

The Audio CAPTCHA. Such a confirmation system already exists in the form of audio CAPTCHAs [26] which is a challenge-response protocol in which the challenge consists of speech that is constructed to be difficult for computers to recognize while being easily understood by humans. The response portion of the protocol varies by the type of CAPTCHA, but commonly requires the human to transcribe the challenge.

Audio CAPTCHAs present an possible defense to hidden voice commands: before accepting a voice command, a device would require the user to correctly re-

spond to an audio CAPTCHA, something an attacker using machine speech recognition would find difficult. While it is clear that such a defense potentially has usability issues, it may be worthwhile for commands that are damaging or difficult to undo.

Audio CAPTCHAs are useful defenses against hidden voice commands only if they are indeed secure. Previous generations of audio CAPTCHAs have been shown to be broken using automated techniques [6, 39]. As audio CAPTCHAs have improved over time [11, 27], the question arises if currently fielded audio CAPTCHAs have kept pace with improvements in speech recognition technologies. In short, they have not.

We focus our examination on two popular audio CAPTCHA systems: Google’s *reCaptcha* [33] offers audio challenges initially consisting of five random digits spread over approximately ten seconds; and *NLP Captcha* [30] provides audio challenges of about three seconds each composed of four or five alphanumeric characters, with the addition of the word “and” before the last character in some challenges.

We tested 50 challenges of *reCaptcha* and *NLP Captcha* each by segmenting the audio challenges before transcribing them using Google’s speech recognition service. Figure 5 shows the results of transcription. Here, we show the normalized edit distance, which is the Levenshtein edit distance using characters as alphabet symbols divided by the length of the challenge. More than half and more than two-thirds of NLP Captchas and *reCaptcha*, respectively, are perfectly transcribed using automated techniques. Moreover, approximately 80% of CAPTCHAs produced by either system have a normalized edit distance of 0.3 or less, indicating a high frequency of at least mostly correct interpretations. This is relevant, since audio CAPTCHAs are unfortunately not easily understood by humans; to increase usability, *reCaptcha* provides some “leeway” and accepts almost-correct answers.

Given the ease at which they can be solved using automated techniques, the current generation of deployed audio CAPTCHA systems seems unsuitable for defending against hidden voice commands. Our results do not indicate whether or not audio CAPTCHAs are necessarily insecure. However, we remark that since computers continue to get better at speech recognition developing robust audio CAPTCHA puzzles is likely to become increasingly more difficult.

5.3 Defenses that detect and prevent

Speaker recognition. Speaker recognition (sometimes called voice authentication) has been well-explored as a biometric for authentication [7], with at least Google recently including speaker recognition as

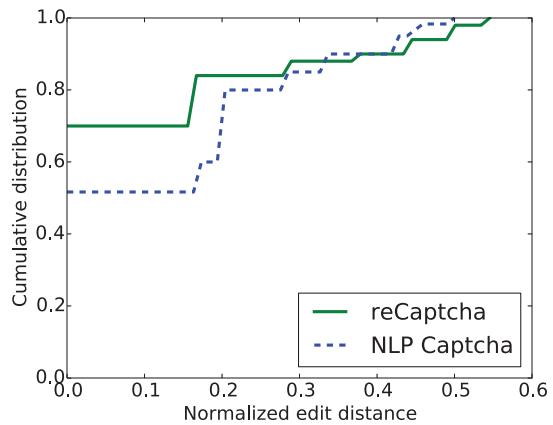

Figure 5: Accuracy of breaking audio CAPTCHA using machine based speech-to-text conversion. A normalized edit distance of zero signifies exact prediction.

an optional feature in its Android platform [18]. Apple also introduced similar functionality in iOS [2].

However, it is unclear whether speaker verification necessarily prevents the use of hidden voice commands, especially in settings in which the adversary may be able to acquire samples of the user’s voice. Existing work has demonstrated that voices may be mimicked using statistical properties⁴; for example, Aylett and Yamagishi [3] are able to mimic President George W. Bush’s voice with as little of 10 minutes of his speech. Hence, it may be possible to construct an obfuscated voice command based on recordings of the user’s voice that will be accepted both by the speaker recognition and the voice recognition systems. This is an interesting technical question which we defer to future work.

Importantly, speaker recognition presents three well-understood usability issues. First, a non-negligible false negative rate might limit authorized use, which provides an incentive for users to deactivate speaker recognition. Second, speaker recognition requires training, and likely necessitates the collection of a large speech corpus in order to ensure the level of accuracy necessary for reliable authentication. This need is compounded for devices such as Amazon Echo that are intended to be used by multiple users. Users may be unwilling to perform such training. Finally, speaker recognition is unsuited for applications that have no prior interactions with the user, for example, in kiosks for the visually impaired. We argue that such usability issues motivate the need for less intrusive defenses, such as the ones described next.

The “Filter”. This defense decreases the fidelity of the input audio before applying speech recognition. This

⁴CereVoice offers an online service for “[creating] a computer version of your own voice” [8].

somewhat counterintuitive approach leverages the precision required by hidden voice commands: by slightly degrading the audio quality, normal commands are affected only slightly while obfuscated inputs, already at the cusp of being comprehensible by machine, are no longer recognized. The goal of the filter is thus to find a “sweet spot” such that a slight decrease in fidelity will not too adversely affect normal audio, but will eliminate hidden voice commands.

Our filter implementation considers audio in the time domain. For a filter rate f and an audio file consisting of s samples, we preserve $f \cdot s$ samples chosen uniformly at random and remove without replacement the remaining $(1 - f)s$ samples.

We evaluate the efficacy of the filter defense using the West Point Company English speech data corpus from the University of Pennsylvania’s Linguistic Data Consortium (LDC) [29]. The LDC corpus consists of American English-language speakers, 30 of them speaking the same 50 sentences each, and another 109 speakers each speaking a separate set of 185 sentences. For each sentence in the corpus, we construct multiple obfuscated audio files using the black-box techniques described in §3. We do not introduce any background noise to either the normal or obfuscated samples, and send all samples to Google’s speech recognition system and evaluate the accuracy of its transcriptions. We tested the filter against 16,440 normal commands and 27,589 obfuscated commands, sampled uniformly at random without replacement. The audio files were in WAV format with single channel sampled at 22050 kHz with 32-bit bit depth in float data type.

We define *phoneme edit distance* δ as the Levenshtein edit distance between phoneme sequences of two transcriptions, and L as the phoneme length of unfiltered sentence. Finally we define *relative phoneme edit distance* as $\delta / (\delta + L)$, to reflect how close the two transcriptions might sound to a human listener. Figure 6 plots the cumulative distribution of the *relative phoneme edit distances* for our tested audio samples. Out of five transcripts Google returned, we pick the transcript with the smallest phoneme edit distance and calculate the *relative phoneme edit distance*. With an 80% filter (i.e., 80% of the original audio is preserved), the hidden voice command is significantly perturbed—the fraction of correctly transcribed sentences decreases from 41.74% to 7.49% when the filter is applied. However, the filter also significantly degrades normal audio, decreasing accuracy by 14.35%, which is likely unacceptable for users who depend on voice functionality. Through manual tuning, we find that a 92% filter offers an attractive sweet spot, causing the fraction of correctly transcribed obfuscated files to fall from 41.74% to 26.60%, while negligibly affecting normal files, whose accuracy drops only 1.06%.

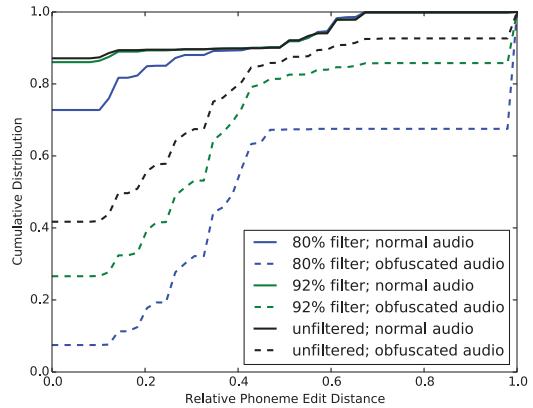

Figure 6: The cumulative distribution of relative phoneme edit distances for normal and obfuscated commands, for filtering rates of 80% and 92%.

The “Classifier”. As a final defense we examine whether automated techniques can detect our hidden voice commands—that is, can a computer classify interpreted speech as being generated by a human or a machine? In practice, a speech recognition system could incorporate a machine learning classifier as a final processing step, dropping voice commands that are determined to be machine-generated.

We construct a hidden voice command detector using logistic regression. Our classifier uses mid-term features (mean and standard deviation) derived from short term features shown in Appendix F, extracted using the pyAudioAnalysis library [16] from the original audio signal.

We use the same LDC speech corpus as used in our filter experiments, and label each sample from the corpus as *normal*. Using the black-box procedure described in §3, we produce obfuscated hidden voice commands, which we label as *obfuscated*. We overlay the background noise samples described in §3.3 to mimic a noisy environment to both the *normal* and *obfuscated* samples.

We apply tenfold cross validation and report averages across the ten runs. The confusion matrix that results from classification is reported in Table 4. 99.8% of obfuscated audio were detected as such, while only incurring a 0.2% false positive rate, meaning that the classifier would incorrectly discard two out of 1000 valid commands.

To better gauge the classifier’s accuracy when presented with diverse inputs, we performed additional classification tests against 51 commands generated using the white-box technique from §4 and audio from the Accent GMU dataset [43]. The Accent GMU dataset is comprised of 569 audio samples of English text spoken by different individuals with different regional accents. Neither the GMU or white-box samples were used to con-

Table 4: Confusion matrix of our classifier.

	Normal	Obfuscated
Normal	49.9%	0.1%
Obfuscated	0.1%	49.9%

Table 5: Confusion matrix of our classifier, when classifying audio from outside corpora.

	Normal	Attack
White-box Attack	30.7%	69.3%
Accent GMU	99.2%	0.8%

struct the classifier. That is, our results show the efficacy of a classifier constructed with only normal and black-box obfuscated command samples as training data. Importantly, the GMU dataset consists of all normal (non-obfuscated) samples, while the white-box dataset contains only attack commands. The confusion matrix for this classification task is presented in Table 5. For the GMU dataset, our classifier performs well, incurring less than a 1% false positive rate. The performance is worse for the white-box attack. Still, even against this strong attack which requires complete knowledge of the backend speech recognition system, the classifier is able to flag nearly 70% of the hidden voice commands as being malicious.

5.4 Summary of defenses

We present the first examination of defenses against hidden voice commands. Our analysis of notification defenses (§5.1) shows that security alerts are difficult to mask, but may be ignored by users. Still, given their ease of deployment and small footprint, such defenses are worth considering. Active defenses, such as audio CAPTCHAs (§5.2) have the advantage that they require users to affirm voice commands before they become effected. Unfortunately, active defenses also incur large usability costs, and the current generation of audio-based reverse Turing tests seem easily defeatable. Most promising are prevention and detection defenses (§5.3). Our findings show that filters which slightly degrade audio quality can be tuned to permit normal audio while effectively eliminating hidden voice commands. Likewise, our initial exploration of machine learning-based defenses shows that simple classification techniques yield high accuracy in distinguishing between user- and computer-generated voice commands.

6 Limitations and Discussion

While the results of our defenses are encouraging, a limitation of this paper is that the defenses do not offer proofs of security. In particular, an adversary may be able to

construct hidden voice commands that are engineered to withstand filtering and defeat classifiers.

The random sampling used by our filter complicates the task of designing a “filter-resistant” hidden voice command since the adversary has no advanced knowledge of what components of his audio command will be discarded. The adversary is similarly constrained by the classifier, since the attacks we describe in §3 and §4 significantly affect the features used in classification. Of course, there might be other ways to conceal voice commands that are more resistant to information loss yet retain many characteristics of normal speech, which would likely defeat our existing detection techniques. Designing such attacks is left as a future research direction.

The attacks and accompanying evaluations in §3 and §4 demonstrate that hidden voice commands are effective against modern voice recognition systems. There is clearly room for another security arms race between more clever hidden voice commands and more robust defenses. We posit that, unfortunately, the adversary will likely always maintain an advantage so long as humans and machines process speech dissimilarly. That is, there will likely always be some room in this asymmetry for “speaking directly” to a computational speech recognition system in a manner that is not human parseable.

Future work. CMU Sphinx is a “traditional” approach to speech recognition which uses a hidden Markov model. More sophisticated techniques have recently begun to use neural networks. One natural extension of this work is to extend our white-box attack techniques to apply to RNNs.

Additional work can potentially make the audio even more difficult for a human to detect. Currently, the white-box hidden voice commands sound similar to white noise. An open question is if it might be possible to construct working attacks that sound like music or other benign noise.

7 Conclusion

While ubiquitous voice-recognition brings many benefits its security implications are not well studied. We investigate hidden voice commands which allow attackers to issue commands to devices which are otherwise unintelligible to users.

Our attacks demonstrate that these attacks are possible against currently-deployed systems, and that when knowledge of the speech recognition model is assumed more sophisticated attacks are possible which become much more difficult for humans to understand. (Audio files corresponding to our attacks are available at <http://hiddenvoicecommands.com>.)

These attacks can be mitigated through a number of different defenses. Passive defenses that notify the user

an action has been taken are easy to deploy and hard to stop but users may miss or ignore them. Active defenses may challenge the user to verify it is the owner who issued the command but reduce the ease of use of the system. Finally, speech recognition may be augmented to detect the differences between real human speech and synthesized obfuscated speech.

We believe this is an important new direction for future research, and hope that others will extend our analysis of potential defenses to create sound defenses which allow for devices to securely use voice-commands.

A Additional Background on Sphinx

As mentioned in §4, the first transform taken by Sphinx is to split the audio in to overlapping frames, as shown in Figure 7. In Sphinx, frames are 26ms (410 samples) long, and a new frame begins every 10ms (160 samples).

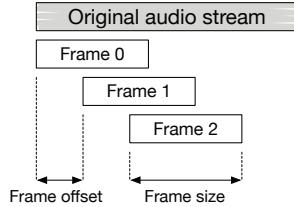

Figure 7: The audio file is split into overlapping frames.

MFC transform. Once Sphinx creates frames, it runs the MFC algorithm. Sphinx’s MFC implementation involves five steps:

1. **Pre-emphasizer:** Applies a high-pass filter that reduces the amplitude of low-frequencies.
2. **Cosine windower:** Weights the samples of the frame so the earlier and later samples have lower amplitude.
3. **FFT:** Computes the first 257 terms of the (complex-valued) Fast Fourier Transform of the signal and returns the squared norm of each.
4. **Mel filter:** Reduces the dimensionality further by splitting the 257 FFT terms into 40 buckets, summing the values in each bucket, then returning the log of each sum.
5. **DCT:** Computes the first 13 terms of the Discrete Cosine Transform (DCT) of the 40 bucketed values.⁵

Despite the many steps involved in the MFC pipeline, the entire process (except the running average and derivatives steps) can be simplified into a single equation:

$$\text{MFCC}(x) = C \log(B \|Ax\|^2)$$

where the norm, squaring and log are done component-wise to each element of the vector. A is a 410×257 matrix which contains the computation performed by the pre-emphasizer, cosine windower, and FFT. B is a 257×40 matrix which computes the Mel filter, and C is a 40×13 matrix which computes the DCT.

Sphinx is configured with a dictionary file, which lists all valid words and maps each word to its phonemes,

⁵While it may seem strange to take the DCT of the frequency-domain data, this second FFT is able to extract higher-level features about which frequencies are common, and is more tolerant to a change in pitch.

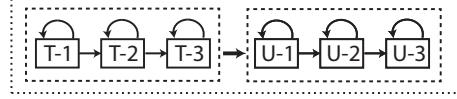

Figure 8: The HMM used by Sphinx encoding the word “two”. Each phoneme is split into three HMM states (which may repeat). These HMM states must occur in sequence to complete a phoneme. The innermost boxes are the phoneme HMM states; the two dashed boxes represent the phoneme, and the outer dashed box the word “two”.

and a grammar file, which specifies a BNF-style formal grammar of what constitutes a valid sequence of words. In our experiments we omit the grammar file and assume any word can follow any other with equal probability. (This makes our job as an attacker more difficult.)

The HMM states can be thought of as phonemes, with an edge between two phonemes that can occur consecutively in some word. Sphinx’s model imposes additional restrictions: its HMM is constructed so that all paths in the HMM correspond to a valid sequence of words in the dictionary. Because of this, any valid path through the HMM corresponds to a valid sequence of words. For example, since the phoneme “g” never follows itself, the HMM only allows one “g” to follow another if they are the start and end of words, respectively.

The above description is slightly incomplete. In reality, each phoneme is split into three HMM states, which must occur in a specific order, as shown in Figure 8. Each state corresponds to the beginning, middle, or end of a phoneme. A beginning-state has an edge to the middle-state, and the middle-state has an edge to the end-state. The end-phoneme HMM state connects to beginning-phoneme HMM states of other phonemes. Each state also has a self-loop that allows the state to be repeated.

Given a sequence of 39-vectors, Sphinx uses the Viterbi algorithm to try to find the 100 most likely paths through the HMM model (or an approximation thereto).

B Detailed Machine Comprehension of Black-box Attack

The detailed results of machine comprehension of black-box attacks are presented in Figure 9.

We note that Figure 9 contains an oddity: in a few instances, the transcription success rate decreases as the SNR increases. We suspect that this is due to our use of median SNR, since the background samples contain non-uniform noise and transient spikes in ambient noise levels may adversely affect recognition. Overall, however, we observe a clear (and expected) trend in which transcription accuracy improves as SNR increases.

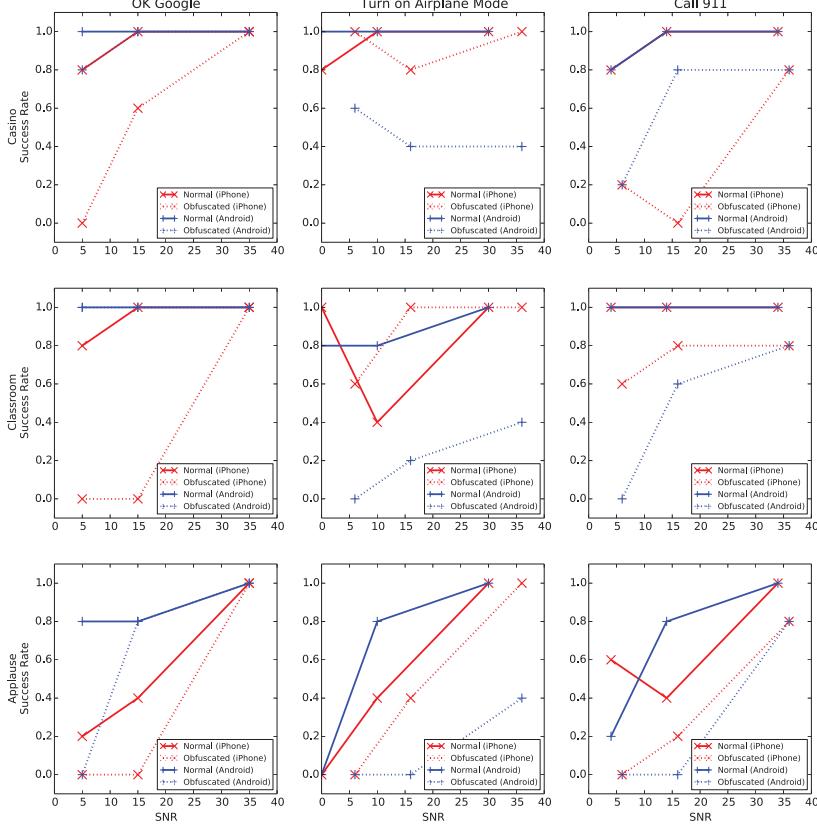

Figure 9: Machine understanding of normal and obfuscated variants of “OK Google”, “Turn on Airplane Mode”, and “Call 911” voice commands (*column-wise*) under different background noises (*row-wise*). Each graph shows the measured average success rate (the fraction of correct transcripts) on the y-axis as a function of the signal-to-noise ratio.

C Analysis of Transcriptions using Phoneme-Based Edit Distance Metrics

C.1 Black-box attack

To verify the results of the white-box survey and to better understand the results of Amazon Mechanical Turk Study, we first performed a simple binary classification of transcription responses provided by Turk workers.

We define *phoneme edit distance* δ as the Levenshtein edit distance between phonemes of two transcriptions. We define ϕ as δ/L , where L is the phoneme length of normal command sentence. The use of ϕ reflects how close the transcriptions might sound to a human listener. $\phi < 0.5$ indicates that the human listener successfully comprehended at least 50% of the underlying voice command. We consider this as successful comprehension by human, implying attack failure; otherwise, we consider it a success for the attacker. Table 6 shows the results of our binary classification. The difference in success rates of normal and obfuscated commands is similar to that of human listeners in Table 2, validating the survey results.

We used *relative phoneme edit distance* to show the gap between transcriptions of normal and obfuscated commands submitted by turk workers. The *relative phoneme edit distance* is calculated as $\delta/(\delta + L)$, L is again the phoneme length of normal command sentence. The relative phoneme edit distance has a range of $[0, 1]$, where 0 indicates exact match and larger relative phoneme edit distances mean the evaluator’s transcription further deviates from the ground truth. By this definition, a value of 0.5 is achievable by transcribing silence. Values above 0.5 indicate no relationship between the transcription and correct audio.

Figure 10 shows the CDF of the relative phoneme edit distance for the (*left*) “OK Google”, (*center*) “Turn on Airplane Mode” and (*right*) “Call 911” voice commands. These graphs show similar results as reported in Table 2: Turk workers were adept at correctly transcribing normal commands even in presence of background noise; over 90% of workers made perfect transcriptions with an edit distance of 0. However, the workers were far less able to correctly comprehend obfuscated commands: less than 30% were able to achieve a relative edit distance less than 0.2 for “OK Google” and “Turn on Airplane Mode”.

Table 6: Black-box attack. Percentages show the fraction of human listeners who were able to comprehend at least 50% of voice commands.

	OK Google	Turn On Airplane Mode	Call 911
Normal	97% (97/100)	89% (102/114)	92% (75/81)
Obfuscated	24% (23/94)	47% (52/111)	95% (62/65)

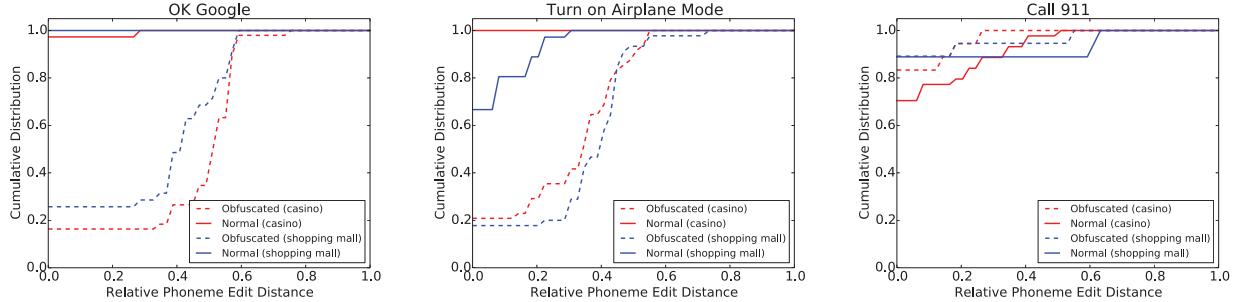

Figure 10: Cumulative distribution of relative phoneme edit distances of Amazon Mechanical Turk workers’ transcriptions for (left) “OK Google”, (center) “Turn on Airplane Mode” and (right) “Call 911” voice commands, with casino and shopping mall background noises. The attack is successful for the first two commands, but fails for the third.

Table 7: White-box attack. Percentages show the fraction of human listeners who were able to comprehend at least 50% of phonemes in a command.

	Command
Normal	97% (297/310)
Obfuscated	10% (37/377)

C.2 White-box attack

To verify the results of our authors review of the Turk study, we computed the edit distance of transcribed commands with actual commands. Table 7 says a command is a match if at least 50% of phonemes were transcribed correctly, to eliminate potential author bias. This metric is less strict both for normal commands and obfuscated commands, but the drop in quality is nearly as strong.

D Canceling out the Beep

Even when constrained to simplistic and conservative mathematical models, it is difficult to cancel out a beep played by a mobile device.

D.1 Two ears difficulties

Setup: The victim has two ears located at points E and F , and a device at point P . The attacker has complete control over a speaker at point A .

Threat model: The attacker has complete knowledge of the setup, including what the beep sounds like, when the beep will begin playing, and the location of all four points E, F, P and A . We assume for simplicity that sound amplitude does not decrease with distance.

The attacker loses the game if the victim hears a sound in either ear. Our question, then, is: *can the attacker cancel out the sound of the beep in both ears simultaneously?* Since sound amplitude does not attenuate with distance, the attacker can focus solely on phase matching: to cancel out a sound, the attacker has to play a signal that is exactly π radians out of phase with the beep. This means the attacker has to know the phase of the signal to a good degree of accuracy.

In our model, canceling out sound at one ear (say E) is easy for the attacker. The attacker knows the distance d_{PE} , and so knows t_{PE} , the time it will take for the sound to propagate from P to E . Similarly, the attacker knows t_{AE} . This is enough to determine the delay that he needs to introduce: he should start playing his signal $\frac{(d_{PE}-d_{AE}) \pmod \lambda}{c}$ (where λ is the wavelength) seconds after the start of the beep (where c is the speed of sound), and the signal he should play from his speaker is the inverse of the beep (an “anti-beep”).

However, people have two ears, and so there will still be some remnant of the beep at the other ear F : the beep will arrive at that ear $\frac{d_{PF}}{c}$ seconds after being played, while the anti-beep will arrive $\frac{d_{AF}}{c}$ seconds after the anti-beep starts, i.e., $\frac{d_{PE}-d_{AE}+d_{AF}}{c}$ seconds after the beep starts. This means that the anti-beep will be delayed by $\frac{d_{PE}-d_{AE}+d_{AF}-d_{PF}}{c}$ seconds compared to the beep.

Therefore, the attacker must be sure that they are placed exactly correctly so that the cancellation occurs at just the right time for both ears. This is the set of points where $(d_{PE} - d_{AE} + d_{AF} - d_{PF}) = 0$. That is, the attacker can be standing anywhere along half of a hyperbola around the user.

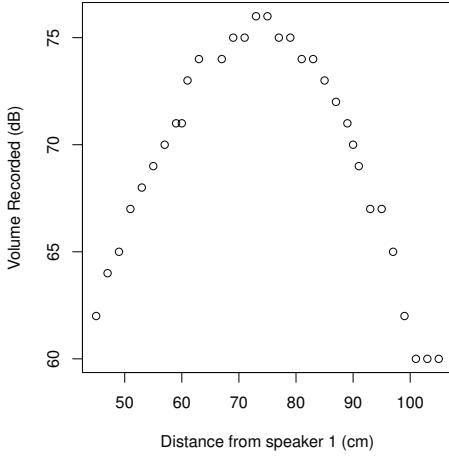

Figure 11: Plot of the amplitude of attempted noise cancellation of a tone at 440Hz

Finally, there is one more issue: any device which can perform voice recognition must have a microphone, and so can therefore listen actively for an attack. This then requires not only that the attacker be able to produce exactly the inverse signal at both ears, but also zero total volume at the device’s location. This then fixes the attacker’s location to only one potential point in space.

D.2 Real-world difficulties

In the above setup we assumed a highly idealized model of the real world. For instance, we assumed that the attacker knows all distances involved very precisely. This is of course difficult to achieve in practice (especially if the victim moves his head). Our calculations show that canceling over 90% of the beep requires an error of at most 3% in the phase. Putting this into perspective, for a 1Khz beep, to eliminate 90% of the noise, the adversary needs to be accurate to within 3 inches.

In practice, the attack is even more difficult than described above. The adversary may have to contend with multiple observers, and has to consider background noise, amplitude attenuation with distance, and so on.

Even so, to investigate the ability of an attacker to cancel sound in near-ideal conditions, we conducted an experiment to show how sound amplitude varies as a function of the phase difference in ideal conditions. The setup is as follows: two speakers are placed facing each other, separated by a distance d . Both speakers play the same pure tone at the same amplitude. We placed a microphone in between, and measured the sound amplitude at various points on the line segment joining the two. For our experiment, $d = 1.5\text{m}$ and the frequency of the tone is $f = 440\text{Hz}$. The results are plotted in Figure 11.

As can be seen, the total cancellation does follow a

sine wave as would be expected, however there is noise due to real-world difficulties. This only makes the attacker’s job more difficult.

E Machine Interpretation of Obfuscated Command

Table 8: For each of the three phrases generated in our white-box attack, the phrase that Sphinx recognized. This data is used to alter the lengths of each phoneme to reach words more accurately. Some words such as “for” and “four” are pronounced exactly the same: Sphinx has no language model and so makes errors here.

Phrases as recognized by CMU Sphinx	
Count	Phrase
3	okay google browse evil dot com
1	okay google browse evil that come
1	okay google browse evil them com
1	okay google browse for evil dot com
6	okay google browse two evil dot com
2	okay google browse two evil that com
1	okay google browse who evil not com
1	okay google browse who evil that com
1	okay up browse evil dot com
5	okay google picture

F Short-Term Features used by Classifier Defense

Table 9: Short term features used for extracting mid-term features.

Feature	Description
Zero Crossing Rate	The rate of sign-changes of the signal during the duration of a particular frame.
Energy	The sum of squares of the signal values, normalized by the respective frame length.
Entropy of Energy	The entropy of sub-frames’ normalized energies.
Spectral Centroid	The center of gravity of the spectrum.
Spectral Spread	The second central moment of the spectrum.
Spectral Entropy	Entropy of the normalized spectral energies for a set of sub-frames.
Spectral Flux	The squared difference between the normalized magnitudes of the spectra of the two successive frames.
Spectral Rolloff	The frequency below which 90% of the magnitude distribution of the spectrum is concentrated.
MFCCs	Mel Frequency Cepstral Coefficients
Chroma Vector	A 12-element representation of the spectral energy
Chroma Deviation	The standard deviation of the 12 chroma coefficients.

FlowFence: Practical Data Protection for Emerging IoT Application Frameworks

Earlence Fernandes¹, Justin Paupore¹, Amir Rahmati¹, Daniel Simionato²
Mauro Conti², Atul Prakash¹

¹*University of Michigan* ²*University of Padova*

Abstract

Emerging IoT programming frameworks enable building apps that compute on sensitive data produced by smart homes and wearables. However, these frameworks only support permission-based access control on sensitive data, which is ineffective at controlling *how* apps use data once they gain access. To address this limitation, we present FlowFence, a system that requires consumers of sensitive data to declare their intended data flow patterns, which it enforces with low overhead, while blocking all other undeclared flows. FlowFence achieves this by explicitly embedding data flows and the related control flows within app structure. Developers use FlowFence support to split their apps into two components: (1) A set of Quarantined Modules that operate on sensitive data in sandboxes, and (2) Code that does not operate on sensitive data but orchestrates execution by chaining Quarantined Modules together via taint-tracked *opaque handles*—references to data that can only be dereferenced inside sandboxes. We studied three existing IoT frameworks to derive key functionality goals for FlowFence, and we then ported three existing IoT apps. Securing these apps using FlowFence resulted in an average increase in size from 232 lines to 332 lines of source code. Performance results on ported apps indicate that FlowFence is practical: A face-recognition based door-controller app incurred a 4.9% latency overhead to recognize a face and unlock a door.

1 Introduction

The Internet of Things (IoT) consists of several data-producing devices (*e.g.*, activity trackers, presence detectors, door state sensors), and data-consuming apps that optionally actuate physical devices. Much of this data is privacy sensitive, such as heart rates and home occupancy patterns. More importantly, we are seeing an emergence of application frameworks that enable third party developers to build apps that compute

on such data—Samsung SmartThings [55], Google Brillo/Weave [30], Vera [5], and Apple HomeKit [8] are a few examples.

Consider a smart home app that allows unlocking a door via face recognition using a camera at the door. Home owners may also want to check the state of the door from a secure Internet site (thus, the app requires Internet access). Additionally, the user also wants to ensure that the app does not leak camera data to the Internet. Although this app is useful, it also has the potential to steal camera data. Therefore, enabling apps to compute on sensitive data the IoT generates, while preventing data abuse, is an important problem that we address.

Current approaches to data security in emerging IoT frameworks are modeled after existing smartphone frameworks (§2). In particular, IoT frameworks use permission-based access control for data sources and sinks, but they do not control *flows* between the authorized sources and sinks. This method has already proved to be inadequate, as is evident from the growing reports of data-stealing malware in the smartphone [73] and browser extension spaces [36, 14]. The fundamental problem is that users have no choice but to take it on faith that an app will not abuse its permissions. Instead, we need a solution that forces apps to make their data use patterns explicit, and then enforce the declared information flows, while preventing all other flows.

Techniques like the recognizer OS abstraction [39] could enable privacy-respecting apps by reducing the fidelity of data released to apps so that non-essential but privacy violating data is removed. However, these techniques fundamentally depend on the characteristics of a particular class of applications (§7). For example, image processing apps may not need HD camera streams and, thus, removing detail from those streams to improve privacy is feasible. However, this may not be an option in the general case for apps operating on other types of sensitive data.

Dynamic or static taint analysis has been suggested

as a method to address the limitations of the above permission-based systems [60, 53]. Unfortunately, current dynamic taint analysis techniques have difficulty in dealing with implicit flows and concurrency [59], may require specialized hardware [70, 54, 65], or tend to have significant overhead [48]. Static taint analysis techniques [9, 21, 66, 45] alleviate run-time performance overhead issues, but they still have difficulty in handling implicit flows. Furthermore, some flow-control techniques require developers to use special-purpose languages, for example, JFlow [45].

We present FlowFence, a system that enables robust and efficient flow control between sources and sinks in IoT applications. FlowFence addresses several challenges including not requiring the use of special-purpose languages, avoiding implicit flows, not requiring instruction-level information flow control, supporting flow policy rules for IoT apps, as well as IoT-specific challenges like supporting diverse app flows involving a variety of device data sources.

A key idea behind FlowFence is its new information flow model, that we refer to as *Opacified Computation*. A data-publishing app (or sensitive source) tags its data with a taint label. Developers write data-consuming apps so that sensitive data is only processed within designated functions that run in FlowFence-provided sandboxes for which taints are automatically tracked. Therefore, an app consists of a set of designated functions that compute on sensitive data, and code that does not compute on sensitive data. FlowFence only makes sensitive data available to apps via functions that they submit for execution in FlowFence-provided sandboxes.

When such a function completes execution, FlowFence converts the function’s return data into an *opaque handle* before returning control to the non-sensitive code of the app. An opaque handle has a hidden reference to raw sensitive data, is associated with a taint set that represents the taint labels corresponding to sensitive data accessed in generating the handle, and can only be dereferenced within a sandbox. Outside a sandbox, the opaque handle does not reveal any information about the data type, size, taint label, any uncaught exception in the function, or contents. When a opaque handle is passed as a parameter into another function to be executed in a sandbox, the opaque handle is dereferenced before executing the function, and its taint set added to that sandbox. When a function wants to declassify data to a sink, it makes use of FlowFence-provided Trusted APIs that check $\langle \text{source}, \text{sink} \rangle$ flow policies before declassifying data. The functions operating on sensitive data can communicate with other functions, and developers can chain functions together to achieve useful computations but only through well-defined FlowFence-controlled channels and only through the use of opaque handles.

Therefore, at a high level, FlowFence creates a data flow graph at runtime, whose nodes are functions, and whose edges are either raw data inputs or data flows formed by passing opaque handles between functions. Since FlowFence explicitly controls the channels to share handles as well as declassification of handles (via Trusted API), it is in a position to act as a secure and powerful reference monitor on data flows. Since the handles are opaque, untrusted code cannot predicate on the handles outside a sandbox to create implicit flows. Apps can predicate on handles within a sandbox, but the return value of a function will always be tainted with the taint labels of any data consumed, preventing apps from stripping taint. An app can access multiple sources and sinks, and it can support multiple flows among them, subject to a stated flow policy.

Since sensitive data is accessible only to functions executing within sandboxes, developers must identify such functions to FlowFence—they encapsulate functions operating on sensitive data in Java classes and then register those classes with FlowFence infrastructure. Furthermore, FlowFence treats a function in a sandbox as a blackbox, scrutinizing only communications into and out of it, making taint-tracking efficient.

FlowFence builds on concepts from systems for enforcing flow policies at the component level, for example, COWL for JavaScript [63] and Hails for web frameworks [28, 52]. FlowFence is specifically tailored for supporting IoT application development. Specifically, motivated by our study of three existing IoT application frameworks, FlowFence includes a flexible Key-Value store and event mechanism that supports common IoT app programming paradigms. It also supports the notion of a discretionary flow policy for consumer apps that enables apps to declare their flow policies in their manifest (and thus the policy is visible prior to an app’s deployment). FlowFence ensures that the IoT app is restricted to its stated flow policy.

Our work focuses on tailoring FlowFence to IoT domains because they are still emerging, giving us the opportunity to build a flow control primitive directly into application structure. Flow-based protections could, in principle, be applied to other domains, but challenges are often domain-specific. This work solves IoT-specific challenges. We discuss the applicability of Opacified Computation to other domains in §6.

Our Contributions:

- We conduct a study of three major existing IoT frameworks that span the domains of smart homes, and wearables (i.e. Samsung SmartThings, Google Fit, and Android Sensor API) to analyze IoT-specific challenges and security design issues, and to inform the functionality goals for an IoT application framework (§2).

- Based on our findings we design the Opacified Computation model, which enables robust and efficient source to sink flow control (§3).
- We realize the Opacified Computation model through the design of FlowFence for IoT platforms. Our prototype runs on a Nexus 4 with Android that acts as our “IoT Hub” (§4). FlowFence only requires process isolation and IPC services from the underlying OS, thus minimizing the requirements placed on the hardware/OS.
- We perform a thorough evaluation of FlowFence framework (§5). We find that each sandbox requires 2.7MB of memory on average. Average latency for calls to functions across a sandbox boundary in our tests was 92ms or less. To understand the impact of these overheads on end-to-end performance, we ported three existing IoT apps to FlowFence (§5.2). Adapting these apps to use FlowFence resulted in average size of apps going up from 232 lines to 332 lines of source code. A single developer with no prior knowledge of the FlowFence API took five days total to port all these apps. Macro-benchmarks on these apps (latency and throughput) indicate that FlowFence performance overhead is acceptable: we found a 4.9% increase in latency for an app that performs face recognition, and we found a negligible reduction in throughput for a wearable heart beat calculator app. In terms of security, we found that the flow policies correctly enforce flow control over these three apps (§5.2). Based on this evaluation, we find FlowFence to be a practical, secure, and efficient framework for IoT applications.

2 IoT Framework Study: Platforms and Threats

We performed an analysis of existing IoT application programming frameworks, apps, and their security models to inform FlowFence design, distill key functionality requirements, and discover security design shortcomings. Our study involved analyzing three popular programming frameworks covering three classes of IoT apps: (1) Samsung SmartThings for the smart home, (2) Google Fit for wearables, and (3) Android Sensor API for quantified-self apps.¹ We manually inspected API documentation, and mapped it to design patterns. We found that across the three frameworks, access to IoT sensor data falls in one of the following design patterns: (1) The *polling pattern* involving apps polling an IoT device’s current state; and (2) The *callback pattern* involving

¹Quantified Self refers to data acquisition and processing on aspects of a person’s daily life, e.g., calories consumed.

apps registering callback functions that are invoked whenever an IoT device’s state changes.²

We also found that it is desirable for publishers and consumers to operate in a device-agnostic way, without being explicitly connected to each other, *e.g.*, a heart rate monitor may go offline when a wearable is out of Bluetooth range; the consumer should not have to listen to lifecycle events of the heart rate monitor—it only needs the heart beat data whenever that is available. Ideally, the consumer should only need to specify the type of data it requires, and the IoT framework should provide this data, while abstracting away the details. Furthermore, this is desirable because there are many types of individual devices that ultimately provide the same kind of data, *e.g.*, there are many kinds of heart rate monitors eventually providing heart rate data.

A practical IoT programming framework should support the two data sharing patterns described above in a device-agnostic manner. In terms of security, we found that all three frameworks offer permission-based access control, but they do not provide any methods to control data use once apps gain access to a resource. We provide brief detail on each of these frameworks below.

1) Samsung SmartThings. SmartThings is a smart home app programming framework [4] with support for 132 device types ranging from wall plugs to ZWave door locks. SmartThings provides two types of APIs to access device data: `subscribe` and `poll`. The `subscribe` API is the callback design pattern. For instance, to obtain a ZWave door lock’s current state, an app would issue a call of the form `subscribe(lockDevice, "lock.state", callback)`. The `subscribe` API abstracts away details of retrieving data from a device, and directly presents the data to consumers, allowing them to operate in a disconnected manner. The `poll` API is the polling pattern. For example, an app can invoke `lockDevice.currentState` to retrieve the state of the lock at that point in time.

For permission control, the end-user is prompted to authorize an app’s access request to a device [57], based on a matching of *SmartThings capabilities* (a set of operations) that the app wishes to perform, and the set of capabilities that a device supports. Once an app is granted access to a device, it can access all of its data and features. SmartThings does not offer any data flow control primitives.

2) Google Fit. Google Fit enables apps to interface with wearables like smartwatches [32]. The core abstraction in Google Fit is the Fitness Data Type, which provides a

²We also found an orthogonal *virtual sensor* design pattern: An intermediate app computing on sensor data and re-publishing the derived data as a separate virtual sensor. For instance, an app reads in heart rate at beats-per-minute, derives beats-per-hour, and re-publishes this data as a separate sensor.

device-agnostic abstraction for apps to access them in either instantaneous or aggregated form. The API provides raw access to both data types using only the callback pattern; the polling pattern is not supported. For instance, to obtain expended calories, an app registers a data point listener for the `com.google.calories.expended` instantaneous fitness type. A noteworthy aspect is that apps using the Fit API can pre-process data and publish *secondary* data sources, essentially providing a virtual sensor.

Google Fit API defines *scopes* that govern access to fitness data. For instance, the `FITNESS_BODY_READ` scope controls access to heart rate. Apps must request read or write access to a particular scope, and the user must approve or deny the request. Once an app gains access to a scope, it can access all fitness related data in that scope. Google Fit does not offer any data flow control primitives.

3) Android Sensor API. Android provides API access to three categories of smartphone sensor data: Motion, Environment, and Position. Apps must register a class implementing the `SensorEventListener` interface to receive callbacks that provide realtime sensor state. There is no API to poll sensor state, except for the Location API. Android treats the Location API differently but, for our purposes, we consider it to be within the general umbrella of the sensor API. The Location API supports both the polling and callback design patterns. The callback pattern supports consumers operating in a device-agnostic manner since the consumer only specifies the type of data it is interested in.

Surprisingly, the Android sensor API does not provide any access control mechanism protecting sensor data. Any app can register a callback and receive sensor data. The Location API and heart rate sensor API, however, do use Android permissions [22, 31]. Similar to the previous two frameworks, Android does not offer any data flow control primitives.

IoT Architectures. We observe two categories of IoT software architectures: (1) Hub, and (2) Cloud. The hub model is centralized and executes the majority of software on a hub that exists in proximity to various physical devices, which connect to it. The hub has significantly more computational power than individual IoT devices, has access to a power supply, provides network connectivity to physical devices, and executes IoT apps. In contrast, a cloud architecture executes apps in remote servers and may use a minimal hub that only serves as a proxy for relaying commands to physical devices. The hub model is less prone to reliability issues, such as functionality degradation due to network connectivity losses that plague cloud architectures [58]. Furthermore, we observe a general trend toward adoption of the hub model by industry in systems such as Android Auto [1]

and Wear [2], Samsung SmartThings [55]³, and Logitech Harmony [3]. Our work targets the popular hub model, making it widely applicable to these hub-based IoT systems.

Threat Model. IoT apps are exposed to a slew of sensitive data from sensors, devices connected to the hub, and other hub-based apps. This opens up the possibility of sensitive data leaks leading to privacy invasion. For instance, Denning *et al.* outlined emergent threats to smart homes, including misuse of sensitive data for extortion and for blackmail [17]. Fernandes *et al.* recently demonstrated that such threats exist in real apps on an existing IoT platform [26] where they were able to steal and misuse door lock pincodes.

We assume that the adversary controls IoT apps running on a hub whose platform software is trusted. The adversary can program the apps to attempt to leak sensitive data. Our security goal is to force apps to declare their intended data use patterns, and then enforce those flows, while preventing all other flows. This enables the design of more privacy-respecting apps. For instance, if an app on FlowFence declares it will sink camera data to a door lock, then the system will ensure that the app cannot leak that data to the Internet. We assume that side channels and covert channels are outside the scope of this work. We discuss implications of side channels, and possible defense strategies in §6.

3 Opacified Computation Model

Consider the example smart home app from §1, where it unlocks the front door based on people’s faces. It uses the bitmap to extract features, checks the current state of the door, unlocks the door, and sends a notification to the home owner using the Internet. This app uses sensitive camera data, and accesses the Internet for the notification (in addition to ads and crash reporting). An end user wishes to reap the benefits of such a scenario but also wants to ensure that the door control app does not leak camera data to the Internet.

FlowFence supports such scenarios through the use of Opacified Computation, which consists of two main components: (1) Quarantined Modules (“functions”), and (2) opaque handles. A Quarantined Module (QM) is a developer-written code module that computes on sensitive data (which is assigned a taint label at the data source), and runs in a system-provided sandbox. A developer is free to write many such Quarantined Modules. Therefore, each app on FlowFence is split into two parts: (1) some non-sensitive code that does not compute on sensitive data, and (2) a set of QMs that compute on sensitive data. Developers can chain multiple QMs together

³Recent v2 hubs have local processing.

to achieve useful work, with the unit of transfer between QMs being opaque handles—immutable, labeled opaque references to data that can only be dereferenced by QMs when running inside a sandbox. QMs and opaque handles are associated with a taint set, *i.e.*, a set of taint labels that indicates the provenance of data and helps track information flows (we explain label design later in this section).

An opaque handle does not reveal any information about the data value, data type, data size, taint set, or exceptions that may have occurred to non-sensitive code. Although such opaqueness can make debugging potentially difficult, our implementation does support a development-time debugging flag that lifts these opaqueness restrictions (§4).

Listings 1 and 2 shows pseudo-code of example smart home apps. The CamPub app defines `QM_bmp` that publishes the bitmap data. FlowFence ensures that whenever a QM returns to the caller, its results are converted to an opaque handle.

Line 10 of Listing 1 shows the publisher app calling the QM (a blocking call), supplying the function name and a taint label. FlowFence allocates a clean sandbox, and runs the QM. The result of `QM_bmp` running is the opaque handle `hCam`, which refers to the return data, and is associated with the taint label `Taint_CAMERA`. `hCam` is immutable—it will always refer to the data that was used while creating it (immutability helps us reduce overtainting; we discuss it later in this section). Line 11 shows CamPub sending the resultant handle to a consumer.

We also have a second publisher of data `QM_status` that publishes the door state (Line 16 of Listing 1), along with a door identifier, and provides an IPC function for consumers to call (Line 20).

The DoorCon app defines `QM_recog`, which expects a bitmap, and door state (Lines 6-9 of Listing 2). It computes feature vectors from the bitmap, checks if the face is authorized, checks the door state, and unlocks the door. Lines 18, 19 of Listing 2 show this consumer app receiving opaque handles from the publishers. As discussed, non-sensitive code only sees opaque handles. In this case, `hCam` refers to camera-tainted data, and `hStatus` refers to door-state-tainted data, but the consumer app cannot read the data unless it passes the data to a QM. Moreover, for this same reason, non-sensitive code cannot test the value of a handle to create an implicit flow.

Line 20 calls a QM, passing the handles as parameters. FlowFence automatically and transparently dereferences opaque handle arguments into raw data before invoking a QM. Transparent dereferencing of opaque handles offers developers the ability to write QMs normally with standard types even though some parameters may be passed as opaque handles. During this process, FlowFence allocates a clean sandbox for the QM to run, and propagates

the taint labels of the opaque handles to that sandbox. Finally, `QM_recog` receives the raw data and opens the door.

The consumer app uses `QM_report` to send out the state of the door to a remote monitoring website. It also attempts to use `QM_mal` to leak the bitmap data. FlowFence prevents such a leak by enforcing flow policies, which we discuss next.

Flow Policy. A publisher app, which is associated with a sensor (or sensors), can add taint labels to its data that are tuples of the form $(appID, name)$, where $appID$ is the identifier of the publisher app and $name$ is the name of the taint label. This name denotes a standardized type that publishers and consumers can agree upon, for example, `Taint_CAMERA`. We require labels to be statically declared in the app’s manifest. $appID$ is unique to an app and is used to avoid name collisions across apps.⁴ Additionally, in its manifest, the publisher can specify a set of flow rules for each of its taint labels, with the set of flow rules constituting the publisher policy. The publisher policy defines the permissible flows that govern the publisher’s data. A flow rule is of the form `TaintLabel → Sink`, where a sink can be a user interface, actuators, Internet, etc. CamPub’s flow policy is described on Line 3 of Listing 1. The policy states that consumer apps can sink camera data to the sink labeled `UI` (which is a standard label corresponding to a user’s display at the hub).

Since other possible sinks for camera data are not necessarily known to the publisher, new flow policies are added as follows. A consumer app must request approval for flow policies if it wants to access sensitive data. Consumer flow policies can be more restrictive than publisher policies, supporting the least privilege principle. They can also request new flows, in which case the hub user must approve them. DoorCon’s policy requests are described in Lines 2-4 of Listing 2. It requests the flows: `Taint_CAMERA → Door.Open`, `Taint_DOORSTATE → Door.Open`, `Taint_DOORSTATE → Internet`. At app install time, a consumer app will be bound to a publisher that provides data sources with labels `Taint_CAMERA`, `Taint_DOORSTATE`.

To compute the final policy for a given consumer app FlowFence performs two steps. First, it computes the intersection between the publisher policy and the consumer policy flow rules. In our example, the intersection is the null set. If it were not null, FlowFence would authorize the intersecting flows for the consumer app in question. Second, it computes the set difference between the consumer policy and publisher policy. This difference reflects the flows the consumer has requested but the publisher policy has not covered. At this point, FlowFence

⁴ An app cannot forge its ID since our implementation uses Android package name as the ID. See §4 for details.

delegates approval to the IoT hub owner to make the final decision about whether to approve the flows or not. If the hub owner decides to approve a flow that a publisher policy does not cover, that exception is added for subsequent runs of that consumer app. Such a approval does not apply to other apps that may also use the data.

If a QM were to attempt to declassify the camera data to the Internet (*e.g.*, `QM_mal`) directly without requesting a flow policy, the attempt would be denied as none of the flow policies allow it. An exception is thrown to the calling QM whenever it tries to perform an unauthorized declassification. Similar to exception processing in languages like Java, if a QM does not catch an exception, any output handle of this QM is moved into the exception state. Non-QM code cannot view this exception state. If an app uses such a handle in a subsequent QM as a parameter, then that QM will silently fail, with all of its output handles also in the exception state. App developers can avoid this by ensuring that a QM handles all possible exceptions before returning and, if necessary, encodes any errors into the return object, which can then be examined in a subsequent QM that receives the returned handle.

FlowFence is in a position to make security decisions because the publisher assigns taint labels while creating the handles, and when `DoorCon` reads in the handles, it results in the taint labels propagating to the sandbox running `QM_mal`. FlowFence simply reads the taint labels of the sandbox at the time of declassification.

All declassification of sensitive data can only occur through well-known trusted APIs that FlowFence defines. Although our prototype provides a fixed set of trusted APIs that execute in a separate trusted process, we envision a plug-in architecture that supports community built and vetted APIs (§4). FlowFence sets up sandbox isolation such that attempts at declassifying data using non-trusted APIs, such as arbitrary OS system calls, are denied.

Table 1 summarizes the taint logic. When a clean sandbox loads a QM, it has no taint. A taint label, belonging to the app, may be added to a handle at creation, or to a sandbox at any time, allowing data providers to label themselves as needed. A call from QM executing in S_0 to another QM that is launched in sandbox S_1 results in the taint labels of S_0 being copied to S_1 . When a called QM returns, FlowFence copies the taint of the sandbox into the automatically created opaque handle. At that point, the QM no longer exists. The caller is not tainted by the returned handle, unless the caller (which must be a QM) dereferences the handle. These taint arithmetic rules, combined with QMs, opaque handles, and sandboxes conceptually correspond to a directed data flow graph from sources to sinks, as we illustrate with the example below.

```

1 application CamPub
2 taint_label Taint_CAMERA;
3 allow { Taint_CAMERA -> UI }
4
5 Bitmap QM_bmp():
6     Bitmap face = camDevice.snapshot();
7     return face;
8
9 if (motion at FrontDoor)
10    hCam = QM.call(QM_bmp, Taint_CAMERA);
11    send hCam to DoorCon;
12 -----
13 application DoorStatePub
14 taint_label Taint_DOORSTATE;
15
16 Status QM_status():
17     return (door[0].state(), 0); //state, idx
18
19 /* IPC */ Handle getDoorState():
20     return QM.call(QM_status,
21                     Taint_DOORSTATE);

```

Listing 1: Pseudocode for two publishers—camera data, and door state. Quarantined Modules are shown in light gray.

```

1 application DoorCon
2 request { Taint_CAMERA -> Door.Open,
3             Taint_DOORSTATE -> Door.Open,
4             Taint_DOORSTATE -> Internet }
5
6 void QM_recog(faceBmp, status):
7     Features f = extractFeatures(faceBmp);
8     if(status != unlocked AND isAuthenticated(f))
9         TrustedAPI.door[0].open();
10
11 void QM_report(status):
12     TrustedAPI.network.send(status);
13
14 void QM_mal(faceBmp):
15     /* this is denied */
16     TrustedAPI.network.send(faceBmp);
17
18 receive hCam from CamPub;
19 Handle hStatus =
20     DoorStatePub.getDoorState();
21 QM.call(QM_recog, hCam, hStatus);
22 QM.call(QM_mal, hCam);
23 QM.call(QM_report, hStatus);

```

Listing 2: Consumer app pseudocode that reads camera and door state data, and controls a door. Quarantined Modules are shown in light gray.

FlowFence Data Flow Graph. We now discuss the taint flow logic of FlowFence in more detail, and show how it creates and tracks, at runtime, a directed data flow graph that enables it to make security decisions on flows. Figure 1 shows two publishers of sensitive data that generate $OH_{T_1}(d_1)$ —an opaque handle that refers to camera bitmap data d_1 , and $OH_{T_2}(d_2)$ —an opaque handle that refers to door state data d_2 , using QM_{bmp} and QM_{status}

Operation	Taint Action
Sandbox S loads a QM	$T[S] := \emptyset$
QM inside S reads opaque handle $d = OH^{-1}(h)$	$T[S] += T[h]$
QM inside S returns $h = OH(d)$	$T[h] := T[S]$
QM manually adds taints $\{t\}$ to its sandbox	$T[S] += \{t\}$
QM_0 inside S_0 calls QM_1 inside S_1	$T[S_1] = T[S_0]$

Table 1: Taint Arithmetic in FlowFence. $T[S]$ denotes taint labels of a sandbox running a QM. $T[h]$ denotes taint label of a handle h .

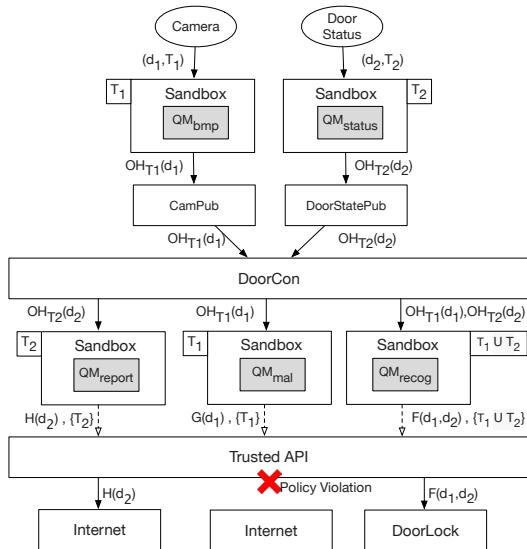

Figure 1: Data flow graph for our face recognition example. FlowFence tracks taint labels as they propagate from sources, to handles, to QMs, to sinks. The dotted lines represent a declassification attempt. The trusted API uses labels on the sandboxes to match a flow policy.

respectively. T_1 and T_2 are taint labels for data d_1 and d_2 . The user wants to ensure that camera data does not flow to the internet.

The consumer app (DoorCon) consists of non-sensitive code that reads the above opaque handles from the publishers, and invokes three QMs. QM_{recog} operates on both $OH_{T_1}(d_1)$ and $OH_{T_2}(d_2)$. When the non-sensitive code requests execution of QM_{recog} , FlowFence will allocate a clean sandbox, dereference the handles into raw values, and invoke the module. The sandbox inherits the taint label $T_1 \cup T_2$. Later on, when QM_{recog} tries to declassify its results by invoking the trusted API, FlowFence will read the taint labels (dotted line in Figure 1)— $T_1 \cup T_2$. That is, FlowFence taint arithmetic defines that the taint label of the result is the combination of input

data taint labels. In our example, declassifying camera and door state tainted data to the door lock is permitted, since the user authorized the flow earlier.

If the consumer app tries to declassify sensitive data d_1 by invoking a trusted API using QM_{mal} , the API reads the taint labels on the handle being declassified, determines that there is no policy that allows $d_1 \rightarrow \text{Internet}$, and denies the declassification.

Immutable opaque handles are key to realizing this directed data flow graph. Consider Figure 1. If handles were mutable, and if QM_{mal} read in some data with taint label T_3 , then we would have to assume that $OH_{T_1}(d_1)$ is tainted with T_3 , leading to overtainting. Later on, when QM_{recog} executes, its sandbox would inherit the taint label T_3 due to the overtainting. If there was a policy that prevented T_3 from flowing to the door lock, FlowFence would prevent QM_{recog} from executing the declassification. FlowFence avoids these overtainting issues by having immutable handles, which enable better precision when reasoning about flows. There are other sources of overtainting related to how a programmer structures the computation and IoT-specific mechanisms that FlowFence introduces. We discuss their implications and how to manage them in §4 and §6.

As discussed above, taint flows transitively from data sources, to opaque handles, to sandboxes, back to opaque handles, and eventually to sinks via the trusted API, where FlowFence can enforce security policies. This design allows taint flow to be observed in a black-box manner, simply by tracking the inputs and outputs. This allows QMs to internally use any language, without the overhead of native taint tracking, only by using sandbox processes to enforce isolation as described in §4.

FlowFence Security Guarantees. FlowFence uses its taint arithmetic rules to maintain the invariant that the taint set of a QM executing in a sandbox at any time represents the union of the taints of sensitive data used by the QM through opaque handles or through calls from another QM. Furthermore, FlowFence avoids propagating taint on QM returns with the help of opaque handles. Since these handles are opaque outside a QM, non-sensitive code must pass them into QMs to dereference them, allowing FlowFence to track taints. If the non-sensitive code of a consumer app transmits an opaque handle to another app via an OS-provided IPC mechanism, FlowFence still tracks that flow since the receiving app also has to use a QM to make use of the handle.

To prevent flow policy violations, a sandbox must be designed such that writes from a QM to a sink go through a trusted API that enforces specified flow policies. We discuss how we achieve this sandbox design in §4.

4 FlowFence Architecture

FlowFence supports executing untrusted IoT apps using two major components (Figure 2): (1) A series of *sandboxes* that execute untrusted, app-provided QMs in an isolated environment that prevents unwanted communication, and (2) A *Trusted Service* that maintains handles and the data they represent; converting data to opaque handles and dereferencing opaque handles back; mediating data flow between sources, QMs, and sinks, including taint propagation and policy enforcement; and creating, destroying, scheduling, and managing lifetime of sandboxes.

We discuss the design of these components in the context of an IoT hub with Android OS running on top. We selected Android because of the availability of source code. Google’s recently announced IoT-specific OS—Brillo [29], is also an Android variant.⁵ Furthermore, with the introduction of Google Weave [30], we expect to see Android apps adding IoT capabilities in the future.

Untrusted IoT Apps & QMs. Developers write apps for FlowFence in Java and can optionally load native code into QMs. As shown in Figure 2, each app consists of code that does not use sensitive data inputs, and a set of QMs that use sensitive data inputs. Although abstractly, QMs are functions, we designed them as methods operating on serializable objects. Each method takes some number of parameters, each of which can either be (1) raw, serialized data, or (2) opaque handles returned from previous method calls on this or another QM. A developer can write a method to return raw data, but returning raw data would allow leakage. Thus, FlowFence converts that raw data to an opaque handle prior to returning to the untrusted app.⁶

Trusted Service & APIs. This service manages all sensitive data flowing to and from QMs that are executing in sandboxes. It schedules QMs for execution inside sandboxes, dereferencing any opaque handle parameters, and assigning the appropriate taint labels to the sandboxes. The Trusted Service also ensures that a sandbox is correctly tainted whenever a QM reads in sensitive data (Tainter component of Figure 2), as per the taint arithmetic rules in FlowFence (Table 1). Once it taints a sandbox, the Trusted Service maintains the current taint labels securely in its process memory.

FlowFence does not track or update taints for variables inside a QM. Instead, it treats a QM as a blackbox for the

⁵Brillo OS is only a limited release at the time of writing. Therefore, we selected the more mature codebase for design, since core services are the same on Android and Brillo.

⁶A QM can theoretically leak sensitive data through side channels (*e.g.*, by varying the execution time of the method prior to returning). We assume side channels to be out of scope of our system and thus we do not address them in our current threat model. If such leaks were to be a concern, we discuss potential defense strategies in §6.

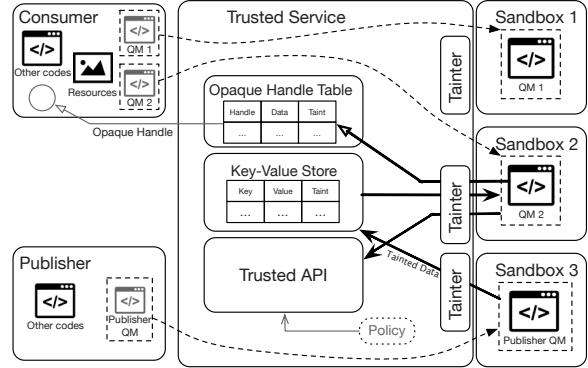

Figure 2: FlowFence Architecture. Developers split apps into Quarantined Modules, that run in sandbox processes. Data leaving a sandbox is converted to an opaque handle tainted with the sandbox taint set.

purpose of taint analysis and it only needs to examine sensitive inputs being accessed or handles provided to a method as inputs. We expect QMs to be limited to the subset of code that actually processes sensitive data, with non-sensitive code running without change. Although this does reduce performance overhead and avoids implicit flow leaks by forcing apps to only use controlled and well-defined data transfer mechanisms, it does require programmers to properly split their app into least-privilege QMs, which if done incorrectly, could lead to overtainting.

When a QM Q running inside a sandbox S returns, the Trusted Service creates a new opaque handle h corresponding to the return data d , and then creates an entry $\langle h, \langle d, T[S] \rangle \rangle$ in its opaque handle Table (Figure 2), and returns h to the caller.

The Trusted Service provides APIs for QMs allowing them to access various sinks. Our current prototype has well-known APIs for access to network, ZWave switches, ZWave locks, camera streams, camera pictures, and location. As an example of bridging FlowFence with such cyber-physical devices, we built an API for Samsung SmartThings. This API makes remote calls to a web services SmartThings app that proxies device commands from FlowFence to devices like ZWave locks. The Trusted API also serves as a policy enforcement point, and makes decisions whether to allow or deny flows based on the specific policy set for the consumer app.

We envision a plug-in architecture that enables community-built and vetted Trusted APIs to integrate with our framework. The plugin API should ideally be in a separate address space. The Trusted Service will send already declassified data to this plugin API via secure IPC. This limits risk by separating the handle table from external code.

Sandboxes. The Trusted Service uses operating system support to create sandbox processes that FlowFence uses to execute QMs. When a QM arrives for execution, FlowFence reserves a sandbox for exclusive use by that QM, until execution completes. Once a QM finishes executing, FlowFence sanitizes sandboxes to prevent data leaks. It does this by destroying and recreating the process.

For efficiency reasons, the Trusted Service maintains a pool of clean spare sandboxes, and will sanitize idle sandboxes in the background to keep that pool full. In addition, the Trusted Service can reassign sandboxes without needing to sanitize them, if the starting taint (based on the input parameters) of the new QM is a superset of or equal to the ending taint of the previous occupant of that sandbox. This is true in many common cases, including passing the return value of one QM directly into another QM. In practice, sandbox restarts only happen on a small minority of calls.

FlowFence creates the sandboxes with the `isolatedProcess` flag set, which causes Android to activate a combination of restrictive user IDs, IPC limitations, and strict SELinux policies. These restrictions have the net effect of preventing the isolated process from communicating with the outside world, except via an IPC interface connected to the Trusted Service.

As shown in Figure 2, this IPC interface belongs to the Trusted API discussed earlier. When the sandboxes communicate with the Trusted Service over an IPC interface, the IPC request is matched to the sandbox it originated from as well as to the QM that initiated the call. As discussed, the Trusted Service maintains information about each sandbox, including its taint labels and running QM, in a lookup table in its own memory, safely out of reach of, possibly malicious, QMs.

Debugging. Code outside QMs cannot dereference opaque handles to inspect corresponding data or exceptions, complicating debugging during development. To alleviate this, FlowFence supports a development time debugging option that allows code outside a QM to dereference handles and inspect their data and any exception traces. However, a deployment of FlowFence has this debugging flag removed. Also, as discussed previously, use of a opaque handle in exception state as a parameter to a QM results in the QM returning a new opaque handle that is also in the exception state. Providing a mechanism for exception handling in the called QM without increasing programmer burden is challenging and a work-in-progress. Currently, we use the idiom of a QM handling all exceptions it can and encoding any error as part of the returned value. This allows any subsequent QM that is called with the handle as a parameter to examine the value and handle the error.

Key-Value Store. This is one of the primary data-sharing mechanisms in FlowFence between publishers of tainted sensitive data and consumer apps that use the data. This design was inspired by our framework study in §2, and it supports publishers and consumers operating in a device-agnostic manner, with consumers only having to know the type of data (taint label) they are interested in processing. Each app receives its own KV store (Figure 2) into which it can update the value associated with a key by storing a $\langle key, sensitive_value, taint_label \rangle$ while executing a QM. For instance, a camera image publisher may create a key such as `CAM_BITMAP`, with an image byte array as the value, and a taint label `Taint_CAMERA` to denote the type of published data (declared in the app manifest). A key is public information—non-sensitive code outside a QM must create a key before it can write a corresponding value. This ensures that a publisher cannot use creation of keys as a signaling mechanism. An app on FlowFence can only write to its own KV store. Taints propagate as usual when a consumer app keys from the KV store. Finally, the publishing QM associated with a sensor usually would not read other sensitive information sources, and thus would not have any additional taint. In the case this QM has read other sources of information, then the existing taint is applied to any published data automatically.

If a QM reads a key’s value, the value’s taint label will be added to that QM’s sandbox. All key accesses are pass-by-value, and any subsequent change in a value’s taint label does not affect the taint labels of QMs that accessed that value in prior executions. Consider an example value V with taint label T_1 . Assuming a QM Q_1 accessed this value, it would inherit the taint. Later on, if the publisher changes the taint label of V to $T_1 \cup T_2$, this would not affect the taint label of Q_1 , until it reads V again.

The polling design pattern is easy to implement using a Key-Value Store. A consumer app’s QM can periodically access the value of a given key until it finds a new value or a non-null value. Publicly accessible keys simplify making sensitive data available to third-party apps, subject to flow policies.

Event Channels. This is the second data-sharing mechanism in FlowFence; it supports the design pattern of registering callbacks for IoT device state changes (*e.g.*, new data being available). The channel mechanism supports all primitive and serializable data types. An app creates channels statically by declaring them in a manifest file at development time (non-sensitive code outside QMs could also create it), making it the owner for all declared channels. Once an app is installed, its channels are available for use—there are no operations to explicitly open or close channels. Other app’s QMs can then register to such channels for updates. When a channel-owner’s

QM puts data on the channel, FlowFence invokes all registered QMs with that data as a parameter. FlowFence automatically assigns the current set of taint labels of the channel-owner to any data it puts on the channel, so that all QMs that receive the callback will be automatically tainted correctly. If a QM is executed as a callback for a channel update, it does not return any data to the non-sensitive code of the app.

Although the publishers and consumers can share opaque handles using OS-provided sharing mechanisms, we designed the Key-Value store, and Event channels explicitly so that publishers and consumers can operate in a device-agnostic manner by specifying the types of data they are interested in, ignoring lower level details.

As described here, both inter-app communication mechanisms, the KV store and event channels, can potentially lead to poison-pill attacks [37] where a compromised or malicious publisher adds arbitrary taint labels, with the goal of overtainting consumers and preventing them from writing to sinks. See the discussion of overtainting in §6 for a defense strategy.

FlowFence Policies and User Experience. In our prototype, users install the app binary package with associated policies. FlowFence prompts users to approve consumer flow policies that are not covered by publisher policies at install time. This install-time prompting behavior is similar to the existing Android model. FlowFence models its flow request UI after the existing Android runtime permission request screens, in an effort to remain close to existing permission-granting paradigms and to leverage existing user training with permission screens. However, unlike Android, FlowFence users are requested to authorize flows rather than permissions, ensuring their control over how apps use data. If a user approves a set of flows, FlowFence guarantees that only those flows can occur.

Past work has shown that users often do not comprehend or ignore prompts [25], however, existing research does point out interesting directions for future work in improving such systems. Felt *et al.* discuss techniques to better design prompting mechanisms [23], and Roesner *et al.* discuss contextual prompting [50, 51] as possible improvements.

5 Evaluation

We evaluated FlowFence from multiple perspectives. First, we ran a series of microbenchmarks to study call latency, serialization overhead, and memory overhead of FlowFence. We found that FlowFence adds modest computational and memory costs. Running a sandbox takes $2.7MB$ RAM on average, and running multiple such sandboxes will fit easily within current hardware

for IoT hubs.⁷ We observed a $92ms$ QM call latency with 4 spare sandboxes, which is comparable to the latency of common network calls in IoT apps. FlowFence supports a maximum bandwidth of $31.5MB/s$ for transferring data into sandboxes, which is large enough to accommodate typical IoT apps. Second, we ported three IoT apps to FlowFence to examine developer effort, security, and impact of FlowFence on macro-performance factors. Our results show that developers can use FlowFence with modest changes to their apps and with acceptable performance impact, making FlowFence practical for building secure IoT apps. Porting the three apps required adding 99 lines of code on average per app. We observed a 4.9% latency increase to perform face recognition in a door controller app. More details follow.

5.1 Microbenchmarks

We performed our microbenchmarks on an LG Nexus 4 running FlowFence on Android 5.0. The Nexus 4 serves as our “IoT hub” that runs QMs and enforces flow policies. In our experiments, we evaluated three factors that can affect apps running on FlowFence.

Memory overhead. We evaluated memory overhead of FlowFence using the `MemoryInfo` API. We ran FlowFence with 0 – 15 empty sandboxes and recorded the memory consumption. Our results show that the FlowFence core requires $6.35MB$ of memory while each sandbox requires $2.7MB$ of memory on average. To put this in perspective, LG Nexus 4 has 2GB memory and loading a blank page on the Chrome browser on it used $98MB$ of memory, while loading FlowFence with 16 sandboxes used $49.5MB$. Therefore, we argue that the memory overhead of FlowFence is within acceptable limits for the platform.

QM Call Latency. We measured QM call latency for non-tainted and tainted parameters (30 trials each with 100 QM call-reply sequences) to assess performance in scenarios that allowed reuse of a sandbox without sanitizing and those that required sanitizing. For tainted calls, each QM takes a single boolean parameter that is tainted. We also varied the number of clean spare sandboxes that are available for immediate QM scheduling initially before each trial. Regardless of the number of spare sandboxes, untainted calls (which did not taint the sandboxes and thus could reuse them without sanitizing) showed a consistent latency of $2.1ms$ ($SD=0.4ms$). The tainted calls were made so as to always require a previously-tainted sandbox to be sanitized. Figure 3 shows average latency of tainted calls across 30 trials for different number of spare sandboxes. As the number of spare sandboxes increases from 0 to 4, the average call

⁷For example, Samsung SmartThings hub has $512MB$ RAM [56], and Apple TV hub has $1GB$ RAM [7].

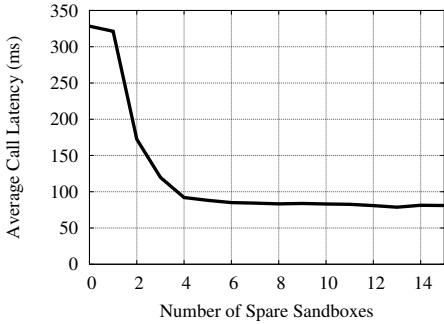

Figure 3: QM Call latency of FlowFence given various number of spare sandboxes, for calls that require previously-used sandboxes to be sanitized before a call. Calls that can reuse sandboxes without sanitizing (untainted calls in our tests) show a consistent latency of 2.1ms , which is not shown in this graph.

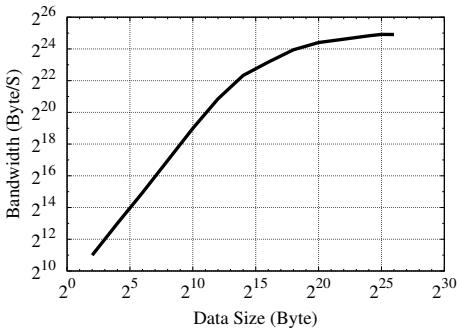

Figure 4: Serialization bandwidth for different data sizes. Bandwidth caps off at 31.5MB/s .

latency decreases from 328ms to 92ms . Further increase in the number of spare sandboxes does not improve latency of QM calls. At 4 spares, the call latency is less than 100ms , making it comparable to latencies seen in controlling many IoT devices (*e.g.*, Nest, SmartThings locks) over a wide-area network. This makes QMs especially suitable to run existing IoT apps that already accept latencies in this range.

Serialization Overhead. To understand FlowFence overhead for non-trivial data types, we computed serialization bandwidth for calls on QMs that cross sandbox boundaries with varying parameter sizes. Figure 4 presents the results for data ranging from 4B to 16MB . The bandwidth increases as data size increases and caps off at 31.5MB/s . This is large enough to support typical IoT apps—for example, the Nest camera uses a maximum bandwidth of 1.2Mbps under high activity [33]. A single camera frame used by one of our ported apps (see below), is 37kB , requiring transferring data at 820kB/s to a QM.

5.2 Ported IoT Applications

We ported three existing IoT apps to FlowFence to measure its impact on security, developer effort, end-to-end latency, and throughput on operations relevant to the apps (Table 2). SmartLights is a common smart home app (*e.g.*, available in SmartThings) that computes a predicate based on a location value from a beacon such as a smartphone, or car [47]. If the location value inside the home’s geofence, the app turns on lights (and adjusts other devices like thermostats) around the home. When the location value is outside the home’s geofence, the app takes the reverse action.

FaceDoor performs face recognition and unlocks a door, if a detected face is authorized [34]. The app uses the camera to take an image of a person at the door, and runs the Qualcomm face recognition SDK (chipset-specific native code, available only as a binary).

HeartRateMonitor accesses a camera to compute heart rate using photoplethysmography [67]. The app uses image processing code on streamed camera frames.

FlowFence provides trusted API to access switches, locks, and camera frames. These three existing apps cover the popular IoT areas of smart homes and quantified self. Furthermore, face recognition and camera-frame-streaming apps are among the more computationally expensive types of IoT apps, and stress test FlowFence performance. We ran all our experiments on Android 5.0 (Nexus 4).

Security. We discuss data security risks that each of the three IoT apps pose when run on existing platforms, and find that FlowFence eliminates those risks successfully under leakage tests.

1) SmartLights: It has the potential to leak location information to attackers via the Internet. The app has Internet access for ads, and crash reporting. On FlowFence, the developer separates code that computes on location in a QM which isolates the flow: `loc → switch`, while allowing other code to use the Internet freely.

2) FaceDoor: This app can leak camera data to the Internet. We note that this app requires Internet access for core functionality—it sends a notification to the user whenever the door state changes. Therefore, under current IoT frameworks it is very easy for this app to leak camera data. FlowFence isolates the flow of camera and door state data to door locks from the flow of door state data to the Internet using two QMs, eliminating any possibility of cross-flows between the camera and the Internet. This app uses the flows: `cam → lock`, `doorstate → lock`, `doorstate → Internet`.

3) HeartRateMonitor: The app can leak images of people, plus heart rate information derived from the camera stream. However, similar to previous apps, the developer of this app too will use FlowFence support to isolate the

Name	Description	Data Security Risk without FlowFence	LoC original	LoC FlowFence	Flow Request
SmartLights [47]	Reads a location beacon and if the beacon is inside a geofence around the home, automatically turn on the lights	App can leak user location information	118	193	<code>loc → switch</code>
FaceDoor [34]	Uses a camera to recognize a face; If the face is authorized, unlock a doorlock	App can leak images of people	322	456	<code>cam → lock, doorstate → lock, doorstate → net</code>
HeartRateMonitor [67]	Uses a camera to measure heart rate and display on UI	App can leak images of people, and heart rate information	257	346	<code>cam → ui</code>

Table 2: Features of the three IoT apps ported to FlowFence. Implementing FlowFence adds 99 lines of code on average to each app (less than 140 lines per app).

flow: `cam → ui` into a QM. We note that in all apps, the QMs can return opaque handles to the pieces of code not dealing with sensitive information, where the handle can be leaked, but this is of no value to the attacker since a handle is not sensitive data.

Developer Effort. Porting apps to FlowFence requires converting pieces of code operating on sensitive data to QMs. On average, 99 lines of code were added to each app (Table 2). We note that typical IoT apps today are relatively small in size compared to, say, Android apps. The average size across 499 apps for which we have source code for SmartThings platform is 162 line of source code. Most are event-driven, receiving data from various publishers that they are authorized to at install time and then publish to various sinks, including devices or Internet. Much of the extra code deals with resolving the appropriate QMs, and creating services to communicate with FlowFence. It took a developer with no prior knowledge of the FlowFence API to port the first two apps in two 8-hour (approx.) days each, and the last app in a single day. We envision that with appropriate developer tool support, many boiler plate tasks, including QM resolution, can be automated. We note that the increase in LoC is not co-related to the original LoC of the app. Instead, there is an increase in LoC only for pieces of the original app that deals with sensitive data. Furthermore, it is our experience that refactoring an existing app requires copying logic as-is, and building QMs around it. For instance, we did not have source-code access to the Qualcomm Face Recognition SDK, but we were able to successfully port the app to FlowFence.

Porting FaceDoor. Here, we give an example of the steps involved in porting an app. First, we removed all code from the app related to camera access, because FlowFence provides a camera API that allows QMs to

take pictures, and access the corresponding bitmaps. Next, we split out face recognition operations into its own Quarantined Module— QM_{recog} , that loads the native code face recognition SDK. We modified QM_{recog} to use the Trusted API to access a camera image, an operation that causes it to be tainted with camera data. We modified the pieces of code related to manipulating a ZWave lock to instead use FlowFence-provided API for accessing door locks. We also created QM_{report} that reads the door state source and then sends a notification to the user using the Internet. These two QMs isolate the flow from camera and door state to door lock, and the flow from door state to the Internet, effectively preventing any privacy violating flow of camera data to the Internet, which would otherwise be possible with current IoT frameworks.

End-to-End Latency. We quantified the impact of FlowFence on latency for various operations in the apps that are crucial to their functionality. We measured latency as the time it takes for an app to perform one entire computational cycle. In the case of SmartLights, one cycle is the time when the beacon reports a location value, till the time the app issues an operation to manipulate a switch. We observed a latency of $160ms$ ($SD=69.9$) for SmartLights in the baseline case, and a latency of $270ms$ ($SD=96.1$) in the FlowFence case. The reason for increased latency is due to QM load time, and cross-process transfers of the location predicate value.

FaceDoor has two operations where latency matters. First, the enroll latency is the time it takes the app to extract features from a provided bitmap of a person’s face. Second, recognition latency is the time it takes the app to match a given bitmap of a person’s face to an item in the app’s database of features. We used images of our team members (6), measuring 612×816 pixels with an average

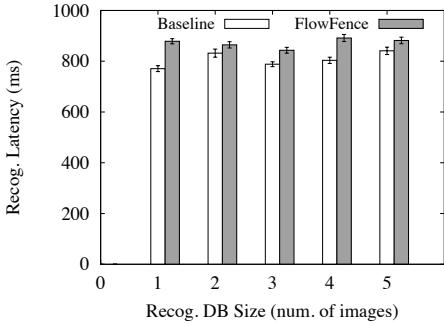

Figure 5: FaceDoor Recognition Latency (*ms*) on varying DB sizes for Baseline and FlowFence. Using FlowFence causes 5% increase in average latency.

HeartRateMonitor Metric (fps)	Baseline	FlowFence
	Avg (SD)	Avg (SD)
Throughput with no Image Processing	23.0 (0.7)	22.9 (0.7)
Throughput with Image Processing	22.9 (0.7)	22.7 (0.7)

Table 3: Throughput for HeartRateMonitor on Baseline (Stock Android) and FlowFence. FlowFence imposes little overhead on the app.

size of 290.3kB (SD=15.2).

We observed an enroll latency of 811ms (SD=37.1) in the baseline case, and 937ms (SD=60.4) for FlowFence, averaged over 50 trials. The increase in latency (15.5%) is due to QM load time, and marshaling costs for transferring bitmaps over process boundaries. While the increase in latency is well within bounds of network variations, and undetectable by user in both previous cases; it is important to recognize that most of this increase is resulted from setup time and the effect on actual processing time is much more modest. Figure 5 shows latency for face recognition, averaged over 10 trials, for Baseline, and FlowFence. We varied the recognition database size from 1 to 5 images. In each test, the last image enrolled in the database is a specific person’s face that we designated as the test face. While invoking the recognition operation, we used another image of the same test person’s face. We observe a modest, and expected increase in latency when FaceDoor runs on FlowFence. For instance, it took 882ms to successfully recognize a face in a DB of 5 images and unlock the door on FlowFence, compared to 841ms on baseline—a 4.9% increase. This latency is smaller than 100ms and thus small enough to not cause user-noticeable delays in unlocking a door once a face is recognized [13].

Throughput. Table 3 summarizes the throughput in

frames per second (fps) for HeartRateMonitor. We observed a throughput of 23.0*fps* on Stock Android for an app that read frames at maximum rate from a camera over a period of 120 seconds. We repeated the same experiment with the image processing load of heart rate detection, and observed no change in throughput. These results matched our expectations, given that the additional serialization and call latency is too low to impact the throughput of reading from the camera (camera was the bottleneck). Thus, we observed no change in the app’s abilities to derive heart rate.

6 Discussion and Limitations

Overtainting. Overtainting is difficult to avoid in taint propagation systems. FlowFence limits overtainting in two ways: (1) by not propagating taint labels from a QM to its caller—an opaque handle returned as a result of a call to a QM has an associated taint but does not cause the caller to become tainted (unless the caller is a QM that dereferences the handle), limiting the taints to QMs; and (2) a QM (and associated sandbox) is ephemeral. Since FlowFence sanitizes sandboxes if a new occupant’s taints differ from the previous occupant, reusing sandboxes does not cause overtainting. Nevertheless, FlowFence does not prevent overtainting due to poor application decomposition into QMs.

A malicious publisher can potentially overtaint a consumer by publishing overtainted data that the consumer subscribes to, leading to poison-pill attacks [37]. A plausible defense strategy is to allow a consumer to inspect an item’s taint and not proceed with a read if the item is overtainted [63]. However, this risks introducing a signaling mechanism from a high producer to a low consumer via changes to the item’s taint set. To address the attack in the context of our system. We first observe that most publishers will publish their sensor data under a known, fixed taint. The key idea is to simply require publishers to define a *taint bound* TM_c , whenever a channel c is created.⁸ If the publisher writes data with a taint set T that is not a subset of TM_c to the channel c , the write operation is denied and results in an exception; else the write is allowed. The consumer, to avoid getting overtainted, can inspect this channel’s taint bound (but not the item’s taint) before deciding to read an item from the channel. The taint bound cannot be modified, once defined, avoiding the signaling problem. A similar defense mechanism was proposed in label-based IFC systems [63, 62].

Applicability of Opacified Computation to other domains. In this work we only discussed Opacified Com-

⁸Same idea applies when creating keys, with a taint bound defined at that time for any future value associated with the key.

putation in the context of IoT frameworks (*e.g.*, FlowFence Key-Value Store and Event Channels are inspired by our IoT framework study). The basic Opacified Computation model is broadly applicable. For example, there is nothing fundamental preventing our hub from being a mobile smartphone and the app running on it being a mobile app. But, applying FlowFence to existing mobile apps is challenging because of the need to refactor apps and the libraries they use (many of the libraries access sensitive data as well as sinks). As another design point, there is no fundamental limitation that requires IoT hub software to run in a user’s home; it could well be cloud-hosted and provided as a trusted cloud-based service for supporting computations on sensitive data. Use of a cloud-based service for executing apps is not unusual—SmartThings runs all apps on its cloud, using a hub to primarily serve as a gateway for connecting devices to the cloud-based apps.

Usability of Flow Prompts. FlowFence suffers from the same limitation as all systems where users need to make security decisions, in that we cannot prevent users from approving flows that they should not. FlowFence does offer additional information during prompts since it presents flow requests with sources and sinks indicating *how* the app intends to use data, possibly leading to more informed decision-making. Flow prompts to request user permissions could be avoided if publisher policies always overrode consumer policies, with no user override allowed. But that just shifts the burden to specifying publisher policies correctly, which still may require user involvement. User education on flow policies and further user studies are likely going to be required to examine usability of flow prompts. In some IoT environments, the right to configure policies or grant overrides could be assigned to specially-trained administrators who manage flow policies on behalf of users and install apps and devices for them.

Measuring flows. Almuhamidi *et al.* performed a user study that suggests that providing metrics on frequency of use of a previously granted permission can nudge users to patch their privacy policy [6]. For example, if a user is told that an app read their location 5,398 times over a day, they may be more inclined to prevent that app from getting full access to the location. Adding support for measuring flows (both permitted and denied) to assist users in evaluating past flow permissions is part of future work.

Side Channels. A limitation of our current design is that attackers can encode sensitive data values in the time it takes for QMs to return. Such side channel techniques are primarily applicable to leaking low-bandwidth data. Nevertheless, we are investigating techniques to restrict this particular channel by making QMs return immediately, and have them execute asynchronously, thus elim-

inating the availability of fine-grain timing information in the opaque handles (as in LIO [61]). This would involve creating opaque handle dependency graphs that determine how to schedule QMs for later execution. Furthermore, timing channel leakages can be bounded using predictive techniques [72].

7 Related Work

IoT Security. Current research focuses around analyzing the security of devices [35, 27], protocols [44, 11], or platforms [26, 12]. For example, Fernandes *et al.* showed how malicious apps can steal pincodes [26]. Current IoT frameworks only offer access control but not data-flow control primitives (§2). In contrast, our work introduces, to the best of our knowledge, the first security model targeted at controlling data flows in IoT apps.

Permission Models. We observe that IoT framework permissions are modeled after smartphone permissions. There has been a large research effort at analyzing, and improving access control in smartphone frameworks [20, 49, 22, 24, 51, 50, 10, 16, 43, 68]. For instance, Enck *et al.* introduced the idea that dangerous permission combinations are indicative of possibly malicious activity [20]. Roesner *et al.* introduced User-Driven Access control where apps prompt for permissions only when they need it [51, 50]. However, permissions are fundamentally only gate-keepers. The *PlaceRaider* sensory malware abuses granted permissions and uses smartphone sensors (*e.g.*, camera) to reconstruct the 3D environment of the user for reconnaissance [64]. This malware exploits the inability of permission systems to control data usage once access is granted. The IoT fundamentally has a lot more sensitive data than a single smartphone camera, motivating the need for a security model that is capable of strictly controlling data use once apps obtain access. PiBox does offer privacy guarantees using differential-privacy algorithms after apps gain permissions, but it is primarily applicable to apps that gather aggregate statistics [43]. In contrast, FlowFence controls data flows between arbitrary types of publishers and consumers.

Label-based Information Flow Control. FlowFence builds on substantial prior work on information flow control that use labeling architectures [52, 42, 18, 71, 63, 28, 62, 41, 15, 38, 46]. For example, Flume [42] enforces flow control at the level of processes while retaining existing OS abstractions, Hails [28] presents a web framework that uses MAC to confine untrusted web apps, and COWL [63] introduces labeled compartments for JavaScript code in web apps. Although FlowFence is closely related to such systems, it also makes design choices tailored to meet the needs specific to the IoT domain. In terms of similarities, FlowFence shares the design principles of making information flow explicit, con-

trolling information flow at a higher granularity than the instruction-level, and supporting declassification. However, these systems only support producer (source) defined policies whereas FlowFence supports policies defined by both producing and consuming apps. This feature allows for more versatility in environments such as IoT, where a variety of consuming apps could request for a diverse set of flows. Our evaluation shows hows such a mix of flow policies supports real IoT apps (§5.2).

Computation on Opacified Data. Jana *et al.* built the recognizer OS abstraction and Darkly [39, 40]—systems that enable apps to compute on perceptual data while protecting the user’s privacy. These systems also use opaque handles, but they only support trusted functions operating on the raw data that handles refer to. In contrast, FlowFence supports untrusted third-party functions executing over raw data while providing flow control guarantees. Furthermore, these systems leverage characteristics of the data they are trying to protect to achieve security guarantees. For example, Darkly depends on camera streams being amenable to privacy transforms, allowing it to substitute low-fidelity data for high-fidelity data, and it depends on apps being able to tolerate the differences. However, in the general case, neither IoT data nor their apps may be amenable to such transforms. FlowFence is explicitly designed to support computation over sensitive IoT data in the general case.

Taint Tracking. Taint tracking systems [69, 19] are popular techniques for enforcing flow control that monitor data flows through programs [60]. Beyond performance issues [48], such techniques suffer from an inability to effectively handle implicit flows, and concurrency [59]. Although there are techniques to reduce computational burden [54, 65], they often require specialized hardware, not necessarily available in IoT environments. These techniques are also difficult to apply to situations where taint labels are not known *a priori* (*e.g.*, manage tainted data that is generated by apps, rather than known sources). Compared to these techniques, FlowFence adds little performance overhead. Furthermore, FlowFence does not require specialized hardware, and does not suffer from implicit flow attacks.

Static Analysis. Another class of systems such as FlowDroid [9], and Amandroid [66] use static taint tracking to enforce flow control. While these techniques do not suffer from performance issues associated with dynamic systems, they still suffer from same shortcomings associated with concurrency and implicit flows [9]. Besides static analysis techniques, there are also language-based techniques, such as JFlow [45], that require the developer to learn and use a single security-typed language. In contrast, FlowFence supports building apps using unmodified existing languages and development tools, enabling developers to quickly port their apps.

8 Conclusions

Emerging IoT programming frameworks only support permission based access control on sensitive data, making it possible for malicious apps to abuse permissions and leak data. In this work, we introduce the Opacified Computation model, and its concrete instantiation, FlowFence, which requires consumers of sensitive data to explicitly declare intended data flows. It enforces the declared flows and prevents all other flows, including implicit flows, efficiently. To achieve this, FlowFence requires developers to split their apps into: (1) A set of communicating Quarantined Modules with the unit of communication being opaque handles—taint tracked, opaque references to data that can only be dereferenced inside sandboxes; (2) Non-sensitive code that does not compute on sensitive data, but it still orchestrates execution of Quarantined Modules that compute on sensitive data. We ported three IoT apps to FlowFence, each requiring less than 140 additional lines of code. Latency and throughput measurements of crucial operations of the ported apps indicate that FlowFence adds little overhead. For instance, we observed a 4.9% latency increase to recognize a face in a door controller app.

Appendix A: FlowFence API

We summarize the object-oriented FlowFence API for developers in Table 4. There are two kinds of API: QM-management, and Within-QM. Developers use the QM-management API to request loading QMs into sandboxes, making QM calls, and receiving opaque handles as return values. The primary data types are: $QM <T>$, and $Handle$. The former data type represents a reference to a loaded QM. The latter data type represents an opaque handle, that FlowFence creates as a return value of a QM. Developers use `resolveCtor`, or `resolveM` to load a specific QM into a sandbox (FlowFence automatically manages sandboxes), and receive a reference to the loaded QM. Then, developers specify the string name of a QM method to execute.

The Within-QM API is available to QMs while they are executing within a sandbox. Currently, FlowFence has two data types available for QMs. *KVStore* offers ways to get and put values in the Key-Value store. The Trusted API offers facilities like network communication, logging, and smart home control (our prototype has a bridge to SmartThings).

QM-management Data Types and API	Semantics
<code>Handle</code>	An opaque handle. Data is stored in the Trusted Service, with its taint labels.
$QM <T>$	A reference to a QM of type T, on which developers can issue method calls.
$QM <T> \text{ ctor} = \text{resolveCtor}(T)$	Resolve the constructor for QM T, and return a reference to it.
$QM <T> m = \text{resolveM}(\text{retType}, T, \text{methStr}, [\text{paramTypes}])$	Resolve an instance/static method of a QM, loading the QM into a sandbox if necessary.
$Handle \text{ ret} = QM <T>.\text{call}([\text{argList}])$	Call a method on a loaded QM, and return an opaque handle as the result.
<code>subscribeEventChannel(appID, $QM <T>$)</code>	Subscribe to a channel for updates, and register a QM to be executed automatically whenever new data is placed on the channel.
Within-QM Data Types and API	Semantics
<code>KVStore</code>	Provides methods to interact with the Key-Value Store.
<code>KVStore kvs = getKVStore(appID, name)</code>	Get a reference to a named KVStore.
<code>kvs.put<T>(key, value, taint_label)</code>	Put a (key, value) pair into the KVStore along with a taint label, where T can be a basic type such as Int, Float, or a serializable type. Any existing taint of the calling QM will be automatically associated with the value's final set of taint labels.
<code>T value = kvs.get<T>(key)</code>	Get the value of type T corresponding to specified key, and taint the QM with the appropriate set of taint labels.
<code>getTrustedAPI(apiName).invoke([params])</code>	Call a Trusted API method to declassify sensitive data.
<code>getChannel(chanName).fireEvent(taint_label, [params])</code>	Fire an event with parameters, specifying taint label. Any existing taint labels of the calling QM will be added automatically.

Table 4: FlowFence API Summary. QM-management data types and API is only available to the untrusted portion of an app that does not operate with sensitive data. The Within-QM data types and API is available only to QMs.

ARMageddon: Cache Attacks on Mobile Devices

Moritz Lipp, Daniel Gruss, Raphael Spreitzer, Clémentine Maurice, and Stefan Mangard
Graz University of Technology, Austria

Abstract

In the last 10 years, cache attacks on Intel x86 CPUs have gained increasing attention among the scientific community and powerful techniques to exploit cache side channels have been developed. However, modern smartphones use one or more multi-core ARM CPUs that have a different cache organization and instruction set than Intel x86 CPUs. So far, no cross-core cache attacks have been demonstrated on non-rooted Android smartphones. In this work, we demonstrate how to solve key challenges to perform the most powerful cross-core cache attacks *Prime+Probe*, *Flush+Reload*, *Evict+Reload*, and *Flush+Flush* on non-rooted ARM-based devices without any privileges. Based on our techniques, we demonstrate covert channels that outperform state-of-the-art covert channels on Android by several orders of magnitude. Moreover, we present attacks to monitor tap and swipe events as well as keystrokes, and even derive the lengths of words entered on the touchscreen. Eventually, we are the first to attack cryptographic primitives implemented in Java. Our attacks work across CPUs and can even monitor cache activity in the ARM TrustZone from the normal world. The techniques we present can be used to attack hundreds of millions of Android devices.

1 Introduction

Cache attacks represent a powerful means of exploiting the different access times within the memory hierarchy of modern system architectures. Until recently, these attacks explicitly targeted cryptographic implementations, for instance, by means of cache timing attacks [9] or the well-known *Evict+Time* and *Prime+Probe* techniques [43]. The seminal paper by Yarom and Falkner [60] introduced the so-called *Flush+Reload* attack, which allows an attacker to infer which specific parts of a binary are accessed by a victim program with an unprecedented accuracy and probing frequency. Recently, Gruss et al. [19] demonstrated

the possibility to use *Flush+Reload* to automatically exploit cache-based side channels via cache template attacks on Intel platforms. *Flush+Reload* does not only allow for efficient attacks against cryptographic implementations [8, 26, 56], but also to infer keystroke information and even to build keyloggers on Intel platforms [19]. In contrast to attacks on cryptographic algorithms, which are typically triggered multiple times, these attacks require a significantly higher accuracy as an attacker has only one single chance to observe a user input event.

Although a few publications about cache attacks on AES T-table implementations on mobile devices exist [10, 50–52, 57], the more efficient cross-core attack techniques *Prime+Probe*, *Flush+Reload*, *Evict+Reload*, and *Flush+Flush* [18] have not been applied on smartphones. In fact, there was reasonable doubt [60] whether these cross-core attacks can be mounted on ARM-based devices at all. In this work, we demonstrate that these attack techniques are applicable on ARM-based devices by solving the following key challenges systematically:

1. *Last-level caches are not inclusive on ARM and thus cross-core attacks cannot rely on this property.* Indeed, existing cross-core attacks exploit the inclusiveness of shared last-level caches [18, 19, 22, 24, 35, 37, 38, 42, 60] and, thus, no cross-core attacks have been demonstrated on ARM so far. We present an approach that exploits coherence protocols and L1-to-L2 transfers to make these attacks applicable on mobile devices with non-inclusive shared last-level caches, irrespective of the cache organization.¹
2. *Most modern smartphones have multiple CPUs that do not share a cache.* However, cache coherence protocols allow CPUs to fetch cache lines from remote cores faster than from the main memory. We utilize this property to mount both cross-core and cross-CPU attacks.

¹Simultaneously to our work on ARM, Irazoqui et al. [25] developed a technique to exploit cache coherence protocols on AMD x86 CPUs and mounted the first cross-CPU cache attack.

3. *Except ARMv8-A CPUs, ARM processors do not support a flush instruction.* In these cases, a fast eviction strategy must be applied for high-frequency measurements. As existing eviction strategies are too slow, we analyze more than 4 200 eviction strategies for our test devices, based on Rowhammer attack techniques [17].
4. *ARM CPUs use a pseudo-random replacement policy* to decide which cache line to replace within a cache set. This introduces additional noise even for robust time-driven cache attacks [50, 52]. For the same reason, *Prime+Probe* has been an open challenge [51] on ARM, as an attacker needs to predict which cache line will be replaced first and wrong predictions destroy measurements. We design re-access loops that interlock with a cache eviction strategy to reduce the effect of wrong predictions.
5. *Cycle-accurate timings require root access on ARM* [3] and alternatives have not been evaluated so far. We evaluate different timing sources and show that cache attacks can be mounted in any case.

Based on these building blocks, we demonstrate practical and highly efficient cache attacks on ARM.² We do not restrict our investigations to cryptographic implementations but also consider cache attacks as a means to infer other sensitive information—such as inter-keystroke timings or the length of a swipe action—requiring a significantly higher measurement accuracy. Besides these generic attacks, we also demonstrate that cache attacks can be used to monitor cache activity caused within the ARM TrustZone from the normal world. Nevertheless, we do not aim to exhaustively list possible exploits or find new attack vectors on cryptographic algorithms. Instead, we aim to demonstrate the immense attack potential of the presented cross-core and cross-CPU attacks on ARM-based mobile devices based on well-studied attack vectors. Our work allows to apply existing attacks to millions of off-the-shelf Android devices without any privileges. Furthermore, our investigations show that Android still employs vulnerable AES T-table implementations.

Contributions. The contributions of this work are:

- We demonstrate the applicability of highly efficient cache attacks like *Prime+Probe*, *Flush+Reload*, *Evict+Reload*, and *Flush+Flush* on ARM.
- Our attacks work irrespective of the actual cache organization and, thus, are the first last-level cache attacks that can be applied cross-core and also cross-CPU on off-the-shelf ARM-based devices. More specifically, our attacks work against last-

²Source code for ARMageddon attack examples can be found at <https://github.com/IAIK/armageddon>.

level caches that are instruction-inclusive and data-non-inclusive as well as caches that are instruction-non-inclusive and data-inclusive.

- Our cache-based covert channel outperforms all existing covert channels on Android by several orders of magnitude.
- We demonstrate the power of these attacks by attacking cryptographic implementations and by inferring more fine-grained information like keystrokes and swipe actions on the touchscreen.

Outline. The remainder of this paper is structured as follows. In Section 2, we provide information on background and related work. Section 3 describes the techniques that are the building blocks for our attacks. In Section 4, we demonstrate and evaluate fast cross-core and cross-CPU covert channels on Android. In Section 5, we demonstrate cache template attacks on user input events. In Section 6, we present attacks on cryptographic implementations used in practice as well the possibility to observe cache activity of cryptographic computations within the TrustZone. We discuss countermeasures in Section 7 and conclude this work in Section 8.

2 Background and Related Work

In this section, we provide the required preliminaries and discuss related work in the context of cache attacks.

2.1 CPU Caches

Today’s CPU performance is influenced not only by the clock frequency but also by the latency of instructions, operand fetches, and other interactions with internal and external devices. In order to overcome the latency of system memory accesses, CPUs employ caches to buffer frequently used data in small and fast internal memories.

Modern caches organize cache lines in multiple sets, which is also known as set-associative caches. Each memory address maps to one of these cache sets and addresses that map to the same cache set are considered congruent. Congruent addresses compete for cache lines within the same set and a predefined replacement policy determines which cache line is replaced. For instance, the last generations of Intel CPUs employ an undocumented variant of least-recently used (LRU) replacement policy [17]. ARM processors use a pseudo-LRU replacement policy for the L1 cache and they support two different cache replacement policies for L2 caches, namely round-robin and pseudo-random replacement policy. In practice, however, only the pseudo-random replacement policy is used due to performance reasons. Switching the cache replacement policy is only possible in privi-

leged mode. The implementation details for the pseudo-random policy are not documented.

CPU caches can either be virtually indexed or physically indexed, which determines whether the index is derived from the virtual or physical address. A so-called tag uniquely identifies the address that is cached within a specific cache line. Although this tag can also be based on the virtual or physical address, most modern caches use physical tags because they can be computed simultaneously while locating the cache set. ARM typically uses physically indexed, physically tagged L2 caches.

CPUs have multiple cache levels, with the lower levels being faster and smaller than the higher levels. ARM processors typically have two levels of cache. If all cache lines from lower levels are also stored in a higher-level cache, the higher-level cache is called *inclusive*. If a cache line can only reside in one of the cache levels at any point in time, the caches are called *exclusive*. If the cache is neither inclusive nor exclusive, it is called *non-inclusive*. The last-level cache is often shared among all cores to enhance the performance upon transitioning threads between cores and to simplify cross-core cache lookups. However, with shared last-level caches, one core can (intentionally) influence the cache content of all other cores. This represents the basis for cache attacks like *Flush+Reload* [60].

In order to keep caches of multiple CPU cores or CPUs in a coherent state, so-called coherence protocols are employed. However, coherence protocols also introduce exploitable timing effects, which has recently been exploited by Irazoqui et al. [25] on x86 CPUs.

In this paper, we demonstrate attacks on three smartphones as listed in Table 1. The Krait 400 is an ARMv7-A CPU, the other two processors are ARMv8-A CPUs. However, the stock Android of the Alcatel One Touch Pop 2 is compiled for an ARMv7-A instruction set and thus ARMv8-A instructions are not used. We generically refer to ARMv7-A and ARMv8-A as “ARM architecture” throughout this paper. All devices have a shared L2 cache. On the Samsung Galaxy S6, the flush instruction is unlocked by default, which means that it is available in userspace. Furthermore, all devices employ a cache coherence protocol between cores and on the Samsung Galaxy S6 even between the two CPUs [6].

2.2 Shared Memory

Read-only shared memory can be used as a means of memory usage optimization. In case of shared libraries it reduces the memory footprint and enhances the speed by lowering cache contention. The operating system implements this behavior by mapping the same physical memory into the address space of each process. As this memory sharing mechanism is independent of how a file was

opened or accessed, an attacker can map a binary to have read-only shared memory with a victim program. A similar effect is caused by content-based page deduplication where physical pages with identical content are merged.

Android applications are usually written in Java and, thus, contain self-modifying code or just-in-time compiled code. This code would typically not be shared. Since Android version 4.4 the Dalvik VM was gradually replaced by the Android Runtime (ART). With ART, Java byte code is compiled to native code binaries [1] and thus can be shared too.

2.3 Cache Attacks

Initially, cache timing attacks were performed on cryptographic algorithms [9, 30, 31, 40, 41, 44, 55]. For example, Bernstein [9] exploited the total execution time of AES T-table implementations. More fine-grained exploitations of memory accesses to the CPU cache have been proposed by Percival [45] and Osvik et al. [43]. More specifically, Osvik et al. formalized two concepts, namely *Evict+Time* and *Prime+Probe*, to determine which specific cache sets were accessed by a victim program. Both approaches consist of three basic steps.

Evict+Time:

1. Measure execution time of victim program.
2. Evict a specific cache set.
3. Measure execution time of victim program again.

Prime+Probe:

1. Occupy specific cache sets.
2. Victim program is scheduled.
3. Determine which cache sets are still occupied.

Both approaches allow an adversary to determine which cache sets are used during the victim’s computations and have been exploited to attack cryptographic implementations [24, 35, 43, 54] and to build cross-VM covert channels [37]. Yarom and Falkner [60] proposed *Flush+Reload*, a significantly more fine-grained attack that exploits three fundamental concepts of modern system architectures. First, the availability of shared memory between the victim process and the adversary. Second, last-level caches are typically shared among all cores. Third, Intel platforms use inclusive last-level caches, meaning that the eviction of information from the last-level cache leads to the eviction of this data from all lower-level caches of other cores, which allows any program to evict data from other programs on other cores. While the basic idea of this attack has been proposed by Gullasch et al. [21], Yarom and Falkner extended this idea to shared last-level caches, allowing cross-core attacks. *Flush+Reload* works as follows.

Flush+Reload:

1. Map binary (e.g., shared object) into address space.
2. Flush a cache line (code or data) from the cache.

Table 1: Test devices used in this paper.

Device	SoC	CPU (cores)	L1 caches	L2 cache	Inclusiveness
OnePlus One	Qualcomm Snapdragon 801	Krait 400 (2) 2.5 GHz	2× 16 KB, 4-way, 64 sets	2 048 KB, 8-way, 2 048 sets	non-inclusive
Alcatel One Touch Pop 2	Qualcomm Snapdragon 410	Cortex-A53 (4) 1.2 GHz	4× 32 KB, 4-way, 128 sets	512 KB, 16-way, 512 sets	instruction-inclusive, data-non-inclusive
Samsung Galaxy S6	Samsung Exynos 7 Octa 7420	Cortex-A57 (4) 1.5 GHz 2.1 GHz	4× 32 KB, 4-way, 128 sets 2× 32 KB, 2-way, 256 sets	256 KB, 16-way, 256 sets 2 048 KB, 16-way, 2 048 sets	instruction-inclusive, data-non-inclusive instruction-non-inclusive, data-inclusive

3. Schedule the victim program.
4. Check if the corresponding line from step 2 has been loaded by the victim program.

Thereby, *Flush+Reload* allows an attacker to determine which specific instructions are executed and also which specific data is accessed by the victim program. Thus, rather fine-grained attacks are possible and have already been demonstrated against cryptographic implementations [22, 27, 28]. Furthermore, Gruss et al. [19] demonstrated the possibility to automatically exploit cache-based side-channel information based on the *Flush+Reload* approach. Besides attacking cryptographic implementations like AES T-table implementations, they showed how to infer keystroke information and even how to build a keylogger by exploiting the cache side channel. Similarly, Oren et al. [42] demonstrated the possibility to exploit cache attacks on Intel platforms from JavaScript and showed how to infer visited websites and how to track the user’s mouse activity.

Gruss et al. [19] proposed the *Evict+Reload* technique that replaces the flush instruction in *Flush+Reload* by eviction. While it has no practical application on x86 CPUs, we show that it can be used on ARM CPUs. Recently, *Flush+Flush* [18] has been proposed. Unlike other techniques, it does not perform any memory access but relies on the timing of the flush instruction to determine whether a line has been loaded by a victim. We show that the execution time of the ARMv8-A flush instruction also depends on whether or not data is cached and, thus, can be used to implement this attack.

While the attacks discussed above have been proposed and investigated for Intel processors, the same attacks were considered not applicable to modern smartphones due to differences in the instruction set, the cache organization [60], and in the multi-core and multi-CPU architecture. Thus, only same-core cache attacks have been demonstrated on smartphones so far. For instance, Weïß et al. [57] investigated Bernstein’s cache-timing attack [9] on a Beagleboard employing an ARM Cortex-A8 processor. Later on, Weïß et al. [58] investigated this timing attack in a multi-core setting on a development

board. As Weïß et al. [57] claimed that noise makes the attack difficult, Spreitzer and Plos [52] investigated the applicability of Bernstein’s cache-timing attack on different ARM Cortex-A8 and ARM Cortex-A9 smartphones running Android. Both investigations [52, 57] confirmed that timing information is leaking, but the attack takes several hours due to the high number of measurement samples that are required, *i.e.*, about 2^{30} AES encryptions. Later on, Spreitzer and Gérard [50] improved upon these results and managed to reduce the key space to a complexity which is practically relevant.

Besides Bernstein’s attack, another attack against AES T-table implementations has been proposed by Bogdanov et al. [10], who exploited so-called wide collisions on an ARM9 microprocessor. In addition, power analysis attacks [13] and electromagnetic emanations [14] have been used to visualize cache accesses during AES computations on ARM microprocessors. Furthermore, Spreitzer and Plos [51] implemented *Evict+Time* [43] in order to attack an AES T-table implementation on Android-based smartphones. However, so far only cache attacks against AES T-table implementations have been considered on smartphone platforms and none of the recent advances have been demonstrated on mobile devices.

3 ARMageddon Attack Techniques

We consider a scenario where an adversary attacks a smartphone user by means of a malicious application. This application *does not require any permission* and, most importantly, it can be executed in unprivileged userspace and *does not require a rooted device*. As our attack techniques do not exploit specific vulnerabilities of Android versions, they work on stock Android ROMs as well as customized ROMs in use today.

3.1 Defeating the Cache Organization

In this section, we tackle the aforementioned challenges 1 and 2, *i.e.*, the last-level cache is not inclusive and multiple processors do not necessarily share a cache level.

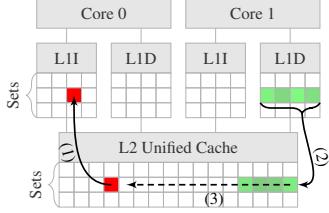

Figure 1: Cross-core instruction cache eviction through data accesses.

When it comes to caches, ARM CPUs are very heterogeneous compared to Intel CPUs. For example, whether or not a CPU has a second-level cache can be decided by the manufacturer. Nevertheless, the last-level cache on ARM devices is usually shared among all cores and it can have different inclusiveness properties for instructions and data. Due to cache coherence, shared memory is kept in a coherent state across cores and CPUs. This is of importance when measuring timing differences between cache accesses and memory accesses (cache misses), as fast remote-cache accesses are performed instead of slow memory accesses [6]. In case of a non-coherent cache, a cross-core attack is not possible but an attacker can run the spy process on all cores simultaneously and thus fall back to a same-core attack. However, we observed that caches are coherent on all our test devices.

To perform a cross-core attack we load enough data into the cache to fully evict the corresponding last-level cache set. Thereby, we exploit that we can fill the last-level cache directly or indirectly depending on the cache organization. On the Alcatel One Touch Pop 2, the last-level cache is instruction-inclusive and thus we can evict instructions from the local caches of the other core. Figure 1 illustrates such an eviction. In step 1, an instruction is allocated to the last-level cache and the instruction cache of one core. In step 2, a process fills its core's data cache, thereby evicting cache lines into the last-level cache. In step 3, the process has filled the last-level cache set using only data accesses and thereby evicts the instructions from instruction caches of other cores as well.

We access cache lines multiple times to perform transfers between L1 and L2 cache. Thus, more and more addresses used for eviction are cached in either L1 or L2. As ARM CPUs typically have L1 caches with a very low associativity, the probability of eviction to L2 through other system activity is high. Using an eviction strategy that performs frequent transfers between L1 and L2 increases this probability further. Thus, this approach also works for other cache organizations to perform cross-core and cross-CPU cache attacks. Due to the cache coherence protocol between the CPU cores [6, 33], remote-core fetches are faster than memory accesses and thus can be distinguished from cache misses. For instance,

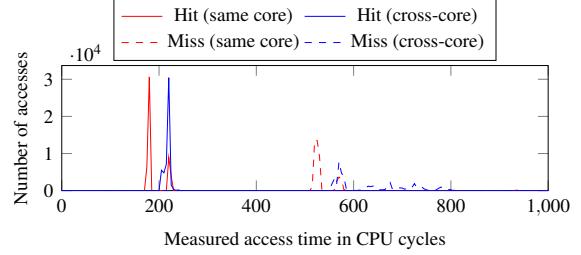

Figure 2: Histograms of cache hits and cache misses measured same-core and cross-core on the OnePlus One.

Figure 2 shows the cache hit and miss histogram on the OnePlus One. The cross-core access introduces a latency of 40 CPU cycles on average. However, cache misses take more than 500 CPU cycles on average. Thus, cache hits and misses are clearly distinguishable based on a single threshold value.

3.2 Fast Cache Eviction

In this section, we tackle the aforementioned challenges 3 and 4, *i.e.*, not all ARM processors support a flush instruction, and the replacement policy is pseudo-random.

There are two options to evict cache lines: (1) the flush instruction or (2) evict data with memory accesses to congruent addresses, *i.e.*, addresses that map to the same cache set. As the flush instruction is only available on the Samsung Galaxy S6, we need to rely on eviction strategies for the other devices and, therefore, to defeat the replacement policy. The L1 cache in Cortex-A53 and Cortex-A57 has a very small number of ways and employs a least-recently used (LRU) replacement policy [5]. However, for a full cache eviction, we also have to evict cache lines from the L2 cache, which uses a pseudo-random replacement policy.

Eviction strategies. Previous approaches to evict data on Intel x86 platforms either have too much overhead [23] or are only applicable to caches implementing an LRU replacement policy [35, 37, 42]. Spreitzer and Plos [51] proposed an eviction strategy for ARMv7-A CPUs that requires to access more addresses than there are cache lines per cache set, due to the pseudo-random replacement policy. Recently, Gruss et al. [17] demonstrated how to automatically find fast eviction strategies on Intel x86 architectures. We show that their algorithm is applicable to ARM CPUs as well. Thereby, we establish eviction strategies in an automated way and significantly reduce the overhead compared to [51]. We evaluated more than 4 200 access patterns on our smartphones and identified the best eviction strategies. Even though the cache employs a random replace-

Table 2: Different eviction strategies on the Krait 400.

<i>N</i>	<i>A</i>	<i>D</i>	Cycles	Eviction rate
-	-	-	549	100.00%
11	2	2	1 578	100.00%
12	1	3	2 094	100.00%
13	1	5	2 213	100.00%
16	1	1	3 026	100.00%
24	1	1	4 371	100.00%
13	1	2	2 372	99.58%
11	1	3	1 608	80.94%
11	4	1	1 948	58.93%
10	2	2	1 275	51.12%

Table 3: Different eviction strategies on the Cortex-A53.

<i>N</i>	<i>A</i>	<i>D</i>	Cycles	Eviction rate
-	-	-	767	100.00%
23	2	5	6 209	100.00%
23	4	6	16 912	100.00%
22	1	6	5 101	99.99%
21	1	6	4 275	99.93%
20	4	6	13 265	99.44%
800	1	1	142 876	99.10%
200	1	1	33 110	96.04%
100	1	1	15 493	89.77%
48	1	1	6 517	70.78%

ment policy, average eviction rate and average execution time are reproducible. Eviction sets are computed based on physical addresses, which can be retrieved via `/proc/self/pagemap` as current Android versions allow access to these mappings to any unprivileged app without any permissions. Thus, eviction patterns and eviction sets can be efficiently computed.

We applied the algorithm of Gruss et al. [17] to a set of physically congruent addresses. Table 2 summarizes different eviction strategies, *i.e.*, loop parameters, for the Krait 400. N denotes the total eviction set size (length of the loop), A denotes the shift offset (loop increment) to be applied after each round, and D denotes the number of memory accesses in each iteration (loop body). The column *cycles* states the average execution time in CPU cycles over 1 million evictions and the last column denotes the average eviction rate. The first line in Table 2 shows the average execution time and the average eviction rate for the privileged flush instruction, which gives the best result in terms of average execution time (549 CPU cycles). We evaluated 1 863 different strategies and our best identified eviction strategy ($N = 11$, $A = 2$, $D = 2$) also achieves an average eviction rate of 100% but takes 1 578 CPU cycles. Although a strategy accessing every address in the eviction set only once ($A = 1$, $D = 1$, also called LRU eviction) performs significantly fewer memory accesses, it consumes more CPU cycles. For an average eviction rate of 100%, LRU eviction requires an eviction set size of at least 16. The average execution time then is 3 026 CPU cycles. Considering the eviction strategy used in [51] that takes 4 371 CPU cycles, clearly demonstrates the advantage of our optimized eviction strategy that takes only 1 578 CPU cycles.

We performed the same evaluation with 2 295 different strategies on the ARM Cortex-A53 in our Alcatel One Touch Pop 2 test system and summarize them in Table 3. For the best strategy we found ($N = 21$, $A = 1$, $D = 6$), we measured an average eviction rate of 99.93% and an average execution time of 4 275 CPU cycles. We observed that LRU eviction ($A = 1$, $D = 1$) on the ARM Cortex-

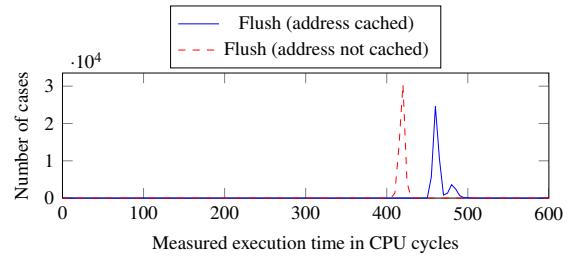

Figure 3: Histograms of the execution time of the flush operation on cached and not cached addresses measured on the Samsung Galaxy S6.

A53 would take 28 times more CPU cycles to achieve an average eviction rate of only 99.10%, thus it is not suitable for attacks on the last-level cache as used in previous work [51]. The reason for this is that data can only be allocated to L2 cache by evicting it from the L1 cache on the ARM Cortex-A53. Therefore, it is better to reaccess the data that is already in the L2 cache and gradually add new addresses to the set of cached addresses instead of accessing more different addresses.

On the ARM Cortex-A57 the userspace flush instruction was significantly faster in any case. Thus, for *Flush+Reload* we use the flush instruction and for *Prime+Probe* the eviction strategy. Falling back to *Evict+Reload* is not necessary on the Cortex-A57. Similarly to recent Intel x86 CPUs, the execution time of the flush instruction on ARM depends on whether or not the value is cached, as shown in Figure 3. The execution time is higher if the address is not cached and lower if the address is cached. This observation allows us to distinguish between cache hits and cache misses depending on the timing behavior of the flush instruction, and therefore to perform a *Flush+Flush* attack. Thus, in case of shared memory between the victim and the attacker, it is not even required to evict and reload an address in order to exploit the cache side channel.

A note on Prime+Probe. Finding a fast eviction strategy for *Prime+Probe* on architectures with a random replacement policy is not as straightforward as on Intel x86. Even in case of x86 platforms, the problem of cache trashing has been discussed by Tromer et al. [54]. Cache trashing occurs when reloading (probing) an address evicts one of the addresses that are to be accessed next. While Tromer et al. were able to overcome this problem by using a doubly-linked list that is accessed forward during the prime step and backwards during the probe step, the random replacement policy on ARM also contributes to the negative effect of cache trashing.

We analyzed the behavior of the cache and designed a prime step and a probe step that work with a smaller set size to avoid set thrashing. Thus, we set the eviction set size to 15 on the Alcatel One Touch Pop 2. As we run the *Prime+Probe* attack in a loop, exactly 1 way in the L2 cache will not be occupied after a few attack rounds. We might miss a victim access in $\frac{1}{16}$ of the cases, which however is necessary as otherwise we would not be able to get reproducible measurements at all due to set thrashing. If the victim replaces one of the 15 ways occupied by the attacker, there is still one free way to reload the address that was evicted. This reduces the chance of set thrashing significantly and allows us to successfully perform *Prime+Probe* on caches with a random replacement policy.

3.3 Accurate Unprivileged Timing

In this section, we tackle the aforementioned challenge 5, *i.e.*, cycle-accurate timings require root access on ARM.

In order to distinguish cache hits and cache misses, timing sources or dedicated performance counters can be used. We focus on timing sources, as cache misses have a significantly higher access latency and timing sources are well studied on Intel x86 CPUs. Cache attacks on x86 CPUs employ the unprivileged `rdtsc` instruction to obtain a sub-nanosecond resolution timestamp. The ARMv7-A architecture does not provide an instruction for this purpose. Instead, the ARMv7-A architecture has a performance monitoring unit that allows to monitor CPU activity. One of these performance counters—denoted as *cycle count register* (PMCCNTR)—can be used to distinguish cache hits and cache misses by relying on the number of CPU cycles that passed during a memory access. However, these performance counters are not accessible from userspace by default and an attacker would need root privileges.

We broaden the attack surface by exploiting timing sources that are accessible without any privileges or permissions. We identified three possible alternatives for timing measurements.

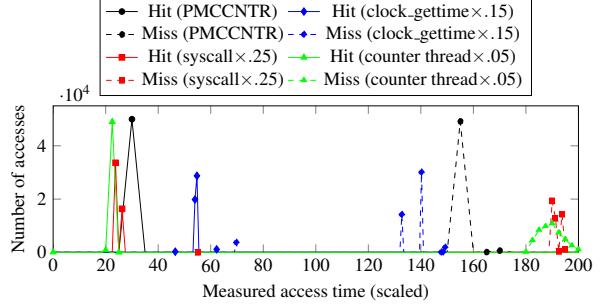

Figure 4: Histogram of cross-core cache hits/misses on the Alcatel One Touch Pop 2 using different methods. X-values are scaled for visual representation.

Unprivileged syscall. The `perf_event_open` syscall is an abstract layer to access performance information through the kernel independently of the underlying hardware. For instance, `PERF_COUNT_HW_CPU_CYCLES` returns an accurate cycle count including a minor overhead due to the syscall. The availability of this feature depends on the Android kernel configuration, *e.g.*, the stock kernel on the Alcatel One Touch Pop 2 as well as the OnePlus One provide this feature by default. Thus, in contrast to previous work [51], the attacker does not have to load a kernel module to access this information as the `perf_event_open` syscall can be accessed without any privileges or permissions.

POSIX function. Another alternative to obtain sufficiently accurate timing information is the POSIX function `clock_gettime()`, with an accuracy in the range of microseconds to nanoseconds. Similar information can also be obtained from `/proc/timer_list`.

Dedicated thread timer. If no interface with sufficient accuracy is available, an attacker can run a thread that increments a global variable in a loop, providing a fair approximation of a cycle counter. Our experiments show that this approach works reliably on smartphones as well as recent x86 CPUs. The resolution of this threaded timing information is as high as with the other methods.

In Figure 4 we show the cache hit and miss histogram based on the four different methods, including the cycle count register, on a Alcatel One Touch Pop 2. Despite the latency and noise, cache hits and cache misses are clearly distinguishable with all approaches. Thus, all methods can be used to implement cache attacks. Determining the best timing method on the device under attack can be done in a few seconds during an online attack.

4 High Performance Covert Channels

To evaluate the performance of our attacks, we measure the capacity of cross-core and cross-CPU cache covert channels. A covert channel enables two unprivileged applications on a system to communicate with each other without using any data transfer mechanisms provided by the operating system. This communication evades the sandboxing concept and the permission system (cf. collusion attacks [36]). Both applications were running in the background while the phone was mostly idle and an unrelated app was running as the foreground application.

Our covert channel is established on addresses of a shared library that is used by both the sender and the receiver. While both processes have read-only access to the shared library, they can transmit information by loading addresses from the shared library into the cache or evicting (flushing) it from the cache, respectively.

The covert channel transmits packets of n -bit data, an s -bit sequence number, and a c -bit checksum that is computed over data and sequence number. The sequence number is used to distinguish consecutive packets and the checksum is used to check the integrity of the packet. The receiver acknowledges valid packets by responding with an s -bit sequence number and an x -bit checksum. By adjusting the sizes of checksums and sequence numbers the error rate of the covert channel can be controlled.

Each bit is represented by one address in the shared library, whereas no two addresses are chosen that map to the same cache set. To transmit a bit value of 1, the sender accesses the corresponding address in the library. To transmit a bit value of 0, the sender does not access the corresponding address, resulting in a cache miss on the receiver's side. Thus, the receiving process observes a cache hit or a cache miss depending on the memory access performed by the sender. The same method is used for the acknowledgements sent by the receiving process.

We implemented this covert channel using *Evict+Reload*, *Flush+Reload*, and *Flush+Flush* on our smartphones. The results are summarized in Table 4. On the Samsung Galaxy S6, we achieve a cross-core transmission rate of 1 140 650 bps at an error rate of 1.10%. This is 265 times faster than any existing covert channel on smartphones. In a cross-CPU transmission we achieve a transmission rate of 257 509 bps at an error rate of 1.83%. We achieve a cross-core transition rate of 178 292 bps at an error rate of 0.48% using *Flush+Flush* on the Samsung Galaxy S6. On the Alcatel One Touch Pop 2 we achieve a cross-core transmission rate of 13 618 bps at an error rate of 3.79% using *Evict+Reload*. This is still 3 times faster than previous covert channels on smartphones. The covert channel is significantly slower on the Alcatel One Touch Pop 2 than on the Samsung Galaxy S6 because the hardware is much

slower, *Evict+Reload* is slower than *Flush+Reload*, and retransmission might be necessary in 0.14% of the cases where eviction is not successful (cf. Section 3.2). On the older OnePlus One we achieve a cross-core transmission rate of 12 537 bps at an error rate of 5.00%, 3 times faster than previous covert channels on smartphones. The reason for the higher error rate is the additional timing noise due to the cache coherence protocol performing a high number of remote-core fetches.

5 Attacking User Input on Smartphones

In this section we demonstrate cache side-channel attacks on Android smartphones. We implement cache template attacks [19] to create and exploit accurate cache-usage profiles using the *Evict+Reload* or *Flush+Reload* attack. Cache template attacks have a profiling phase and an exploitation phase. In the profiling phase, a template matrix is computed that represents how many cache hits occur on a specific address when triggering a specific event. The exploitation phase uses this matrix to infer events from cache hits.

To perform cache template attacks, an attacker has to map shared binaries or shared libraries as read-only shared memory into its own address space. By using shared libraries, the attacker bypasses any potential countermeasures taken by the operating system, such as restricted access to runtime data of other apps or address space layout randomization (ASLR). The attack can even be performed online on the device under attack if the event can be simulated.

Triggering the actual event that an attacker wants to spy on might require either (1) an offline phase or (2) privileged access. For instance, in case of a keylogger, the attacker can gather a cache template matrix offline for a specific version of a library, or the attacker relies on privileged access of the application (or a dedicated permission) in order to be able to simulate events for gathering the cache template matrix. However, the actual exploitation of the cache template matrix to infer events neither requires privileged access nor any permission.

5.1 Attacking a Shared Library

Just as Linux, Android uses a large number of shared libraries, each with a size of up to several megabytes. We inspected all available libraries on the system by manually scanning the names and identified libraries that might be responsible for handling user input, e.g., the `libinput.so` library. Without loss of generality, we restricted the set of attacked libraries since testing all libraries would have taken a significant amount of time. Yet, an adversary could exhaustively probe all libraries.

Table 4: Comparison of covert channels on Android.

Work	Type	Bandwidth [bps]	Error rate
Ours (Samsung Galaxy S6)	<i>Flush+Reload</i> , cross-core	1 140 650	1.10%
Ours (Samsung Galaxy S6)	<i>Flush+Reload</i> , cross-CPU	257 509	1.83%
Ours (Samsung Galaxy S6)	<i>Flush+Flush</i> , cross-core	178 292	0.48%
Ours (Alcatel One Touch Pop 2)	<i>Evict+Reload</i> , cross-core	13 618	3.79%
Ours (OnePlus One)	<i>Evict+Reload</i> , cross-core	12 537	5.00%
Marforio et al. [36]	Type of Intents	4 300	—
Marforio et al. [36]	UNIX socket discovery	2 600	—
Schlegel et al. [48]	File locks	685	—
Schlegel et al. [48]	Volume settings	150	—
Schlegel et al. [48]	Vibration settings	87	—

We automated the search for addresses in these shared libraries and after identifying addresses, we monitored them in order to infer user input events. For instance, in the profiling phase on `libinput.so`, we simulated events via the android-debug bridge (adb shell) with two different methods. The first method uses the `input` command line tool to simulate user input events. The second method is writing event messages to `/dev/input/event*`. Both methods can run entirely on the device for instance in idle periods while the user is not actively using the device. As the second method only requires a `write()` statement it is significantly faster, but it is also more device specific. Therefore, we used the `input` command line except when profiling differences between different letter keys. While simulating these events, we simultaneously probed all addresses within the `libinput.so` library, *i.e.*, we measured the number of cache hits that occurred on each address when triggering a specific event. As already mentioned above, the simulation of some events might require either an offline phase or specific privileges in case of online attacks.

Figure 5 shows part of the cache template matrix for `libinput.so`. We triggered the following events: key events including the power button (`key`), long touch events (`longpress`), `swipe` events, touch events (`tap`), and text input events (`text`) via the `input` tool as often as possible and measured each address and event for one second. The cache template matrix clearly reveals addresses with high cache-hit rates for specific events. Darker colors represent addresses with higher cache-hit rates for a specific event and lighter colors represent addresses with lower cache-hit rates. Hence, we can distinguish different events based on cache hits on these addresses.

We verified our results by monitoring the identified addresses while operating the smartphone manually, *i.e.*, we touched the screen and our attack application reliably reported cache hits on the monitored addresses. For instance, address `0x11040` of `libinput.so` can be used to distinguish tap actions and swipe actions on the screen of the Alcatel One Touch Pop 2. Tap actions cause a smaller

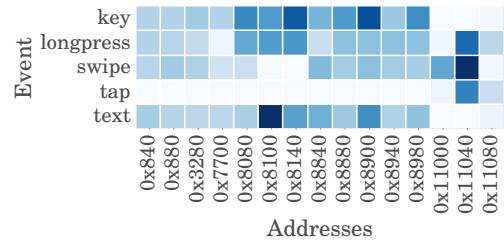

Figure 5: Cache template matrix for `libinput.so`.

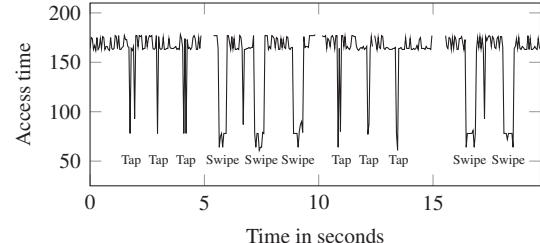

Figure 6: Monitoring address `0x11040` of `libinput.so` on the Alcatel One Touch Pop 2 reveals taps and swipes.

number of cache hits than swipe actions. Swipe actions cause cache hits in a high frequency as long as the screen is touched. Figure 6 shows a sequence of 3 tap events, 3 swipe events, 3 tap events, and 2 swipe events. These events can be clearly distinguished due to the fast access times. The gaps mark periods of time where our program was not scheduled on the CPU. Events occurring in those periods can be missed by our attack.

Swipe input allows to enter words by swiping over the soft-keyboard and thereby connecting single characters to form a word. Since we are able to determine the length of swipe movements, we can correlate the length of the swipe movement with the actual word length in any Android application or system interface that uses swipe input without any privileges. Furthermore, we can determine the actual length of the unlock pattern for the pattern-unlock mechanism.

Figure 7 shows a user input sequence consisting of 3 tap events and 3 swipe events on the Samsung Galaxy S6. The attack was conducted using *Flush+Reload*. An attacker can monitor every single event. Taps and swipes can be distinguished based on the length of the cache hit phase. The length of a swipe movement can be determined from the same information. Figure 8 shows the same experiment on the OnePlus One using *Evict+Reload*. Thus, our attack techniques work on coherent non-inclusive last-level caches.

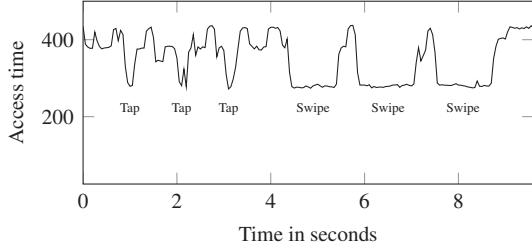

Figure 7: Monitoring address 0xDC5C of libinput.so on the Samsung Galaxy S6 reveals tap and swipe events.

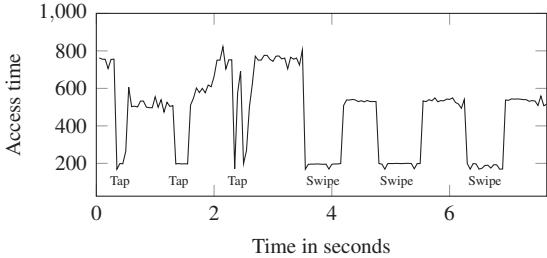

Figure 8: Monitoring address 0xBFF4 of libinput.so on the OnePlus One reveals tap and swipe events.

5.2 Attacking ART Binaries

Instead of attacking shared libraries, it is also possible to apply this attack to ART (Android Runtime) executables [1] that are compiled ahead of time. We used this attack on the default AOSP keyboard and evaluated the number of accesses to every address in the optimized executable that responds to an input of a letter on the keyboard. It is possible to find addresses that correspond to a key press and more importantly to distinguish between taps and key presses. Figure 9 shows the corresponding cache template matrix. We summarize the letter keys in one line (*alphabet*) as they did not vary significantly. These addresses can be used to monitor key presses on the keyboard. We identified an address that corresponds only to letters on the keyboard and hardly on the space bar or the return button. With this information it is pos-

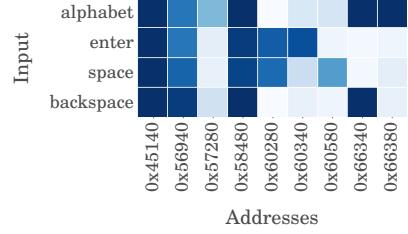

Figure 9: Cache template matrix for the default AOSP keyboard.

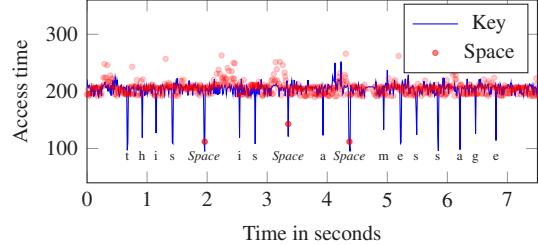

Figure 10: *Evict+Reload* on 2 addresses in custpack@ app@withoutlibs@LatinIME.apk@classes.dex on the Alcatel One Touch Pop 2 while entering the sentence “this is a message”.

sible to precisely determine the length of single words entered using the default AOSP keyboard.

We illustrate the capability of detecting word lengths in Figure 10. The blue line shows the timing measurements for the address identified for keys in general, the red dots represent measurements of the address for the space key. The plot shows that we can clearly determine the length of entered words and monitor user input accurately over time.

5.3 Discussion and Impact

Our proof-of-concept attacks exploit shared libraries and binaries from Android apk files to infer key strokes. The cache template attack technique we used for these attacks is generic and can also be used to attack any other library. For instance, there are various libraries that handle different hardware modules and software events on the device, such as GPS, Bluetooth, camera, NFC, vibrator, audio and video decoding, web and PDF viewers. Each of these libraries contains code that is executed and data that is accessed when the device is in use. Thus, an attacker can perform a cache template attack on any of these libraries and spy on the corresponding device events. For instance, our attack can be used to monitor activity of the GPS sensor, bluetooth, or the camera. An attacker can record such user activities over time to learn more about the user.

We can establish inter-keystroke timings at an accuracy as high as the accuracy of cache side-channel attacks on keystrokes on x86 systems with a physical keyboard. Thus, the inter-keystroke timings can be used to infer entered words, as has been shown by Zhang et al. [61]. Our attack even has a higher resolution than [61], *i.e.*, it is sub-microsecond accurate. Furthermore, we can distinguish between keystrokes on the soft-keyboard and generic touch actions outside the soft-keyboard. This information can be used to enhance sensor-based keyloggers that infer user input on mobile devices by exploiting, *e.g.*, the accelerometer and the gyroscope [7, 11, 12, 39, 59] or the ambient-light sensor [49]. However, these attacks suffer from a lack of knowledge when exactly a user touches the screen. Based on our attack, these sensor-based keyloggers can be improved as our attack allows to infer (1) the exact time when the user touches the screen, and (2) whether the user touches the soft-keyboard or any other region of the display.

Our attacks only require the user to install a malicious app on the smartphone. However, as shown by Oren et al. [42], *Prime+Probe* attacks can even be performed from within browser sandboxes through remote websites using JavaScript on Intel platforms. Gruss et al. [16] showed that JavaScript timing measurements in web browsers on ARM-based smartphones achieve a comparable accuracy as on Intel platforms. Thus, it seems likely that *Prime+Probe* through a website works on ARM-based smartphones as well. We expect that such attacks will be demonstrated in future work. The possibility of attacking millions of users shifts the focus of cache attacks to a new range of potential malicious applications.

In our experiments with the predecessor of ART, the Dalvik VM, we found that the just-in-time compilation effectively prevents *Evict+Reload* and *Flush+Reload* attacks. The just-in-time compiled code is not shared and thus the requirements for these two attacks are not met. However, *Prime+Probe* attacks work on ART binaries and just-in-time compiled Dalvik VM code likewise.

6 Attack on Cryptographic Algorithms

In this section we show how *Flush+Reload*, *Evict+Reload*, and *Prime+Probe* can be used to attack AES T-table implementations that are still in use on Android devices. Furthermore, we demonstrate the possibility to infer activities within the ARM TrustZone by observing the cache activity using *Prime+Probe*. We perform all attacks cross-core and in a synchronized setting, *i.e.*, the attacker triggers the execution of cryptographic algorithms by the victim process. Although more sophisticated attacks are possible, our goal is to demonstrate that our work enables practical cache attacks on smartphones.

6.1 AES T-Table Attacks

Many cache attacks against AES T-table implementations have been demonstrated and appropriate countermeasures have already been proposed. Among these countermeasures are, *e.g.*, so-called bit-sliced implementations [29, 32, 46]. Furthermore, Intel addressed the problem by adding dedicated instructions for AES [20] and ARM also follows the same direction with the ARMv8 instruction set [4]. However, our investigations showed that Bouncy Castle, a crypto library widely used in Android apps such as the WhatsApp messenger [2], still uses a T-table implementation. Moreover, the OpenSSL library, which is the default crypto provider on recent Android versions, uses T-table implementations until version 1.0.1.³ This version is still officially supported and commonly used on Android devices, *e.g.*, the Alcatel One Touch Pop 2. T-tables contain the pre-computed AES round transformations, allowing to perform encryptions and decryptions by simple XOR operations. For instance, let p_i denote the plaintext bytes, k_i the initial key bytes, and $s_i = p_i \oplus k_i$ the initial state bytes. The initial state bytes are used to retrieve pre-computed T-table elements for the next round. If an attacker knows a plaintext byte p_i and the accessed element of the T-table, it is possible to recover the key bytes $k_i = s_i \oplus p_i$. However, it is only possible to derive the upper 4 bits of k_i through our cache attack on a device with a cache line size of 64 bytes. This way, the attacker can learn 64 key bits. In second-round and last-round attacks the key space can be reduced further. For details about the basic attack strategy we refer to the work of Osvik et al. [43, 54]. Although we successfully mounted an *Evict+Reload* attack on the Alcatel One Touch Pop 2 against the OpenSSL AES implementation, we do not provide further insights as we are more interested to perform the first cache attack on a Java implementation.

Attack on Bouncy Castle. Bouncy Castle is implemented in Java and provides various cryptographic primitives including AES. As Bouncy Castle 1.5 still employs AES T-table implementations by default, all Android devices that use this version are vulnerable to our presented attack. To the best of our knowledge, we are the first to show an attack on a Java implementation.

During the initialization of Bouncy Castle, the T-tables are copied to a local private memory area. Therefore, these copies are not shared among different processes. Nevertheless, we demonstrate that *Flush+Reload* and *Evict+Reload* are efficient attacks on such an implemen-

³Later versions use a bit-sliced implementation if ARM NEON is available or dedicated AES instructions if ARMv8-A instructions are available. Otherwise, a T-table implementation is used. This is also the case for Google’s BoringSSL library.

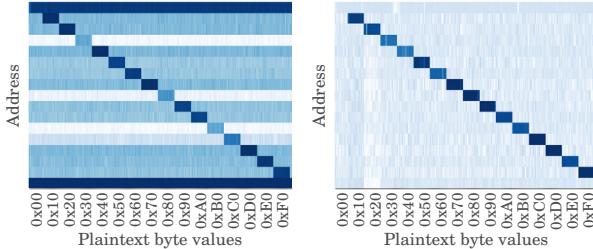

Figure 11: Attack on Bouncy Castle’s AES using *Evict+Reload* on the Alcatel One Touch Pop 2 (left) and *Flush+Reload* on the Samsung Galaxy S6 (right).

tation if shared memory is available. Further, we demonstrate a cross-core *Prime+Probe* attack without shared memory that is applicable in a real-world scenario.

Figure 11 shows a template matrix of the first T-table for all 256 values for plaintext byte p_0 and a key that is fixed to 0 while the remaining plaintext bytes are random. These plots reveal the upper 4 key bits of k_0 [43, 51]. Thus, in our case the key space is reduced to 64 bits after 256–512 encryptions. We consider a first-round attack only, because we aim to demonstrate the applicability of these attacks on ARM-based mobile devices. However, full-key recovery is possible with the same techniques by considering more sophisticated attacks targeting different rounds [47, 54], even for asynchronous attackers [22, 26].

We can exploit the fact that the T-tables are placed on a different boundary every time the process is started. By restarting the victim application we can obtain arbitrary disalignments of T-tables. Disaligned T-tables allow to reduce the key space to 20 bits on average and for specific disalignments even full-key recovery without a single brute-force computation is possible [51, 53]. We observed not a single case where the T-tables were aligned. Based on the first-round attack matrix in Figure 11, the expected number of encryptions until a key byte is identified is $1.81 \cdot 128$. Thus, full key recovery is possible after $1.81 \cdot 128 \cdot 16 = 3707$ encryptions by monitoring a single address during each encryption.

Real-world cross-core attack on Bouncy Castle. If the attacker has no way to share a targeted memory region with the victim, *Prime+Probe* instead of *Evict+Reload* or *Flush+Reload* can be used. This is the case for dynamically generated data or private memory of another process. Figure 12 shows the *Prime+Probe* histogram for cache hits and cache misses. We observe a higher execution time if the victim accesses a congruent memory location. Thus, *Prime+Probe* can be used for a real-world cross-core attack on Bouncy Castle and also allows to exploit disaligned T-tables as mentioned above.

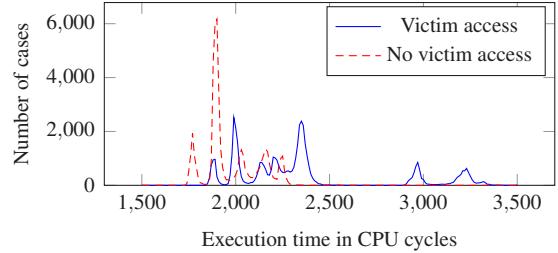

Figure 12: Histogram of *Prime+Probe* timings depending on whether the victim accesses congruent memory on the ARM Cortex-A53.

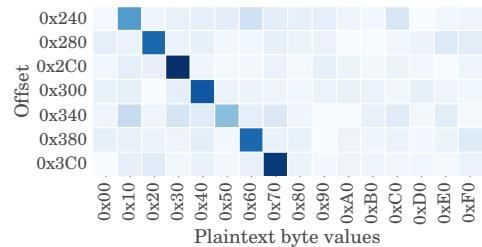

Figure 13: Excerpt of the attack on Bouncy Castle’s AES using *Prime+Probe*.

In a preprocessing step, the attacker identifies the cache sets to be attacked by performing random encryptions and searching for active cache sets. Recall that the cache set (index) is derived directly from the physical address on ARM, *i.e.*, the lowest n bits determine the offset within a 2^n -byte cache line and the next s bits determine one of the 2^s cache sets. Thus, we only have to find a few cache sets where a T-table maps to in order to identify all cache sets required for the attack. On x86 the replacement policy facilitates this attack and allows even to deduce the number of ways that have been replaced in a specific cache set [43]. On ARM the random replacement policy makes *Prime+Probe* more difficult as cache lines are replaced in a less predictable way. To launch a *Prime+Probe* attack, we apply the eviction strategy and the crafted reaccess patterns we described in Section 3.2.

Figure 13 shows an excerpt of the cache template matrix resulting from a *Prime+Probe* attack on one T-table. For each combination of plaintext byte and offset we performed 100 000 encryptions for illustration purposes. We only need to monitor a single address to obtain the upper 4 bits of s_i and, thus, the upper 4 bits of $k_i = s_i \oplus p_i$. Compared to the *Evict+Reload* attack from the previous section, *Prime+Probe* requires 3 times as many measurements to achieve the same accuracy. Nevertheless, our results show that an attacker can run *Prime+Probe* attacks on ARM CPUs just as on Intel CPUs.

6.2 Spy on TrustZone Code Execution

The ARM TrustZone is a hardware-based security technology built into ARM CPUs to provide a secure execution environment [4]. This trusted execution environment is isolated from the *normal world* using hardware support. The TrustZone is used, e.g., as a hardware-backed credential store, to emulate secure elements for payment applications, digital rights management as well as verified boot and kernel integrity measurements. The services are provided by so-called trustlets, *i.e.*, applications that run in the secure world.

Since the secure monitor can only be called from the supervisor context, the kernel provides an interface for the userspace to interact with the TrustZone. On the Alcatel One Touch Pop 2, the TrustZone is accessible through a device driver called QSEECom (Qualcomm Secure Execution Environment Communication) and a library `libQSEEComAPI.so`. The key master trustlet on the Alcatel One Touch Pop 2 provides an interface to generate hardware-backed RSA keys, which can then be used inside the TrustZone to sign and verify signatures.

Our observations showed that a *Prime+Probe* attack on the TrustZone is not much different from a *Prime+Probe* attack on any application in the normal world. However, as we do not have access to the source code of the TrustZone OS or any trustlet, we only conduct simple attacks.⁴ We show that *Prime+Probe* can be used to distinguish whether a provided key is valid or not. While this might also be observable through the overall execution time, we demonstrate that the TrustZone isolation does not protect against cache attacks from the normal world and any trustlet can be attacked.

We evaluated cache profiles for multiple valid as well as invalid keys. Figure 14 shows the mean squared error over two runs for different valid keys and one invalid key compared to the average of valid keys. We performed *Prime+Probe* before and after the invocation of the corresponding trustlet, *i.e.*, prime before the invocation and probe afterwards. We clearly see a difference in some sets (cache sets 250–320) that are used during the signature generation using a valid key. These cache profiles are reproducible and can be used to distinguish whether a valid or an invalid key has been used in the TrustZone. Thus, the secure world leaks information to the non-secure world.

On the Samsung Galaxy S6, the TrustZone flushes the cache when entering or leaving the trusted world. However, by performing a *Prime+Probe* attack in parallel, *i.e.*, multiple times while the trustlet performs the corresponding computations, the same attack can be mounted.

⁴More sophisticated attacks would be possible by reverse engineering these trustlets.

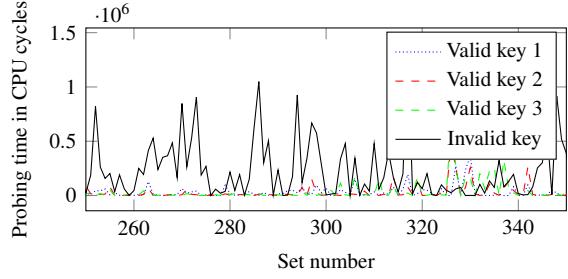

Figure 14: Mean squared error between the average *Prime+Probe* timings of valid keys and invalid keys on the Alcatel One Touch Pop 2.

7 Countermeasures

Although our attacks exploit hardware weaknesses, software-based countermeasures could impede such attacks. Indeed, we use unprotected access to system information that is available on all Android versions.

As we have shown, the operating system cannot prevent access to timing information. However, other information supplied by the operating system that facilitates these attacks could be restricted. For instance, we use `/proc/pid/` to retrieve information about any other process on the device, *e.g.*, `/proc/pid/pagemap` is used to resolve virtual addresses to physical addresses. Even though access to `/proc/pid/pagemap` and `/proc/self/pagemap` has been restricted in Linux in early 2015, the Android kernel still allows access to these resources. Given the immediately applicable attacks we presented, we stress the urgency to merge the corresponding patches into the Android kernel. Furthermore, we use `/proc/pid/maps` to determine shared objects that are mapped into the address space of a victim. Restricting access to `procfs` to specific privileges or permissions would make attacks harder. We recommend this for both the Linux kernel as well as Android.

We also exploit the fact that access to shared libraries as well as `dex` and `art` optimized program binaries is only partially restricted on the file system level. While we cannot retrieve a directory listing of `/data/dalvik-cache/`, all files are readable for any process or Android application. We recommend to allow read access to these files to their respective owner exclusively to prevent *Evict+Reload*, *Flush+Reload*, and *Flush+Flush* attacks through these shared files.

In order to prevent cache attacks against AES T-tables, hardware instructions should be used. If this is not an option, a software-only bit-sliced implementation must be employed, especially when disalignment is possible, as it is the case in Java. Since OpenSSL 1.0.2 a bit-sliced implementation is available for devices capable of the ARM

NEON instruction set and dedicated AES instructions are used on ARMv8-A devices. Cryptographic algorithms can also be protected using cache partitioning [34]. However, cache partitioning comes with a performance impact and it can not prevent all attacks, as the number of cache partitions is limited.

We responsibly disclosed our attacks and the proposed countermeasures to Google and other development groups prior to the publication of our attacks. Google has applied upstream patches preventing access to `/proc/pid/pagemap` in early 2016 and recommended installing the security update in March 2016 [15].

8 Conclusion

In this work we demonstrated the most powerful cross-core cache attacks *Prime+Probe*, *Flush+Reload*, *Evict+Reload*, and *Flush+Flush* on default configured unmodified Android smartphones. Furthermore, these attacks do not require any permission or privileges. In order to enable these attacks in real-world scenarios, we have systematically solved all challenges that prevented highly accurate cache attacks on ARM so far. Our attacks are the first cross-core and cross-CPU attacks on ARM CPUs. Furthermore, our attack techniques provide a high resolution and a high accuracy, which allows monitoring singular events such as touch and swipe actions on the screen, touch actions on the soft-keyboard, and inter-keystroke timings. In addition, we show that efficient state-of-the-art key-recovery attacks can be mounted against the default AES implementation that is part of the Java Bouncy Castle crypto provider and that cache activity in the ARM TrustZone can be monitored from the normal world.

The presented example attacks are by no means exhaustive and launching our proposed attack against other libraries and apps will reveal numerous further exploitable information leaks. Our attacks are applicable to hundreds of millions of today’s off-the-shelf smartphones as they all have very similar if not identical hardware. This is especially daunting since smartphones have become the most important personal computing devices and our techniques significantly broaden the scope and impact of cache attacks.

DRAMA: Exploiting DRAM Addressing for Cross-CPU Attacks

Peter Pessl, Daniel Gruss, Clémentine Maurice, Michael Schwarz *and Stefan Mangard*
Graz University of Technology, Austria

Abstract

In cloud computing environments, multiple tenants are often co-located on the same multi-processor system. Thus, preventing information leakage between tenants is crucial. While the hypervisor enforces software isolation, shared hardware, such as the CPU cache or memory bus, can leak sensitive information. For security reasons, shared memory between tenants is typically disabled. Furthermore, tenants often do not share a physical CPU. In this setting, cache attacks do not work and only a slow cross-CPU covert channel over the memory bus is known. In contrast, we demonstrate a high-speed covert channel as well as the first side-channel attack working across processors and without any shared memory. To build these attacks, we use the undocumented DRAM address mappings.

We present two methods to reverse engineer the mapping of memory addresses to DRAM channels, ranks, and banks. One uses physical probing of the memory bus, the other runs entirely in software and is fully automated. Using this mapping, we introduce DRAMA attacks, a novel class of attacks that exploit the DRAM row buffer that is shared, even in multi-processor systems. Thus, our attacks work in the most restrictive environments. First, we build a covert channel with a capacity of up to 2 Mbps, which is three to four orders of magnitude faster than memory-bus-based channels. Second, we build a side-channel template attack that can automatically locate and monitor memory accesses. Third, we show how using the DRAM mappings improves existing attacks and in particular enables practical Rowhammer attacks on DDR4.

1 Introduction

Due to the popularity of cloud services, multiple tenants sharing the same physical server through different virtual machines (VMs) is now a common situation. In

such settings, a major requirement is that no sensitive information is leaked between tenants, therefore proper isolation mechanisms are crucial to the security of these environments. While software isolation is enforced by hypervisors, shared hardware presents risks of information leakage between tenants. Previous research shows that microarchitectural attacks can leak secret information of victim processes, e.g., by clever analysis of data-dependent timing differences. Such side-channel measurements allow the extraction of secret information like cryptographic keys or enable communication over isolation boundaries via covert channels.

Cloud providers can deploy different hardware configurations, however multi-processor systems are becoming ubiquitous due to their numerous advantages. They offer high peak performance for parallelized tasks while enabling sharing of other hardware resources such as the DRAM. They also simplify load balancing while still keeping the area and cost footprint low. Additionally, cloud providers now commonly disable memory deduplication between VMs for security reasons.

To attack such configurations, successful and practical attacks must comply with the following requirements:

1. *Work across processors:* As these configurations are now ubiquitous, an attack that does not work across processors is severely limited and can be trivially mitigated by exclusively assigning processors to tenants or via the scheduler.
2. *Work without any shared memory:* With memory deduplication disabled, shared memory is not available between VMs. All attacks that require shared memory are thus completely mitigated in cross-VM settings with such configurations.

In the last years, the most prominent and well-studied example of shared-hardware exploits is cache attacks. They use the processor-integrated cache and were shown to be effective in a multitude of settings, such as cross-VM key-recovery attacks [9, 12, 20, 30], including attacks across cores [5, 14, 16, 28]. However, due to the

cache being local to the processor, these attacks do not work across processors and thus violate requirement 1. Note that in a recent concurrent work, Irazoqui et al. [11] presented a cross-CPU cache attack which exploits cache coherency mechanisms in multi-processor systems. However, their approach requires shared memory and thus violates requirement 2. The whole class of cache attacks is therefore not applicable in multi-processor systems without any shared memory.

Other attacks leverage the main memory that is a shared resource even in multi-processor systems. Xiao et al. [26] presented a covert channel that exploits memory deduplication. This covert channel has a low capacity and requires the availability of shared memory, thus violating requirement 2. Wu et al. [25] presented a covert channel exploiting the locking mechanism of the memory bus. While this attack works across processors, the capacity of the covert channel is orders of magnitude lower than that of current cache covert channels.

Therefore, only a low capacity covert channel and no side-channel have been showed with the two aforementioned requirements so far. In contrast, we demonstrate two attacks that do not use shared memory and work across processors: a high-speed covert channel as well as the first side-channel attack.

Contributions. Our attacks require knowledge of the undocumented mapping of memory addresses to DRAM channels, ranks, and banks. We therefore present two methods to reverse engineer this mapping. The first method retrieves the correct addressing functions by performing physical probing of the memory bus. The second method is entirely software-based, fully automatic, and relies only on timing differences.¹ Thus, it can be executed remotely and enables finding DRAM address mappings even in VMs in the cloud. We reverse engineered the addressing functions on a variety of processors and memory configurations. Besides consumer-grade PCs, we also analyzed a dual-CPU server system – similar to those found in cloud setups – and multiple recent smartphones.

Using this reverse-engineered mapping, we present *DRAM* attacks, a novel class of attacks that exploit the *DRAM Addressing*. In particular, they leverage DRAM row buffers that are a shared component in multi-processor systems. Our attacks require that at least one memory module is shared between the attacker and the victim, which is the case even in the most restrictive settings. In these settings, attacker and victim cannot access the same memory cells, *i.e.*, we do not circumvent system-level memory isolation. We do not make any assumptions on the cache, nor on the location of executing

¹The source code of this reverse-engineering tool and exemplary DRAMA attacks can be found at <https://github.com/IAIK/drama>.

cores, nor on the availability of shared memory such as cross-VM memory deduplication.

First, we build a covert channel that achieves transmission rates of up to 2 Mbps, which is three to four orders of magnitude faster than previously presented memory-bus based channels. Second, we build a side channel that allows to automatically locate and monitor memory accesses, *e.g.*, user input or server requests, by performing template attacks. Third, we show how the reverse-engineered mapping can be used to improve existing attacks. Existing Flush+Reload cache attacks use an incorrect cache-miss threshold, introducing noise and reducing the spatial accuracy. Knowledge of the DRAM address mapping also enables practical Rowhammer attacks on DDR4.

Outline. The remainder of the paper is organized as follows. In Section 2, we provide background information on side channels on shared hardware, on DRAM, and on the Rowhammer attack. In Section 3, we provide definitions that we use throughout the paper. In Section 4, we describe our two approaches to reverse engineer the DRAM addressing and we provide the reverse-engineered functions. In Section 5, we build a high-speed cross-CPU DRAMA covert channel. In Section 6, we build a highly accurate cross-CPU DRAMA side channel attack. In Section 7, we show how the knowledge of the DRAM addressing improves cache attacks like Flush+Reload and we show how it makes Rowhammer attacks practical on DDR4 and more efficient on DDR3. We discuss countermeasures against our attack in Section 8. We conclude in Section 9.

2 Background and related work

In this section, we discuss existing covert and side channels and give an introduction to DRAM. Furthermore, we briefly explain the Rowhammer bug and its implications.

2.1 Hardware covert and side channels

Attacks exploiting hardware sharing can be grouped into two categories. In side-channel attacks, an attacker spies on a victim and extracts sensitive information such as cryptographic keys. In covert channels however, sender and receiver are actively cooperating to exchange information in a setting where they are not allowed to, *e.g.*, across isolation boundaries.

Cache attacks. Covert and side channels using the CPU cache exploit the fact that cache hits are faster than cache misses. The methods Prime+Probe [14, 16, 19] and Flush+Reload [2, 12, 28] have been presented to either build covert or side channels. These two methods work at a different granularity: Prime+Probe can spy on cache

sets, while Flush+Reload has the finer granularity of a cache line but requires shared memory, such as shared libraries or memory deduplication.

Attacks targeting the last-level cache are cross-core, but require the sender and receiver to run on the same physical CPU. Gruss et al. [5] implemented cross-core covert channels using Prime+Probe and Flush+Reload as well as a new one, Flush+Flush, with the same protocol to normalize the results. The covert channel using Prime+Probe achieves 536 Kbps, Flush+Reload 2.3 Mbps, and Flush+Flush 3.8 Mbps. The most recent cache attack by Irazoqui et al. [11] exploits cache coherency mechanisms and work across processors. It however requires shared memory.

An undocumented function maps physical addresses to the slices of the last-level cache. However, this function has been reverse engineered in previous work [9, 15, 29], enhancing existing attacks and enabling attacks in new environments.

Memory and memory bus. Xiao et al. [26] presented a covert channel that exploits memory deduplication. In order to save memory, the hypervisor searches for identical pages in physical memory and merges them across VMs to a single read-only physical page. Writing to this page triggers a copy-on-write page fault, incurring a significantly higher latency than a regular write access. The authors built a covert channel that achieves up to 90 bps, and 40 bps on a system under memory pressure. Wu et al. [25] proposed a bus-contention-based covert channel, that uses atomic memory operations locking the memory bus. This covert channel achieves a raw bandwidth of 38 Kbps between two VMs, with an effective capacity of 747 bps with error correction.

2.2 DRAM organization

Modern DRAM is organized in a hierarchy of channels, DIMMs, ranks, and banks. A system can have one or more *channels*, which are physical links between the DRAM modules and the memory controller. Channels are independent and can be accessed in parallel. This allows distribution of the memory traffic, increasing the bandwidth, and reducing the latency in many cases. Multiple *Dual Inline Memory Modules (DIMMs)*, which are the physical memory modules attached to the mainboard, can be connected to each channel. A DIMM typically has one or two *ranks*, which often correspond to the front and back of the physical module. Each rank is composed of *banks*, typically 8 on DDR3 DRAM and 16 on DDR4 DRAM. In the case of DDR4, banks are additionally grouped into *bank groups*, e.g., 4 bank groups with 4 banks each. Banks finally contain the actual memory arrays which are organized in *rows* (typically 2^{14} to 2^{17}) and *columns* (often 2^{10}). On PCs, the DRAM word size

and bus width is 64 bits, resulting in a typical row size of 8 KB. As channel, rank and bank form a hierarchy, two addresses can only be physically adjacent in the DRAM chip if they are in the same channel, DIMM, rank and bank. In this case we just use the term same bank.

The memory controller, which is integrated into modern processors, translates physical addresses to channels, DIMMs, ranks, and banks. AMD publicly documents the addressing function used by its products (see, e.g., [1, p. 345]), however to the best of our knowledge Intel does not. The mapping for one Intel Sandy Bridge machine in one memory configuration has been reverse engineered by Seaborn [23]. However, Intel has changed the mapping used in its more recent microarchitectures. Also, the mapping necessarily differs when using other memory configurations, e.g., a different number of DIMMs.

The row buffer. Apart from the memory array, each bank also features a row buffer between the DRAM cells and the memory bus. From a high-level perspective, it behaves like a directly-mapped cache and stores an entire DRAM row. Requests to addresses in the currently active row are served directly from this buffer. If a different row needs to be accessed, then the currently active row is first closed (with a pre-charge command) and then the new row is fetched (with a row-activate command). We call such an event a row conflict. Naturally, such a conflict leads to significantly higher access times compared to requests to the active row. This timing difference will later serve as the basis for our attacks and for the software-based reverse-engineering method. Note that after each refresh operation, a bank is already in the pre-charged state. In this case, no row is currently activated.

Independently of our work, Hassan et al. [7] also proposed algorithms to reverse engineer DRAM functions based on timing differences. However, their approach requires customized hardware performance-monitoring units. Thus, they tested their approach only in a simulated environment and not on real systems. Concurrently to our work, Xiao et al. [27] proposed a method to reverse engineer DRAM functions based on the timing differences caused by row conflicts. Although their method is similar to ours, their focus is different, as they used the functions to then perform Rowhammer attacks across VMs.

DRAM organization for multi-CPU systems. In modern multi-CPU server systems, each CPU features a dedicated memory controller and attached memory. The DRAM is still organized in one single address space and is accessible by all processors. Requests for memory attached to other CPUs are sent over the CPU interconnect, e.g., Intel’s QuickPath Interconnect (QPI). This memory design is called Non-Uniform Memory Access (NUMA), as the access time depends on the memory location.

On our dual Haswell-EP setup, the organization of this single address space can be configured for the expected workload. In *interleaved mode*, the memory is split into small slices which are spliced together in an alternating fashion. In *non-interleaved* mode, each CPUs memory is kept in one contiguous physical-address block. For instance, the lower half of the address space is mapped to the first CPUs memory, whereas the upper half is mapped to the second CPUs memory.

2.3 The Rowhammer bug

The increasing DRAM density has led to physically smaller cells, which can thus store smaller charges. As a result, the cells have a lower noise margin and the level of parasitic electrical interaction is potentially higher, resulting in the so-called Rowhammer bug [8, 13, 18].

This bug results in corruption of data, not in rows that are directly accessed, but rather in adjacent ones. When performing random memory accesses, the probability for such faults is virtually zero. However, it rises drastically when performing accesses in a certain pattern. Namely, flips can be caused by frequent activation (*hammering*) of adjacent rows. As data needs to be served from DRAM and not the cache, an attack needs to either flush data from the cache using the `clflush` instruction in native environments [13], or using cache eviction in other more restrictive environments, e.g., JavaScript [4].

Seaborn [22] implemented two attacks that exploit the Rowhammer bug, showing the severity of faulting single bits for security. The first exploit is a kernel privilege escalation on a Linux system, caused by a bit flip in a page table entry. The second one is an escape of Native Client sandbox caused by a bit flip in an instruction sequence for indirect jumps.

3 Definitions

In this section we provide definitions for the terms *row hit* and *row conflict*. These definitions provide the basis for our reverse engineering as well as the covert and side channel attacks.

Every physical memory location maps to one out of many rows in one out of several banks in the DRAM. Considering a single access to a row i in a bank there are two major possible cases:

1. The row i is already opened in the row buffer. We call this case a *row hit*.
2. A different row $j \neq i$ in the same bank is opened. We call this case a *row conflict*.

Considering frequent alternating accesses to two (or more) addresses we distinguish three cases:

1. The addresses map to different banks. In this case the accesses are independent and whether the ad-

dresses have the same row indices has no influence on the timing. Row hits are likely to occur for the accesses, *i.e.*, access times are low.

2. The addresses map to the same row i in the same bank. The probability that the row stays open in between accesses is high, *i.e.*, access times are low.
3. The addresses map to the different rows $i \neq j$ in the same bank. Each access to an address in row i will close row j and vice versa. Thus, row conflicts occur for the accesses, *i.e.*, access times are high.

To measure the timing differences of row hits and row conflicts, data has to be flushed from the cache. Figure 1 shows a comparison of standard histograms of access times for cache hits and cache misses. Cache misses are further divided into row hits and row conflicts. For this purpose an unrelated address in the same row was accessed to cause a row hit and an unrelated address in the same bank but in a different row was accessed to cause a row conflict. We see that from 180 to 216 cycles row hits occur, but no row conflicts (cf. highlighted area in Figure 1). In the remainder, we build different attacks that are based on this timing difference between row hits and row conflicts.

4 Reverse engineering DRAM addressing

In this section, we present our reverse engineering of the DRAM address mapping. We discuss two approaches, the first one is based on physical probing, whereas the second one is entirely software-based and fully automated. Finally, we present the outcome of our analysis, *i.e.*, the reverse-engineered mapping functions. In the remainder of this paper, we denote with a a physical memory address. a_i denotes the i -th bit of an address.

4.1 Linearity of functions

The DRAM addressing functions are reverse engineered in two phases. First, a measuring phase and second, a subsequent solving phase. Our solving approaches require that the addressing functions are linear, *i.e.*, they are XORs of physical-address bits.

In fact, Intel used such functions in earlier microarchitectures. For instance, Seaborn [23] reports that on his Sandy Bridge setup the bank address is computed by XORing the bits $a_{14..16}$ with the lower bits of the row number ($a_{18..20}$) (cf. Figure 4a). This is done in order to minimize the number of row conflicts during runtime. Intel also uses linear functions for CPU-cache addressing. Maurice et al. [15] showed that the *complex addressing* function, which is used to select cache slices, is an XOR of many physical-address bits.

As it turns out, linearity holds on all our tested configurations. However, there are setups in which it might be

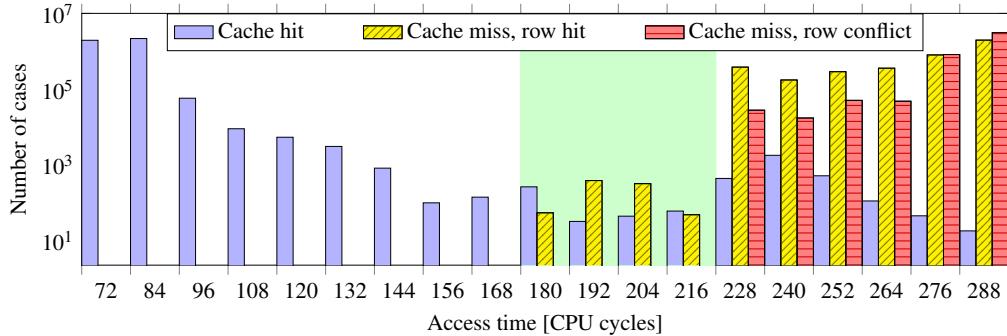

Figure 1: Histogram for cache hits and cache misses divided into row hits and row conflicts on the Ivy Bridge i5 test system. Measurements were performed after a short idle period to simulate non-overlapping accesses by victim and spy. From 180 to 216 cycles row hits occur, but no row conflicts.

violated, such as triple-channel configurations. We did not test such systems and leave a reverse engineering to future work.

4.2 Reverse engineering using physical probing

Our first approach to reverse engineer the DRAM mapping is to physically probe the memory bus and to directly read the control signals. As shown in Figure 2, we use a standard passive probe to establish contact with the pin at the DIMM slot. We then repeatedly accessed a selected physical address² and used a high-bandwidth oscilloscope to measure the voltage and subsequently deduce the logic value of the contacted pin. Note that due to the repeated access to a single address, neither a timely location of specific memory requests nor distinguishing accesses to the chosen address from other random ones is required.

We repeated this experiment for many selected addresses and for all pins of interest, namely the bank-address bits (BA0, BA1, BA2 for DDR3 and BG0, BG1, BA0, BA1 for DDR4) for one DIMM and the chip select CS for half the DIMMs.

For the solving phase we use the following approach. Starting from the top-layer (channel or CPU addressing) and drilling down, for each DRAM addressing function we create an over-defined system of linear equations in the physical address bits. The left-hand-side of this system is made up of the relevant tested physical addresses. For instance, for determining the bank functions we only use addresses that map to the contacted DIMMs channel. The right-hand-side of the system of equations are the previously measured logic values for the respective

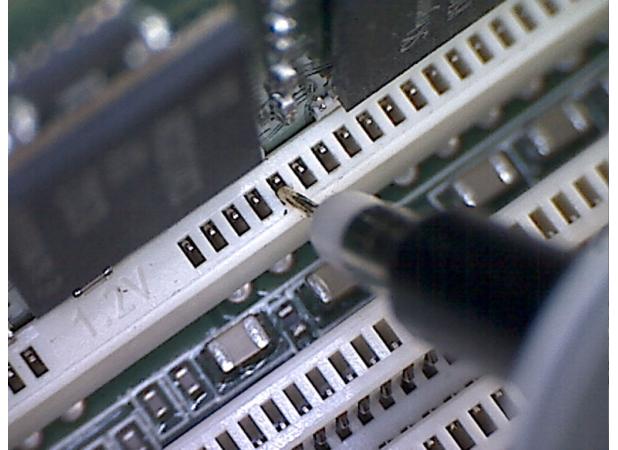

Figure 2: Physical probing of the DIMM slot.

address and the searched-for function. The logic values for CPU and channel addressing are computed by simply ORing all respective values for the chip-select pins. We then solve this system using linear algebra. The solution is the corresponding DRAM addressing function.

Obviously, this reverse-engineering approach has some drawbacks. First, expensive measurement equipment is needed. Second, it requires physical access to the internals of the tested machine. However, it has the big advantage that the address mapping can be reconstructed for each control signal individually and exactly. Thus, we can determine the exact individual functions for the bus pins. Furthermore, every platform only needs to be measured only once in order to learn the addressing functions. Thus, an attacker does not need physical access to the concrete attacked system if the measurements are performed on a similar machine.

²Resolving virtual to physical addresses requires root privileges in Linux. Given that we need physical access to the internals of the system, this is a very mild prerequisite.

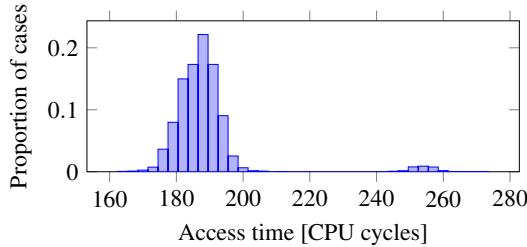

Figure 3: Histogram of average memory access times for random address pairs on our Haswell test system. A clear gap separates the majority of address pairs causing no row conflict (lower access times), because they map to different banks, from the few address pairs causing a row conflict (higher access times), because they map to different rows in the same bank.

4.3 Fully automated reverse engineering

For our second approach to reverse engineer the DRAM mapping we exploit the fact that row conflicts lead to higher memory access times. We use the resulting timing differences to find sets of addresses that map to the same bank but to a different row. Subsequently, we determine the addressing functions based on these sets. The entire process is fully automated and runs in unprivileged and possibly restricted environments.

Timing analysis. In the first step, we aim to find same-bank addresses in a large array mapped into the attackers' address space. For this purpose, we perform repeated alternating access to two addresses and measure the average access time. We use `clflush` to ensure that each access is served from DRAM and not from the CPU cache. As shown in Figure 3, for some address pairs the access time is significantly higher than for most others. These pairs belong to the same bank but to different rows. The alternating access causes frequent row conflicts and consequently the high latency.

The tested pairs are drawn from an address pool, which is built by selecting random addresses from a large array. A small subset of addresses in this pool is tested against all others in the pool. The addresses are subsequently grouped into sets having the same channel, DIMM, rank, and bank. We try to identify as many such sets as possible in order to reconstruct the addressing functions.

Function reconstruction. In the second phase, we use the identified address sets to reconstruct the addressing functions. This reconstruction requires (at least partial) resolution of the tested virtual addresses to physical ones. Similar as later in Section 5.1, one can use either the availability of 2 MB pages, 1 GB pages, or privileged information such as the virtual-to-physical address transla-

tion that can be obtained through `/proc/pid/pagemap` in Linux systems.

In the case of 2 MB pages we can recover all partial functions up to bit a_{20} , as the lowest 21 bit of virtual and physical address are identical. On many systems the DRAM addressing functions do not use bits above a_{20} or only few of them, providing sufficient information to mount covert and side-channel attacks later on. In the case of 1 GB pages we can recover all partial functions up to bit a_{30} . This is sufficient to recover the full DRAM addressing functions on all our test systems. If we have full access to physical address information we will still ignore bits a_{30} and upwards. These bits are typically only used for DRAM row addressing and they are very unlikely to play any role in bank addressing. Additionally, we ignore bits $(a_0..a_5)$ as they are used for addressing within a cache line.

The search space is then small enough to perform a brute-force search of linear functions within seconds. For this, we generate all linear functions that use exactly n bits as coefficients and then apply them to all addresses in one randomly selected set. We start with $n = 1$ and increment n subsequently to find all functions. Only if the function has the same result for all addresses in a set, we test this potential function on all other sets. However, in this case we only pick one address per set and test whether the function is constant over all sets. If so, the function is discarded. We obtain a list of possible addressing functions that also contains linear combinations of the actual DRAM addressing functions. We prioritize functions with a lower number of coefficients, *i.e.*, we remove higher-order functions which are linear combinations of lower-order ones. Depending on the random address selection, we now have a complete set of correct addressing functions. We verify the correctness either by comparing it to the results from the physical probing, or by performing a software-based test, *i.e.*, verifying the timing differences on a larger set of addresses, or verifying that usage of the addressing functions in Rowhammer tests increases the number of bit flips per second by a factor that is the number of sets we found.

Compared to the probing approach, this purely software-based method has significant advantages. It does not require any additional measurement equipment and can be executed on a remote system. We can identify the functions even from within VMs or sandboxed processes if 2 MB or 1 GB pages are available. Furthermore, even with only 4 KB pages we can group addresses into sets that can be directly used for covert or side channel attacks. This software-based approach also allows reverse engineering in settings where probing is not easily possible anymore, such as on mobile devices with hard-wired ball-grid packages. Thus, it allowed us to reverse engineer the mapping on current ARM processors.

Table 1: Experimental setups.

CPU / SoC	Microarch.	Mem.
i5-2540M	Sandy Bridge	DDR3
i5-3230M	Ivy Bridge	DDR3
i7-3630QM	Ivy Bridge	DDR3
i7-4790	Haswell	DDR3
i7-6700K	Skylake	DDR4
2x Xeon E5-2630 v3	Haswell-EP	DDR4
Qualcomm Snapdragon S4 Pro	ARMv7	LPDDR2
Samsung Exynos 5 Dual	ARMv7	LDDR3
Qualcomm Snapdragon 800	ARMv7	LPDDR3
Qualcomm Snapdragon 820	ARMv8-A	LPDDR3
Samsung Exynos 7420	ARMv8-A	LPDDR4

One downside of the software-based approach is that it cannot recover the exact labels (BG0, BA0, ...) of the functions. Thus, we can only guess whether the reconstructed function computes a bank address bit, rank bit, or channel bit. Note that assigning the correct labels to functions is not required for any of our attacks.

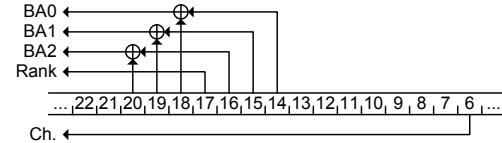

4.4 Results

We now present the reverse-engineered mappings for all our experimental setups. We analyzed a variety of systems (Table 1), including a dual-CPU Xeon system, that can often be found in cloud systems, and multiple current smartphones. Where possible, we used both presented reverse-engineering methods and cross-validated the results.

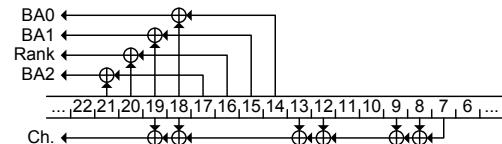

We found that the basic scheme is always as follows. On PCs, the memory bus is 64 bits wide, yet the smallest addressable unit is a byte. Thus, the three lower bits ($a_0..a_2$) of the physical address are used as byte index into a 64-bit (8-byte) memory word and they are never transmitted on the memory bus. Then, the next bits are used for column selection. One bit in between is used for channel addressing. The following bits are responsible for bank, rank, and DIMM addressing. The remaining upper bits are used for row selection.

The detailed mapping, however, differs for each setup. To give a quick overview of the main differences, we show the mapping of one selected memory configuration for multiple Intel microarchitectures and ARM-based SoCs in Figure 4. Here we chose a configuration with two equally sized DIMMs in dual-channel configuration, as it is found in many off-the-shelf consumer PCs. All our setups use dual-rank DIMMs and use 10 bits for column addressing. Figure 4a shows the mapping on the Sandy Bridge platform, as reported by Seaborn [23]. Here, only a_6 is used to select the memory channel, a_{17} is used for rank selection. The bank-address bits are com-

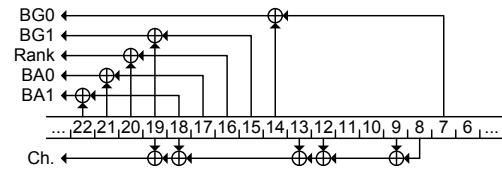

puted by XORing bits $a_{14..a_{16}}$ with the lower bits of the row index ($a_{18..a_{20}}$).

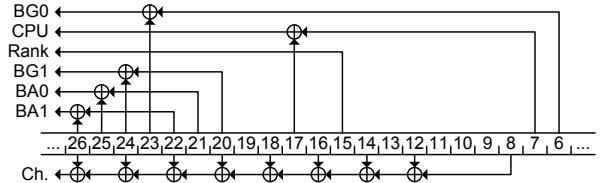

(a) Sandy Bridge – DDR3 [23].

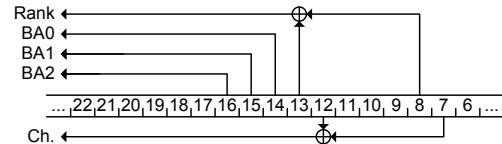

(b) Ivy Bridge / Haswell – DDR3.

(c) Skylake – DDR4.

(d) Dual Haswell-EP (Interleaved Mode) – DDR4.

(e) Samsung Exynos 7420 – LPDDR4.

Figure 4: Reverse engineered dual channel mapping (1 DIMM per channel) for different architectures.

The channel selection function changed with later microarchitectures, such as Ivy Bridge and Haswell. As shown in Figure 4b, the channel-selection bit is now computed by XORing seven bits of the physical address. Further analysis showed that bit a_7 is used exclusively, i.e., it is not used as part of the row- or column address.

Additionally, rank selection is now similar to bank addressing and also uses XORs.

Our Skylake test system uses DDR4 instead of DDR3. Due to DDR4's introduction of bank grouping and the doubling of the available banks (now 16), the addressing function necessarily changed again. As shown in Figure 4c, a_7 is not used for channel selection anymore, but for bank addressing instead.

Figure 4d depicts the memory mapping of a dual-CPU Haswell-EP system equipped with DDR4 memory. It uses 2 modules in dual-channel configuration *per CPU* (4 DIMMs in total). In interleaved mode (cf. Section 2.2), the chosen CPU is determined as $a_7 \oplus a_{17}$. Apart from the different channel function, there is also a difference in the bank addressing, *i.e.*, bank addressing bits are shifted. The range of bits used for row indexing is now split into address bits ($a_{17..a_{19}}$) and a_{23} upwards.

The mapping used on one of our mobile platforms, a Samsung Galaxy S6 with an Exynos 7420 ARMv8-A SoC and LPDDR4 memory, is much simpler (cf. Figure 4e). Here physical address bits are mapped directly to bank address bits. Rank and channel are computed with XORs of only two bits each. The bus width of LPDDR4 is 32 bits, so only the two lowest bits are used for byte indexing in a memory word.

Table 2 shows a comprehensive overview of all platforms and memory configurations we analyzed. As all found functions are linear, we simply list the index of the physical address bits that are XORed together. With the example of the Haswell microarchitecture, one can clearly see that the indices are shifted to accommodate for the different memory setups. For instance, in single-channel configurations a_7 is used for column instead of channel selection, which is why bank addressing starts with a_{13} instead of a_{14} .

5 A high-speed cross-CPU covert channel

In this section, we present a first DRAMA attack, namely a high-speed cross-CPU covert channel that does not require shared memory. Our channel exploits the row buffer, which behaves like a directly-mapped cache. Unlike cache attacks, the only prerequisite is that two communicating processes have access to the same memory module.

5.1 Basic concept

Our covert channel exploits timing differences caused by row conflicts. Sender and receiver occupy different rows in the same bank as illustrated in Figure 5. The receiver process continuously accesses a chosen physical address in the DRAM and measures the average access time over a few accesses. If the sender process now continuously

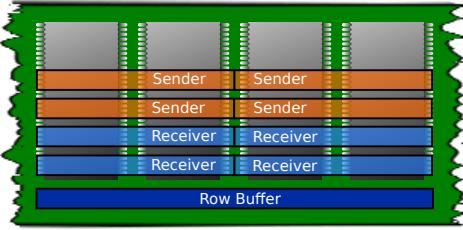

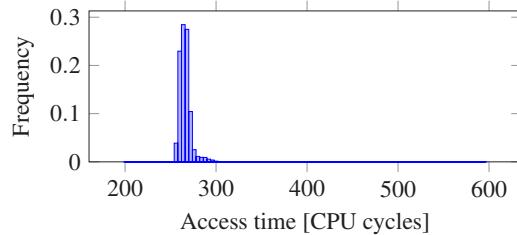

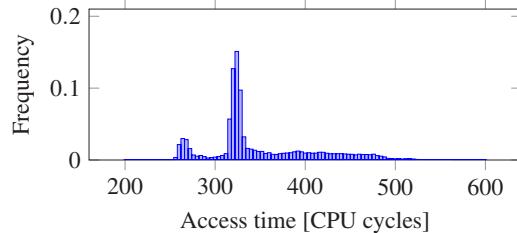

Figure 5: The sender occupies rows in a bank to trigger row conflicts. The receiver occupies rows in the same bank to observe these row conflicts.

(a) Sender inactive on bank: sending a 0.

(b) Sender active on bank: sending a 1.

Figure 6: Timing differences between active and non-active sender (on one bank), measured on the Haswell i7 test system.

accesses a different address in the same bank but in a different row, a row conflict occurs. This leads to higher average access times in the receiver process. Bits can be transmitted by switching the activity of the sender process in the targeted bank on and off. This timing difference is illustrated in Figure 6, an exemplary transmission is shown in Figure 7. The receiver process distinguishes the two values based on the mean access time. We assign a logic value of 0 to low access times (the sender is inactive) and a value of 1 to high access times (the sender is active).

Each (CPU, channel, DIMM, rank, bank) tuple can be used as a separate transmission channel. However, a high number of parallel channels leads to increased noise. Also, there is a strict limit on the usable bank par-

Table 2: Reverse engineered DRAM mapping on all platforms and configurations we analyzed via physical probing or via software analysis. These tables list the bits of the physical address that are XORed. For instance, for the entry (13, 17) we have $a_{13} \oplus a_{17}$.

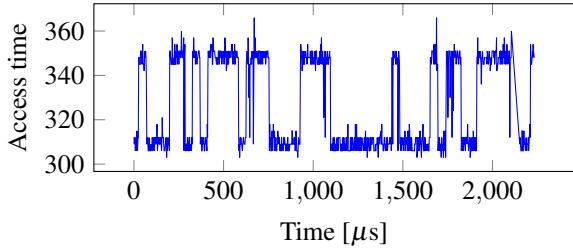

Figure 7: Covert channel transmission on one bank, cross-CPU and cross-VM on a Haswell-EP server. The time frame for one bit is 50 μ s.

allelism. Thus, optimal performance is achieved when using only a subset of available tuples. Transmission channels are unidirectional, but the direction can be chosen for each one independently. Thus, two-way communication is possible.

To evaluate the performance of this new covert channel, we created a proof-of-concept implementation. We restrict ourselves to unidirectional communication, *i.e.*, there is one dedicated sender and one dedicated receiver.

The memory access time is measured using `rdtsc`. The memory accesses are performed using volatile pointers. In order to cause a DRAM access for each request, data has to be flushed from the cache using `clflush`.

Determining channel, rank, and bank address. In an agreement phase, all parties need to agree on the set of (channel, DIMM, rank, bank) tuples that are used for communication. This set needs to be chosen only once, all subsequent communication can use the same set. Next, both sender and receiver need to find at least one address in their respective address space for each tuple. Note that some operating systems allow unprivileged resolution of virtual to physical addresses. In this case, finding correct addresses is trivial.

However, on Linux, which we used on our testing setup, unprivileged address resolution is not possible. Thus, we use the following approach. As observed in previous work [3, 4], system libraries and the operating system assign 2 MB pages for arrays which are significantly larger than 2 MB. On these pages, the 21 lowest bits of the virtual address and the physical address are

identical. Depending on the hardware setup, these bits can already be sufficient to fully determine bank, rank and channel address. For this purpose, both processes request a large array. The start of this array is not necessarily aligned with a 2 MB border. Memory before such a border is allocated using 4 KB pages. We skip to the next 2 MB page border by choosing the next virtual address having the 21 lowest bits set to zero.

On systems that also use higher bits, an attacker can use the following approach, which we explain on the example of the mapping shown in Figure 4b. There an attacker cannot determine the BA2 bit by just using 2 MB pages. Thus, the receiving process selects addresses with chosen BA0, BA1, rank, and channel, but unknown BA2 bit. The sender now accesses addresses for both possibilities of BA2, e.g., by toggling a_{17} between consecutive reads. Thus, only each second access in the sending process targets the correct bank. Yet, due to bank parallelism this does not cause a notable performance decrease. Note however that this approach might not work if the number of unknown bank-address bits is too high.

In a virtualized environment, even a privileged attacker is able to retrieve only the *guest physical address*, which is further translated into the real physical address by the memory management unit. However, if the host system uses 1 GB pages for the second-level address translation (to improve efficiency), then the lowest 30 bits of the guest physical address are identical to the real physical address. Knowledge of these bits is sufficient on all systems we analyzed to use the full DRAM addressing functions.

Finally, the covert channel could also be built without actually reconstructing the DRAM addressing functions. Instead of determining the exact bank address, it can rely solely on the same-bank sets retrieved in Section 4.3. In an initialization phase, both sender and receiver perform the timing analysis and use it to build sets of same-bank addresses. Subsequently, the communicating parties need to synchronize their sets, *i.e.*, they need to agree on which of them is used for transmission. This is done by sending predefined patterns over the channel. After that, the channel is ready for transmission. Thus, it can be established without having any information on the mapping function nor on the physical addresses.

Synchronization. In our proof-of-concept implementation, one set of bits (a data block) is transmitted for a fixed time span which is agreed upon before starting communication. Decreasing this period increases the raw bitrate, but it also increases the error rate, as shown in Figure 8.

For synchronizing the start of these blocks we employ two different mechanisms. If sender and receiver run natively, we use the wall clock as means of synchronization. Here blocks start at fixed points in time. If,

however, sender and receiver run in two different VMs, then a common (or perfectly synchronized) wall clock is typically not available. In this case, the sender uses one of the transmission channels to transmit a clock signal which toggles at the beginning of each block. The receiver then recovers this clock and can thus synchronize with the sender.

We employ multiple threads for both the sender and receiver processes to achieve optimal usage of the memory bus. Thus, memory accesses are performed in parallel, increasing the performance of the covert channel.

5.2 Evaluation

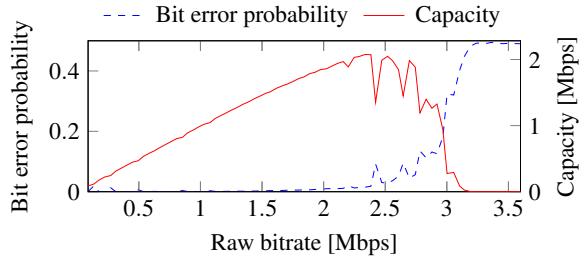

We evaluated the performance of our covert-channel implementation on two systems. First, we performed tests on a standard desktop PC featuring an Intel i7-4790 CPU with Haswell microarchitecture. It was equipped with 2 Kingston DDR3 KVR16N11/8 dual-rank 8 GB DIMMs in dual-channel configuration. The system was mostly idle during the tests, *i.e.*, there were no other tasks causing significant load on the system. The DRAM clock was set to its default of 800 MHz (DDR3-1600).

Furthermore, we also tested the capability of cross-CPU transmission on a server system. Our setup has two Intel Xeon E5-2630 v3 (Haswell-EP microarchitecture). It was equipped with a total of 4 Samsung M393A2G40DB0-CPB DDR4 registered ECC DIMMs. Each CPU was connected to two DIMMs in dual-channel configuration and NUMA was set to interleaved mode. The DRAM frequency was set to its maximum supported value (DDR4-1866).

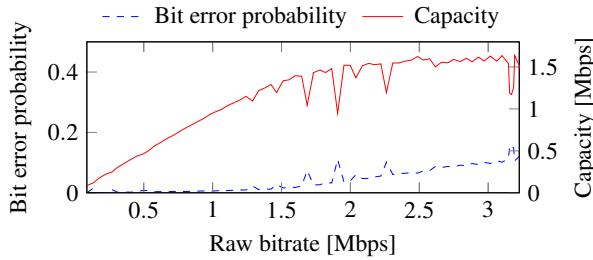

For both systems, we evaluated the performance in both a native scenario, *i.e.*, both processes run natively, and in a cross-VM scenario. We transmit 8 bits per block (use 8 (CPU, channel, DIMM, rank, bank) tuples) in the covert channel and run 2 threads in both the sender and the receiver process. Every thread is scheduled to run on different CPU cores, and in the case of the Xeon system, sender and receiver run on different physical CPUs.

We tested our implementation with a large range of measurement intervals. For each one, we measure the raw channel capacity and the bit error probability. While the raw channel capacity increases proportionally to the reduction of the measurement time, the bit error rate increases significantly if the measurement time is too short. In order to find the best transmission rate, we use the channel capacity as metric. When using the binary symmetric channel model, this metric is computed by multiplying the raw bitrate with $1 - H(e)$, with e the bit error probability and $H(e) = -e \cdot \log_2(e) - (1 - e) \cdot \log_2(1 - e)$ the binary entropy function.

Figure 8 shows the error rate varying depending on the raw bitrate for the case that both sender and receiver

(a) Desktop setup (Haswell)

(b) Server setup, cross-CPU (Haswell-EP)

Figure 8: Performance of our covert channel implementation (native).

run natively. On our desktop setup (Figure 8a), the error probability stays below 1% for bitrates of up to 2 Mbps. The channel capacity reaches up to 2.1 Mbps (raw bitrate of 2.4 Mbps, error probability of 1.8%). Beyond this peak, the increasing error probability causes a decrease in the effective capacity. On our server setup (Figure 8b) the cross-CPU communication achieves 1.2 Mbps with a 1% error rate. The maximum capacity is 1.6 Mbps (raw 2.6 Mbps, 8.7% error probability).

For the cross-core cross-VM scenario, we deployed two VMs which were configured to use 1 GB pages for second-stage address translation. We reach a maximum capacity of 309 kbps (raw 411 kbps, 4.1% error probability) on our desktop system. The server setup (cross-CPU cross-VM) performs much better, we achieved a bitrate of 596 kbps with an error probability of just 0.4%.

5.3 Comparison with state of the art

We compare the bitrate of our DRAM covert channel with the normalized implementation of three cache covert channels by Gruss et al. [5]. For an error rate that is less than 1%, the covert channel using Prime+Probe obtains 536 Kbps, the one using Flush+Reload 2.3 Mbps and the one using Flush+Flush 3.8 Mbps. With a capacity of up to 2 Mbps, our covert channel is within the same order of magnitude of current cache-based channels. However, unlike Flush+Reload and Flush+Flush, it

does not require shared memory. Moreover, in contrast to our attack, these cache covert channels do not allow cross-CPU communication.

The work of Irazoqui et al. [11] focuses on cross-CPU cache-based side-channel attacks. They did not implement a covert channel, thus we cannot compare our performance with their cache attack. However, their approach also requires shared memory and thus it would not work in our attack setting.

The covert channel by Xiao et al. [26] using memory deduplication achieves up to 90 bps. However, due to security concerns, memory deduplication has been disabled in many cloud environments. The covert channel of Wu et al. [25] using the memory bus achieves 746 bps with error correction. Our covert channel is therefore three to four orders of magnitude faster than state-of-the-art memory-based covert channels.

6 A low-noise cross-CPU side channel

In this section, we present a second DRAMA attack, a highly accurate side-channel attack using DRAM addressing information. We again exploit the row buffer and its behavior similar to a directly-mapped cache. In this attack, the spy and the victim can run on separate CPUs and do not share memory, *i.e.*, no access to shared libraries and no page deduplication between VMs. We mainly consider a local attack scenario where Flush+Reload cache attacks are not applicable due to the lack of shared memory. However, our side-channel attacks can also be applied in a cloud scenario where multiple users on a server and one malicious user spies on other users through this side channel. The side channel achieves a timing accuracy that is comparable to Flush+Reload and a higher spatial accuracy than Prime+Probe. Thus, it can be used as a highly accurate alternative to Prime+Probe cache attacks in cross-core scenarios without shared memory.

6.1 Basic concept

In case of the covert channel, an active sender caused row conflicts. In the side-channel attack, we infer the activity of a victim process by detecting *row hits* and *row conflicts* following our definitions from Section 3. For the attack to succeed, spy and victim need to have access to the same row in a bank, as illustrated in Figure 9. This is possible without shared memory due to the DRAM addressing functions.

Depending on the addressing functions, a single 4 KB page can map to multiple DRAM rows. As illustrated in Figure 10, in our Haswell-EP system the contents of a page are split over 8 DRAM rows (with the same row index, but different bank address). Conversely, a

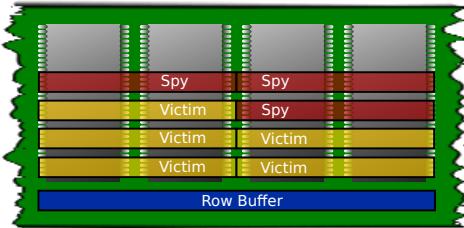

Figure 9: Victim and spy have memory allocated in the same DRAM row. By accessing this memory, the spy can determine whether the victim just accessed it.

DRAM row contains content of at least two 4 KB pages, as the typical row size is 8 KB. More specifically, in our Haswell-EP setup a single row stores content for 16 different 4 KB pages, as again shown in Figure 10. The amount of memory mapping from one page to one specific row, e.g., 512 bytes in the previous case, is the achievable spatial accuracy of our attack. If none of the DRAM addressing functions uses low address bits ($a_0 - a_{11}$), the spatial accuracy is 4 KB, which is the worst case. However, if DRAM addressing functions (channel, BG0, CPU, etc.) use low address bits, a better accuracy can be achieved, such as the 512 B for the server setup. On systems where 6 or more low address bits are used, the spatial accuracy of the attack is 64 B and thus as accurate as a Flush+Reload cache side-channel attack.

Assuming that an attacker occupies at least one other 4 KB page that maps (in part) to the same bank and row, the attacker has established a situation as illustrated in Figure 9.

To run the side-channel attack on a private memory address t in a victim process, the attacker allocates a memory address p that maps to the same bank and the same row as the target address t . As shown in Figure 10, although t and p map to the same DRAM row, they belong to different 4 KB pages (*i.e.*, no shared memory). The attacker also allocates a row conflict address \bar{p} that maps to the same bank but to a different row.

The side-channel attack then works in three steps:

1. Access the row conflict address \bar{p}
2. Wait for the victim to compute
3. Measure the access time on the targeted address p

If the measured timing is below a row-hit threshold (cf. the highlighted ‘‘row hit’’ region in Figure 1), the victim has just accessed t or another address in the target row. Thus, we can accurately determine when a specific non-shared memory location is accessed by a process running on another core or CPU. As p and \bar{p} are on separate private 4 KB pages, they will not be prefetched and we can measure row hits without any false positives. By allocat-

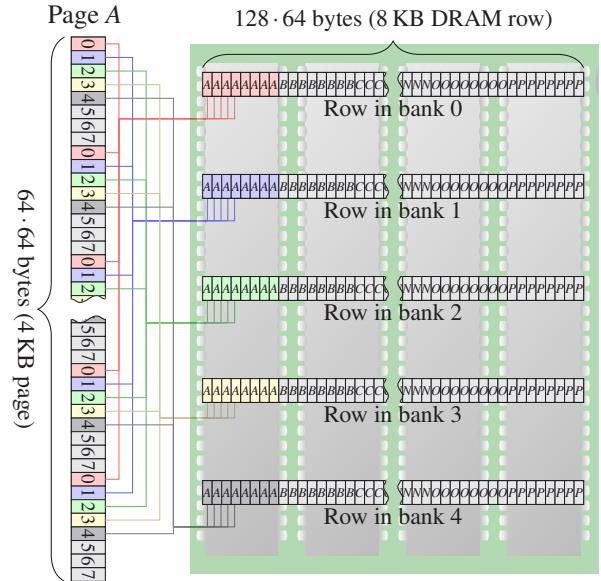

Figure 10: Mapping between a 4 KB page and an 8 KB DRAM row in the Haswell-EP setup. Banks are numbered 0 – 7, pages are numbered $A - P$. Every eighth 64-byte region of a 4 KB page maps to the same bank in DRAM. In total 8 out of 64 regions (= 512 B) map to the same bank. Thus, the memory of each row is divided among 16 different pages ($A - P$) that use memory from the same row. Occupying one of the pages $B - P$ is sufficient to spy on the eight 64-byte regions of page A in the same bank.

ing all but one of the pages that map to a row, the attacker maximizes the spatial accuracy.

Based on this attack principle, we build a fully automated template attack [6] that triggers an event in the victim process running on the other core or CPU (*e.g.*, by sending requests to a web interface or triggering user-interface events). For this attack we do not need to reconstruct the full addressing functions nor determine the exact bank address. Instead, we exploit the timing difference between row hits and row conflicts as shown in Figure 1.

To perform a DRAMA template attack, the attacker allocates a large fraction of memory, ideally in 4 KB pages. This ensures that some of the allocated pages are placed in a row together with pages used by the victim. The attacker then profiles the entire allocated memory and records the row-hit ratio for each address.

False positive detections are eliminated by running the profiling phase with different events. If an address has a high row-hit ratio for a single event, it can be used to monitor that event in the exploitation phase. After such an address has been found, all other remaining mem-

ory pages will be released and the exploitation phase is started.

6.2 Evaluation

We evaluated the performance of our side-channel attack in several tests. These tests were performed on a dual-core laptop with an Ivy Bridge Intel i5-3230M CPU with 2 Samsung DDR3-1600 dual-rank 4 GB DIMMs in dual-channel configuration.

The first test was a DRAMA template attack. The attack ran without any shared memory in an unprivileged user program. In this template attack we profiled access times on a private memory buffer while triggering keystrokes in the Firefox address bar. Figure 11 shows the template attack profile with and without keystrokes being triggered. While scanning a total of 7 GB of allocated memory, we found 1195 addresses that showed at least one row hit during the tests. 59 of these addresses had row hits independent of the event (false positives), *i.e.*, these 59 addresses cannot be used to monitor keystroke events. For the remaining 1136 addresses we only had row hits after triggering a keystroke in the Firefox address bar. Out of these addresses, 360 addresses had more than 20 row hits. Any of these 360 addresses can be used to monitor keystrokes reliably. The time to find an exploitable address varies between a few seconds and multiple minutes. Sometimes the profiling phase does not find any exploitable address, for instance if there is no memory in one row with victim memory. In this case the attacker has to restart the profiling phase.

After automatically switching to the exploitation phase we are able to monitor the exact timestamp of every keystroke in the address bar. We verified empirically that row hits can be measured on the found addresses after keystrokes by triggering keystrokes by hand. Figure 12 shows an access time trace for an address found in a DRAMA template attack, while typing in the Firefox address bar. For every key the user presses, a low access time is measured. We found this address after less than 2 seconds. Over 80 seconds we measured no false positive row hits and when pressing 40 keys we measured no false negatives. During this test the system was entirely idle apart from the attack and the user typing in Firefox. In a real attack, noise would introduce false negatives.

Comparison with cache template attacks. To compare DRAMA template attacks with cache template attacks, we performed two attacks on gedit. The first uses the result from a cache template attack in a DRAMA exploitation phase. The second is a modified cache template attack that uses the DRAMA side channel. Both attacks use shared memory to be able to compare them with cache template attacks. However, the DRAMA side-

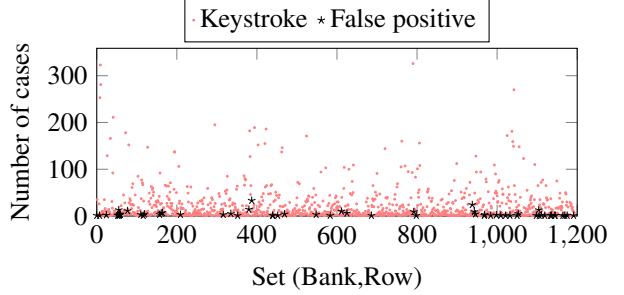

Figure 11: A DRAM template of the system memory with and without triggering keystrokes in the Firefox address bar. 1136 sets had row hits after a keystroke, 59 sets had false positive row hits (row hits without a keystroke), measured on our Ivy Bridge i5 test system.

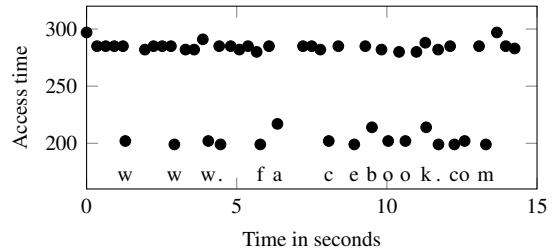

Figure 12: Exploitation phase on non-shared memory in a DRAMA template attack on our Ivy Bridge i5 test system. A low access time is measured when the user presses a key in the Firefox address bar. The typing gaps illustrate the low noise level.

channel attack takes no advantage of shared memory in any attack.

In the first attack on gedit, we target tab open and tab close events. In an experiment over 120 seconds we opened a new tab and closed the new tab, each 50 times. The exploitable address in the shared library was found in a cache template attack. We computed the physical address and thus bank and row of the exploitable address using privileged operating services. Then we allocated large arrays to obtain memory that maps to the same row (and bank). This allows us to perform an attack that has only minimal differences to a Flush+Reload attack.

During this attack, our spy tool detected 1 false positive row hit and 1 false negative row hit. Running stress $-m 1$ in parallel, which allocates and accesses large memory buffers, causes a high number of cache misses, but did not introduce a significant amount of noise. In this experiment the spy tool detected no false positive row hits and 4 false negative row hits. Running stress $-m 2$ in parallel (*i.e.*, the attacker's core is under stress) made any measurements impossible. While no false positive detections occurred, only 9 events were

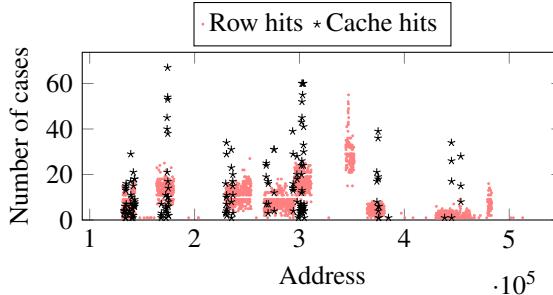

Figure 13: Comparison of a cache hits and row hits over the virtual memory where the gedit binary is mapped, measured on our Ivy Bridge i5 test system.

correctly detected. Thus, our attack is susceptible to noise especially if the attacker only gets a fraction of CPU time on its core.

In the second attack we compared the cache side channel and the DRAM side channel in a template attack on keystrokes in gedit. Figure 13 shows the number of cache hits and row hits over the virtual memory where the gedit binary is mapped. Row hits occur in spatial proximity to the cache hits and at shifted offsets due to the DRAM address mappings.

6.3 Comparison with state of the art

We now compare DRAMA side-channel attacks with same-CPU cache attacks such as Flush+Reload and Prime+Probe, as well as with cross-CPU cache attacks [11]. Our attack is the first to enable monitoring non-shared memory cross-CPU with a reasonably high spatial accuracy and a timing accuracy that is comparable to Flush+Reload. This allows the development of new attacks on programs using dynamically allocated or private memory.

The spatial accuracy of the DRAMA side-channel attack is significantly higher than that of a Prime+Probe attack, which also does not necessitate shared memory, and only slightly lower than that of a Flush+Reload attack in most cases. Our Ivy Bridge i5 system has 8 GB DRAM and a 3 MB L3 cache that is organized in 2 cache slices with each 2048 cache sets. Thus, in a Prime+Probe attack 32768 memory lines map to the same cache set, whereas in our DRAMA side-channel attack, on the same system, only 32 memory lines map to the same row. The spatial accuracy strongly depends on the system. On our Haswell-EP system only 8 memory lines map to the same row whereas still 32768 memory lines map to the same cache set. Thus, on the Haswell-EP system the advantage of DRAMA side-channel attacks over Prime+Probe is even more significant.

To allocate memory lines that are in the same row as victim memory lines, it is necessary to allocate significantly larger memory buffers than in a cache attack like Prime+Probe. This is a clear disadvantage of DRAMA side-channel attacks. However, DRAMA side-channel attacks have a very low probability of false positive row hit detections, whereas Prime+Probe is highly susceptible to noise. Due to this noise, monitoring singular events using Prime+Probe is extremely difficult.⁵

Irazoqui et al. [11] presented cache-based cross-CPU side-channel attacks. However, their work requires shared memory. Our approach works without shared memory. Not only does this allow cross-CPU attacks in highly restricted environments, it also allows to perform a new kind of cross-core attack within one system.

7 Improving attacks

In this section, we describe how the DRAM addressing functions can be used to improve the accuracy, efficiency, and success rate of existing attacks.

Flush+Reload. The first step when performing Flush+Reload attacks is to compute a cache-hit threshold, based on a histogram of cache hits and cache misses (memory accesses). However, as we have shown (cf. Figure 1) row hits have a slightly lower access time than row conflicts. To get the best performance in a Flush+Reload attack it is necessary to take row hits and conflicts into account. Otherwise, if a process accesses any memory location in the same row, a row hit will be misclassified as a cache hit. This introduces a significant amount of noise as the spatial accuracy of a cache hit is 64 bytes and the one of a row hit can be as low as 8 KB, depending on how actively the corresponding pages of the row are used. We found that even after a call to `sched_yield` a row hit is still observed in 2% of the cases on a Linux system that is mostly idle. In a Flush+Reload attack the victim computes in parallel and thus the probability then is even higher than 2%. This introduces a significant amount of noise especially for Flush+Reload attacks on low-frequency events. Thus, the accuracy of Flush+Reload attacks can be improved significantly taking row hits into account for the cache hit threshold computation.

Rowhammer. In a Rowhammer attack, an adversary tries to trigger bit flips in DRAM by provoking a high number of row switches. The success rate and efficiency of this attack benefit greatly from knowing the DRAM mapping, as we now demonstrate.

In order to cause row conflicts, one must alternately access addresses belonging to the same bank, but different row. The probability that 2 random addresses fulfill this criterion is 2^{-B} , where B is the total number of

bank-addressing bits (this includes all bits for channel, rank, etc.). For instance, with the dual-channel DDR4 configuration shown in Figure 4c this probability is only $2^{-6} = 1/64$. By hammering a larger set of addresses, the probability of having at least two targeting the same bank increases. However, so does the time in between row switches, thus the success rate decreases.

The most efficient way of performing the Rowhammer attack is *double-sided hammering*. Here, one tries to cause bit flips in row n by alternately accessing the adjacent rows $n - 1$ and $n + 1$, which are most likely also adjacent in physical memory. The most commonly referenced implementation of the Rowhammer attack, by Seaborn and Dullien [24], performs double-sided hammering by making assumptions on, e.g., the position of the row-index bits. If these are not met, then their implementation does not find any bit flips. Also, it needs to test multiple address combinations as it does not use knowledge of the DRAM addressing functions. We tested their implementation on a Skylake machine featuring G.SKILL F4-3200C16D-16GTZB DDR4 memory at the highest possible refresh interval, yet even after 4 days of nonstop hammering, we did not detect any bit flips.

By using the DRAM addressing functions we can immediately determine whether two addresses map to the same bank. Also, we can very efficiently search for pairs allowing double-sided hammering. After taking the reverse-engineered addressing functions into account, we successfully caused bit flips on the same Skylake setup within minutes. Running the same attack on a Crucial DDR4-2133 memory module running at the default refresh interval, we observed the first bit flip after 16 seconds and subsequently observed on average one bit flip every 12 seconds. Although the LPDDR4 standard includes *target row refresh* (TRR) as an optional countermeasure against the Rowhammer attack, the DDR4 standard does not. Still, some manufacturers include it in their products as a non-standard feature. For both DDR4 and LPDDR4, both the memory controller and the DRAM must support this feature in order to provide any protection. To the best of our knowledge, both our Haswell-EP test system and the Crucial DDR4-2133 memory module, with Micron DRAM chips, support TRR [10, 17]. However, we are still able to reproducibly trigger bit flips in this configuration.

8 Countermeasures

Defending against row buffer attacks is a difficult task. Making the corresponding DRAM operations constant time would introduce unacceptable performance degradation. However, as long as the timing difference exists and can be measured, the side channel cannot be closed.

Our attack implementations use the unprivileged `clflush` instruction in order to cause a DRAM access with every memory request. Thus, one countermeasure might be to restrict said operation. However, this requires architectural changes and an attacker can still use eviction as a replacement. The additional memory accesses caused by eviction could make our row-buffer covert channel impractical. However, other attacks such as the fully automated reverse engineering or our row-hit side-channel attack are still possible. Restricting the `rdtsc` instruction would also not prevent an attack as other timing sources can be used as replacement.

To prevent cross-VM attacks on multi-CPU cloud systems, the cloud provider could schedule each VM on a dedicated physical CPU and only allow access to CPU-local DRAM. This can be achieved by using a non-interleaved NUMA configuration and assigning pages to VMs carefully. This approach essentially splits a multi-CPU machine into independent single-CPU systems, which leads to a loss of many of its advantages.

Saltaformaggio et al. [21] presented a countermeasure to the memory bus-based covert channel of Wu et al.. It intercepts atomic instructions that are responsible for this covert channel, so that only cores belonging to the attacker’s VM are locked, instead of the whole machine. This countermeasure is not effective against our attacks as they do not rely on atomic instructions.

Finally, our attack could be detected due to the high number of cache misses. However, it is unclear whether it is possible to distinguish our attacks from non-malicious applications.

9 Conclusion

In this paper, we presented two methods to reverse engineer the mapping of physical memory addresses to DRAM channels, ranks, and banks. One uses physical probing of the memory bus, the other runs entirely in software and is fully automated. We ran our method on a wide range of architectures, including desktop, server, and mobile platforms.

Based on the reverse-engineered functions, we demonstrated DRAMA (DRAM addressing) attacks. This novel class of attacks exploits the DRAM row buffer that is a shared resource in single and multi-processor systems. This allows our attacks to work in the most restrictive environments, *i.e.*, across processors and without any shared memory. We built a covert channel with a capacity of 2 Mbps, which is three to four orders of magnitude faster than memory-bus-based channels in the same setting. We demonstrated a side-channel template attack automatically locating and monitoring memory accesses, *e.g.*, user input, server requests. This side-channel attack is as accurate as recent cache attacks like

Flush+Reload, while requiring no shared memory between the victim and the spy. Finally, we show how to use the reverse-engineered DRAM addressing functions to improve existing attacks, such as Flush+Reload and Rowhammer. Our work enables practical Rowhammer attacks on DDR4.

We emphasize the importance of reverse engineering microarchitectural components for security reasons. Before we reverse engineered the DRAM address mapping, the DRAM row buffer was transparent to operating system and software. Only by reverse engineering we made this shared resource visible and were able to identify it as a powerful side channel.

Acknowledgments

We would like to thank our anonymous reviewers as well as Anders Fogh, Moritz Lipp, and Mark Lanteigne for their valuable comments and suggestions.

Abstract

It is well-known that static disassembly is an unsolved problem, but how much of a problem is it in real software—for instance, for binary protection schemes? This work studies the accuracy of nine state-of-the-art disassemblers on 981 real-world compiler-generated binaries with a wide variety of properties. In contrast, prior work focuses on isolated corner cases; we show that this has led to a widespread and overly pessimistic view on the prevalence of complex constructs like inline data and overlapping code, leading reviewers and researchers to underestimate the potential of binary-based research. On the other hand, some constructs, such as function boundaries, are much harder to recover accurately than is reflected in the literature, which rarely discusses much needed error handling for these primitives. We study 30 papers recently published in six major security venues, and reveal a mismatch between expectations in the literature, and the actual capabilities of modern disassemblers. Our findings help improve future research by eliminating this mismatch.

1 Introduction

The capabilities and limitations of disassembly are not always clearly defined or understood, making it difficult for researchers and reviewers to judge the practical feasibility of techniques based on it. At the same time, disassembly is the backbone of research in static binary instrumentation [5, 19, 32], binary code lifting to LLVM IR (for reoptimization or analysis) [38], binary-level vulnerability search [27], and binary-level anti-exploitation systems [1, 8, 29, 46]. Disassembly is thus crucial for analyzing or securing untrusted or proprietary binaries, where source code is simply not available.

The accuracy of disassembly strongly depends on the type of binary under analysis. In the most general case, the disassembler can make very few assumptions on the structure of a binary—high-level concepts like functions and loops have no real significance at the binary level [3].

Moreover, the binary may contain complex constructs, such as overlapping or self-modifying code, or inline data in executable regions. This is especially true for obfuscated binaries, making disassembly of such binaries extremely challenging. Disassembly in general is undecidable [43]. On the other hand, one might expect that compilers emit code with more predictable properties, containing a limited set of patterns that the disassembler may try to identify.

Whether this is true is not well recognized, leading to a wide range of views on disassembly. These vary from the stance that disassembly of benign binaries is a solved problem [48], to the stance that complex cases are rampant [23]. It is unclear which view is justified in a given situation. The aim of our work is thus to study binary disassembly in a realistic setting, and more clearly delineate the capabilities of modern disassemblers.

It is clear from prior work that obfuscated code may complicate disassembly in a myriad of ways [18, 21]. We therefore limit our study to non-obfuscated binaries compiled on modern x86 and x64 platforms (the most common in binary analysis and security research). Specifically, we focus on binaries generated with the popular `gcc`, `clang` and Visual Studio compilers. We explore a wide variety of 981 realistic binaries, including stripped, optimized, statically linked, and link-time optimized binaries, as well as library code that includes handcrafted assembly. We disassemble these binaries using nine state-of-the-art research and industry disassemblers, studying their ability to recover all disassembly primitives commonly used in the literature: instructions, function start addresses, function signatures, Control Flow Graphs (CFG) and callgraphs. In contrast, prior studies focus strongly on complex corner cases in isolation [23, 25]. Our results show that such cases are exceedingly rare, even in optimized code, and that focusing on them leads to an overly pessimistic view on disassembly.

We show that many disassembly primitives can be recovered with better accuracy than previously thought. For

instance, instruction accuracy often approaches 100%, even using linear disassembly. On the other hand, we also identify some primitives which are more difficult to recover—most notably, function start information.

To facilitate a better match between the capabilities of disassemblers and the expectations in the literature, we comprehensively study all binary-based papers published in six major security conferences in the last three years. Ironically, this study shows a focus in the literature on rare complex constructs, while little attention is devoted to error handling for primitives that really are prone to inaccuracies. For instance, only 25% of Windows-targeted papers that rely on function information discuss potential inaccuracies, even though the accuracy of function detection regularly drops to 80% or less. Moreover, less than half of all papers implement mechanisms to deal with inaccuracies, even though in most cases errors can lead to malignant failures like crashes.

Contributions & Outline

The contributions of our work are threefold.

- (1) We study disassembly on 981 full-scale compiler-generated binaries, to clearly define the true capabilities of modern disassemblers (Section 3) and the implications on binary-based research (Section 4).
- (2) Our results allow researchers and reviewers to accurately judge future binary-based research—a task currently complicated by the myriad of differing opinions on the subject. To this end, we release all our raw results and ground truth for use in future evaluations of binary-based research¹.
- (3) We analyze the quality of all recent binary-based work published in six major security venues by comparing our results to the requirements and assumptions of this work (Section 5). This shows where disassembler capabilities and the literature are mismatched, and how this mismatch can be resolved moving forward (Section 6).

2 Evaluating Real-World Disassembly

This section outlines our disassembly evaluation approach. We discuss our results, and the implications on binary-based research, in Sections 3–4. Sections 5–6 discuss how closely expectations in the literature match our results.

2.1 Binary Test Suite

We focus our analysis on non-obfuscated x86 and x64 binaries generated with modern compilers. Our experiments are based on Linux (ELF) and Windows (PE) binaries, generated with the popular `gcc` v5.1.1, `clang` v3.7.0 and

¹<https://www.vusec.net/projects/disassembly/>

Visual Studio 2015 compilers—the most recent versions at the time of writing. The x86/x64 instruction set is the most common target in binary-based research. Moreover, x86/x64 is a variable-length instruction set, allowing unique constructs such as overlapping and “misaligned” instructions which can be difficult to disassemble. We exclude obfuscated binaries, as there is no doubt that they can wreak havoc on disassembler performance and we hardly need confirm this in our experiments.

We base our disassembly experiments on a test suite composed of the SPEC CPU2006 C and C++ benchmarks, the widely used and highly optimized `glibc-2.22` library, and a set of popular server applications consisting of `nginx` v1.8.0, `lighttpd` v1.4.39, `opensshd` v7.1p2, `vsftpd` v3.0.3 and `exim` v4.86. This test suite has several properties which make it representative: (1) It contains a wide variety of realistic C and C++ binaries, ranging from very small to large; (2) These correspond to binaries used in evaluations of other work, making it easier to relate our results to the literature; (3) The tests include highly optimized library code, containing handwritten assembly and complex corner cases which regular applications do not; (4) SPEC CPU2006 compiles on both Linux and Windows, allowing a fair comparison of results between `gcc`, `clang`, and Visual Studio.

To study the impact of compiler options on disassembly, we compile the SPEC CPU2006 part of our test suite multiple times with a variety of popular configurations. Specifically: (1) Optimization levels 00, 01, 02 and 03 for `gcc`, `clang` and Visual Studio; (2) Optimization for size (0s) on `gcc` and `clang`; (3) Static linking and link-time optimization (-fLTO) on 64-bit `gcc`; (4) Stripped binaries, as well as binaries with symbols. We compile the servers for both x86 and x64 with `gcc` and `clang`, leaving all remaining settings at the Makefile defaults. Finally, we compile `glibc-2.22` with 64-bit `gcc`, to which it is specifically tailored. In total, our test suite contains 981 binaries and shared objects.

2.2 Disassembly Primitives

We test all five common disassembly primitives used in the literature (see Section 5). Some of these go well beyond basic instruction recovery, and are only supported by a subset of the disassemblers we test.

- (1) *Instructions*: The pure assembly-level instructions.
- (2) *Function starts*: Start addresses of the functions originally defined in the source code.
- (3) *Function signatures*: Parameter lists for functions found by the disassembler.
- (4) *Control Flow Graph (CFG) accuracy*: The soundness and completeness of the CFG digraphs $G_{cfg} = (V_{bb}, E_{cfg})$, which describe how control flow edges $E_{cfg} \subseteq V_{bb} \times V_{bb}$ connect the basic blocks V_{bb} . In practice, dis-

assemblers deviate from the traditional CFG; typically by omitting indirect edges, and sometimes by defining a global CFG rather than per-function CFGs. Therefore, we define the *Interprocedural CFG (ICFG)*: the union of all function-level CFGs, connected through interprocedural call and jump edges. This allows us to abstract from the disassemblers’ varying CFG definitions, by focusing our measurement on the coverage of basic blocks in the ICFG. We pay special attention to hard-to-resolve basic blocks, such as the heads of address-taken functions and switch/case blocks reached via jump tables.

(5) *Callgraph accuracy*: The correctness of the digraph $G = (V_{cs} \cup V_f, E_{call})$ linking the set V_{cs} of call sites to the function starts V_f through call edges $E_{call} \subseteq V_{cs} \times V_f$. Similarly to the CFG, disassemblers deviate from the traditional callgraph definition by including only direct call edges. In our experiments, we therefore measure the completeness of this *direct callgraph*, considering indirect calls and tailcalls separately in our complex case analysis.

2.3 Complex Constructs

We also study the prevalence in real-world binaries of complex corner cases which are often cited as particularly harmful to disassembly [5, 23, 34].

(1) *Overlapping/shared basic blocks*: Basic blocks may be shared between different functions, hindering disassemblers from properly separating these functions.

(2) *Overlapping instructions*: Since x86/x64 uses variable-length instructions without any enforced memory alignment, jumps can target any offset within a multi-byte instruction. This allows the same code bytes to be interpreted as multiple overlapping instructions, some of which may be missed by disassemblers.

(3) *Inline data and jump tables*: Data bytes may be mixed in with instructions in a code section. Examples of potential inline data include jump tables or local constants. Such data can cause false positive instructions, and can desynchronize the instruction stream if the last few data bytes are mistakenly interpreted as the start of a multi-byte instruction. Disassembly then continues parsing this instruction into the actual code bytes, losing track of the instruction stream alignment.

(4) *Switches/case blocks*: Switches are a challenge for basic block discovery, because the switch case blocks are typically indirect jump targets (encoded in jump tables).

(5) *Alignment bytes*: Some code (i.e., `nop`) or data bytes may have no semantic meaning, serving only to align other code for optimization of memory accesses. Alignment bytes may cause desynchronization if they do not encode valid instructions.

(6) *Multi-entry functions*: Functions may have multiple basic blocks used as entry points, which can complicate function start recognition.

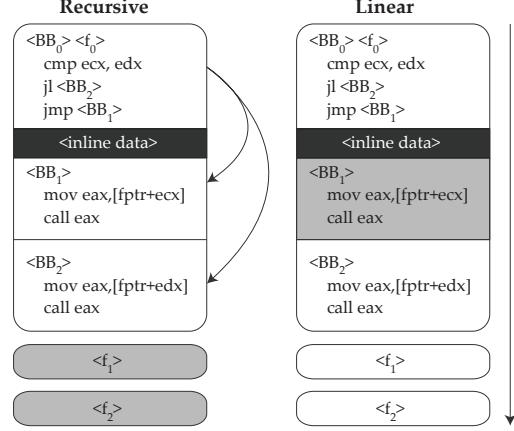

Figure 1: Disassembly methods. Arrows show disassembly flow. Gray blocks show missed or corrupted code.

(7) *Tail calls*: In this common optimization, a function ends not with a return, but with a jump to another function. This makes it more difficult for disassemblers to detect where the optimized function ends.

2.4 Disassembly & Testing Environment

We conducted all disassembly experiments on an Intel Core i5 4300U machine with 8GB of RAM, running Ubuntu 15.04 with kernel 3.19.0-47. We compiled our `gcc` and `clang` test cases on this same machine. The Visual Studio binaries were compiled on an Intel Core i7 3770 machine with 8GB of RAM, running Windows 10.

We tested nine popular industry and research disassemblers: *IDA Pro v6.7*, *Hopper v3.11.5*, *Dyninst v9.1.0* [5], *BAP v0.9.9* [7], *ByteWeight v0.9.9* [4], *Jakstab v0.8.4* [17], *angr v4.6.1.4* [36], *PSI v1.1* [47] (the successor of BinCFI [48]), and *objdump v2.22*. ByteWeight yields only function starts, while Dyninst and PSI support only ELF binaries (for Dyninst, this is due to our Linux testing environment). Jakstab supports only x86 PE binaries. We omit angr results for x86, as angr is optimized for x64. PSI is based on objdump, with added error correction. Section 3 shows that PSI (and all linear disassemblers) perform equivalently to objdump; therefore, we group these under the name *linear disassembly*.

All others are recursive descent disassemblers, illustrated in Figure 1. These follow control flow to avoid desynchronization by inline data, and to discover complex cases like overlapping instructions. In contrast, linear disassemblers like objdump simply decode all code bytes consecutively, and may be confused by inline data, possibly causing garbled code like BB_1 in the figure. Recursive disassemblers avoid this problem, but may miss indirect control flow targets, such as f_1 and f_2 in the figure.

2.5 Ground Truth

Our disassembly experiments require precise ground truth on instructions, basic blocks and function starts, call sites, function signatures and switch/case addresses. This information is normally only available at the source level. Clearly, we cannot obtain our ground truth from any disassembler, as this would bias our experiments.

We base our ELF ground truth on information collected by an LLVM analysis pass, and on DWARF v3 debugging information. Specifically, we use LLVM to collect source-level information, such as the source lines belonging to functions and switch statements. We then compile our test binaries with DWARF information, and link the source-level line numbers to the binary-level addresses using the DWARF line number table. We also use DWARF information on function parameters for our function signature analysis. We strip the DWARF information from the binaries before our disassembly experiments.

The line number table provides a full mapping of source lines to binary, but not all instructions correspond directly to a source line. To find these instructions, we use *Capstone v3.0.4* to start a conservative linear disassembly sweep from each known instruction address, stopping at control flow instructions unless we can guarantee the validity of their destination and fall-through addresses. For instance, the target of a direct unconditional jump instruction can be guaranteed, while its fall-through block cannot (as it might contain inline data).

This approach yields ground truth for over 98% of code bytes in the tested binaries. We manually analyze the remaining bytes, which are typically alignment code unreachable by control flow. The result is a ground truth file for each binary test case, that specifies the type of each code byte, as well as instruction and function starts, switch/case addresses, and function signatures.

We use a similar method for the Windows PE tests, but based on information from PDB (Program Database) files produced by Visual Studio instead of DWARF. This produces files analogous to our ELF ground truth format.

We release all our ground truth files and our test suite, to aid in future evaluations of binary-based research and disassembly.

3 Disassembly Results

This section describes the results of our disassembly experiments, using the methodology outlined in Section 2. We first discuss application binaries (SPEC and servers), followed by a separate discussion on highly optimized libraries. Finally, we discuss the impact of static linking and link-time optimization. We release all our raw results, and present aggregated results here for space reasons.

3.1 Application Binaries

This section presents disassembly results for application code. We discuss accuracy results for all primitives, and also analyze the prevalence of complex cases.

3.1.1 SPEC CPU2006 Results

Figures 2a–2e show the accuracy for the SPEC CPU2006 C and C++ benchmarks of the recovered instructions, function starts, function signatures, CFGs and callgraphs, respectively. We show the percentage of correctly recovered (true positive) primitives for each tested compiler at optimization levels 00–03. Note that the legend in Figure 2a applies to Figures 2a–2e. All lines are geometric mean results (simply referred to as “mean” from this point); arithmetic means and standard deviations are discussed in the text where they differ significantly. We show separate results for the C and C++ benchmarks, to expose variations in disassembly accuracy that may result from different code patterns.

Some disassemblers support only a subset of the tested primitives. For instance, linear disassembly provides only instructions, and IDA Pro is the only tested disassembler that provides function signatures. Moreover, some disassemblers only support a subset of the tested binary types, and are therefore only shown in the plots where they are applicable. For clarity, the graphs only show results for stripped binaries; our tests with standard symbols (not DWARF information) are discussed in the text.

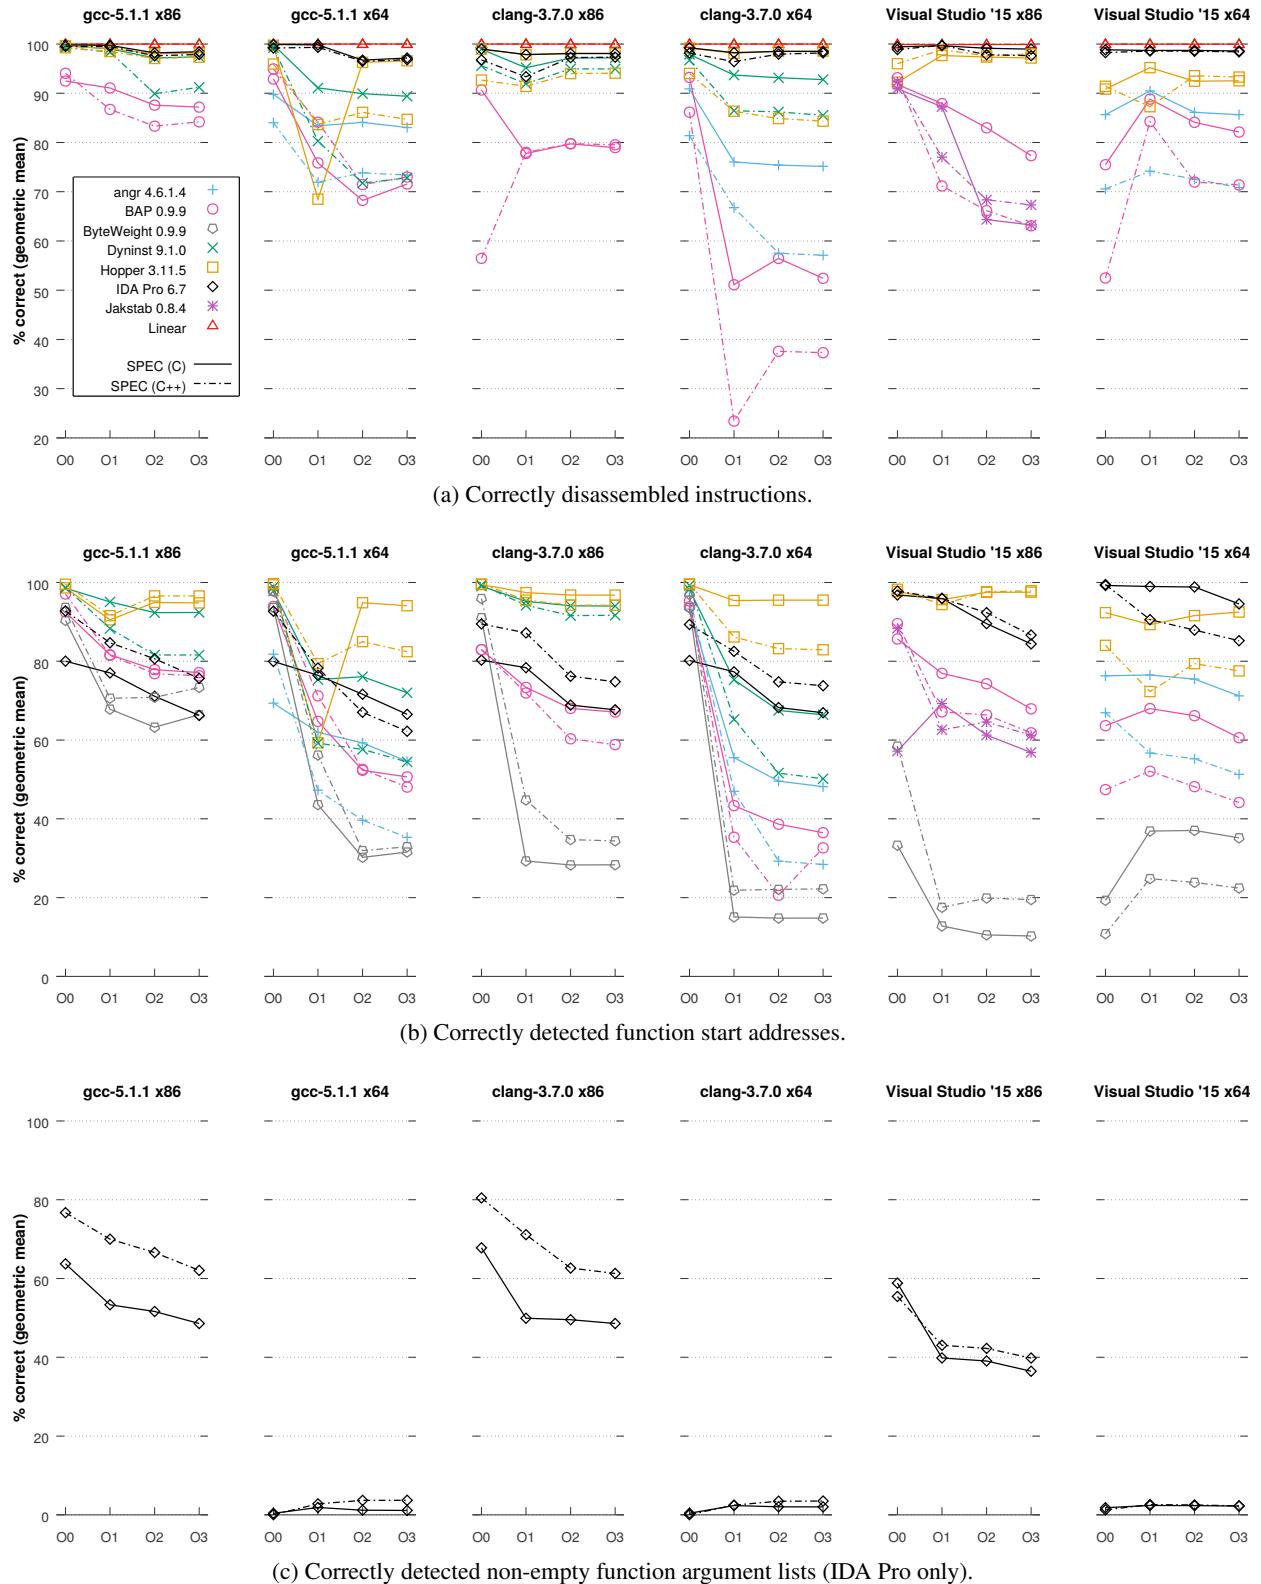

3.1.1.1 Instruction boundaries

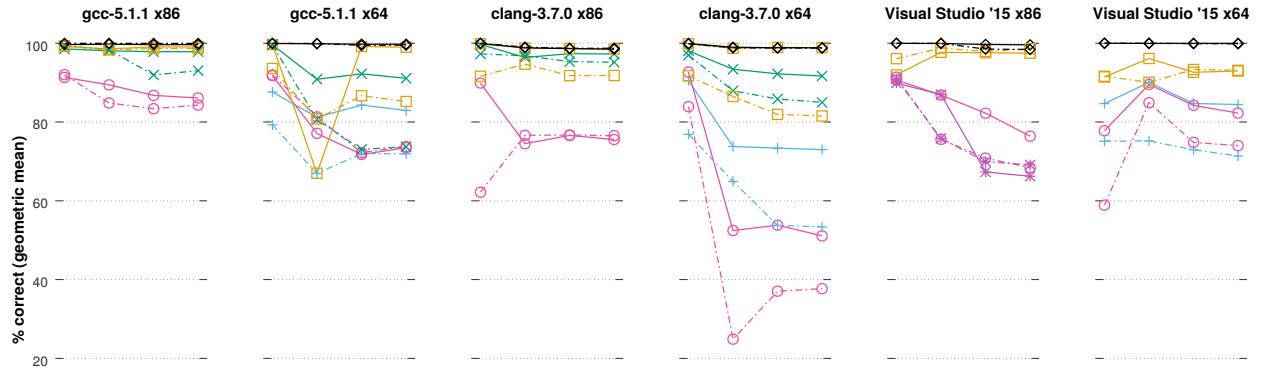

Figure 2a shows the percentage of correctly recovered instructions. Interestingly, linear disassembly consistently outperforms all other disassemblers, finding 100% of the instructions for `gcc` and `clang` binaries (without false positives), and 99.92% in the worst case for Visual Studio.

Linear disassembly. The perfect accuracy for linear disassembly with `gcc` and `clang` owes to the fact that these compilers never produce inline data, not even for jump tables. Instead, jump tables and other data are placed in the `.rodata` section.

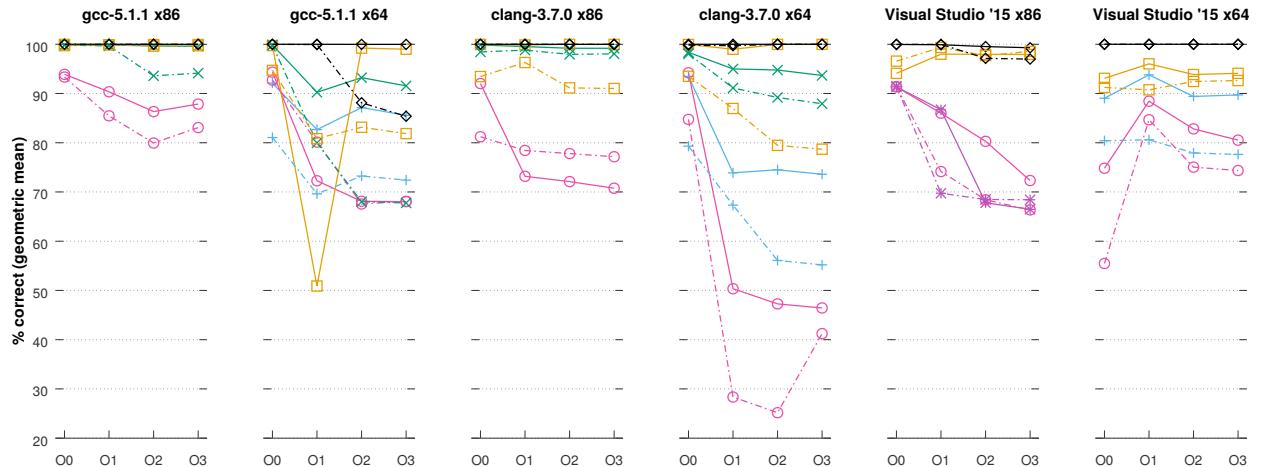

Visual Studio *does* produce inline data, typically jump tables. This leads to some false positives with linear disassembly (data treated as code), amounting to a worst-case mean of 989 false positive instructions (0.56% of the disassembled code) for the x86 C++ tests at 03. The number of missed instructions (false negatives, due to desynchronization) is much lower, at a worst-case mean of 0.09%. This is because x86/x64 disassembly automatically resynchronizes within two or three instructions [21].

Figure 2: Disassembly results. The legend in Figure 2a applies to Figures 2a–2e. Section 2.4 describes which platforms are supported by each tested disassembler.

(d) Correct and complete basic blocks for the ICFG.

(e) Correctly resolved direct function calls (indirect calls discussed separately).

Recursive disassembly. The most accurate recursive disassembler in terms of instruction recovery is IDA Pro 6.7, which closely follows linear disassembly with an instruction coverage exceeding 99% at optimization levels 00 and 01, dropping to a worst case mean of 96% for higher optimization levels. The majority of missed instructions at higher optimization levels are alignment code for functions and basic blocks, which is quite common in optimized binaries. It consists of various (long) nop instructions for `gcc` and `clang`, and of `int 3` instructions for `Visual Studio`, and accounts for up to 3% of all code at 02 and 03. Missing these instructions is not harmful to common binary analysis operations, such as binary instrumentation, manual analysis or decompilation.

False positives in IDA Pro are less prevalent than in linear disassembly. On `gcc` and `clang`, they are extremely rare, amounting to 14 false positives in the worst test case, with a mean of 0. `Visual Studio` binaries produce more false positives, peaking at 0.16% of all recovered instructions. Overall, linear disassembly provides the most

complete instruction listing, but at a relatively high false positive rate for `Visual Studio`. IDA Pro finds only slightly fewer instructions, with significantly fewer false positives. These numbers were no better for binaries with symbols.

Dyninst and Hopper achieve best case accuracy comparable to IDA, but not quite as consistently. Some disassemblers, notably BAP, appear to be optimized for `gcc`, and show large performance drops when used on `clang`. The BAP authors informed us that BAP's results depend strongly on the disassembly starting points (i.e., function starts), provided by ByteWeight. We used the default ELF and PE signature files shipped with ByteWeight v0.9.9. Our angr results are based on the CFGFast analysis recommended to us by the angr authors.

Overall, IDA Pro, Hopper, Dyninst and linear disassembly show arithmetic mean results which are extremely close to the geometric means, exhibiting standard deviations below 1%. Other disassemblers have larger standard deviations, typically around 15%, with outliers up to 36% (for BAP on `clang` x86, as visible in Figure 2a).

C versus C++. Accuracy between C and C++ differs most in the lower scoring disassemblers, but the difference largely disappears in the best performing disassemblers. The largest relative difference appears for clang.

3.1.1.2 Function starts

The results for function start detection are far more diffuse than those for instruction recovery. Consider Figure 2b, which shows the mean percentage of correctly recovered function start addresses. No one disassembler consistently dominates these results, though Hopper is at the upper end of the spectrum for most compiler configurations in terms of true positives. Dyninst also provides high true positive rates, though not as consistently as Hopper. However, as shown in Figure 3, both Hopper and Dyninst suffer from high false positive rates, with worst case mean false positive rates of 28% and 19%, respectively. IDA Pro provides lower false positive rates of under 5% in most cases (except for x86 Visual Studio, where it peaks at 20%). However, its true positive rate is substantially lower than those of Hopper and Dyninst, regularly missing 20% or more of functions even at low optimization levels. As with instruction recovery, the results for BAP and ByteWeight depend heavily on the compiler configuration, ranging from over 90% accuracy on gcc x86 at 00, to under 20% on clang x64.

Even for the best performing disassemblers, function start identification is far more challenging than instruction recovery. Accuracy drops particularly as the optimization level increases, repeatedly falling from close to 99% true positives at 00, to only 82% at 03, and worsened by high false positive rates. For IDA Pro, the worst case mean true positive rate is even lower, falling to 62% for C++ on x64 gcc at 03. Moreover, the standard deviation increases to over 15% even for IDA Pro.

```

Listing 4: False positive function (shaded) for Dyninst, due to code misinterpreted as epilogue, perlbench compiled with gcc at 03 for x64 ELF.

False negatives. The vast majority of false negatives is caused by indirectly called or tailcalled functions (reached by a `jmp` instead of a `call`), as shown in Listing 1. This explains why the true positive rate drops steeply at high optimization levels, where tail calls and functions lacking standard prologues are common (see Section 3.1.3). Symbols, if available, help greatly in improving accuracy. They are used especially effectively by IDA Pro, which consistently yields over 99% true positives for binaries with symbols, even at higher optimization levels.

False positives. Several factors contribute to the false positive rate. We analyzed a random sample of 50 false positives for Dyninst, Hopper and IDA Pro, the three best performing disassemblers in function detection.

For Dyninst, false positives are mainly due to erroneously applied signatures for function prologues and epilogues. As an example, Listing 2 shows a false positive in Dyninst due to a misidentified prologue: Dyninst scans for the `push %r15` instruction (as well as several other prologue signatures), missing preceding instructions in the function. We observe similar cases for function epilogues. For instance, as shown in Listings 3 and 4, Dyninst assumes a new function following a `ret`; `nop` instruction sequence. This is not always correct: as shown in the examples, the same code pattern can result from a multi-exit function with padding between basic blocks. Note that both examples could be handled correctly by control flow and semantics-aware disassemblers. In Listing 4, there are intraprocedural jumps towards the basic block at `0x46bb50`, showing that it is not a new function.

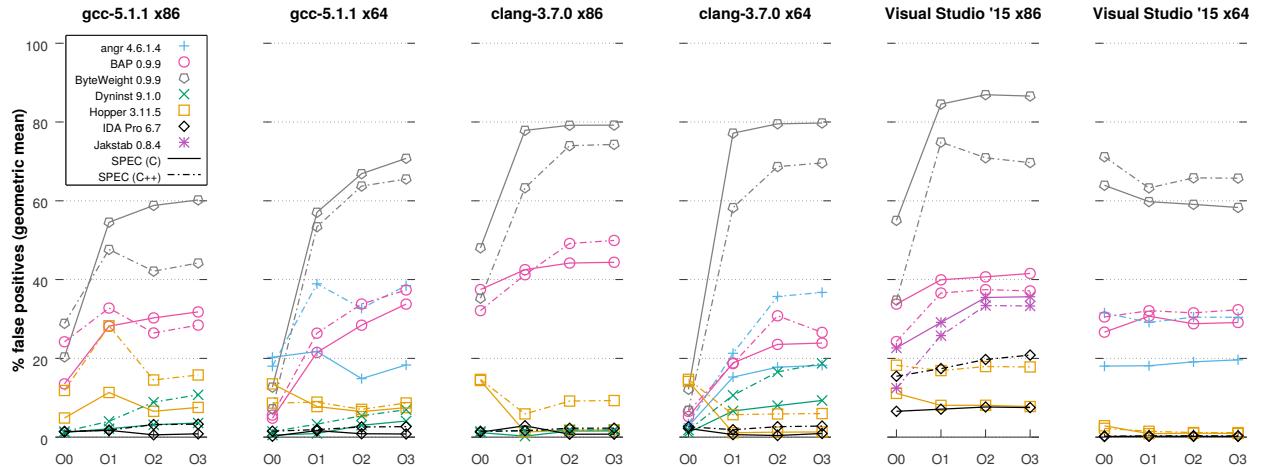

Figure 3: False positives for function start detection (percentage of total detected functions).

42cec3: movss %xmm0,-0x340(%rbp)
42ceb2: jmpq 42cf8 <P7PriorifyTransitionVector+0x622>
42ced0: mov -0x344(%rbp),%eax

```

Listing 5: False positive function (shaded) for Hopper, due to misclassified switch case block, hmmer compiled with gcc at 00 for x64 ELF.

The false positive in Listing 3 is in effect a `nop` instruction, emitted for padding by `gcc` on x86.

All false positives we sampled for Hopper are located directly after padding code, or after a direct `jmp` (without a fallthrough edge), and are not directly reached by other instructions. An example is shown in Listing 5. Since these instructions are never reached directly, Hopper assumes that they represent function starts. This is not always correct; for instance, the same pattern frequently results from case blocks belonging to switch statements, as seen in Listing 5.

Similarly, the majority of false positives for IDA Pro is also caused by unreachable code assumed to be a new function. However, these cases are far less common in IDA Pro than in Hopper, as IDA Pro more accurately resolves difficult control flow constructs such as switches. Interestingly, the false positive rate for IDA Pro drops to a mean of under 0.3% for x64 Visual Studio 2015. This is because 64-bit Visual Studio uses just one well-defined calling convention, while other compilers use a variety [22].

3.1.1.3 Function signatures

Of the tested disassemblers, only IDA Pro supports function signature analysis. Figure 2c shows the percentage of non-empty function argument lists where IDA Pro correctly identified the number of arguments. We focus on

non-empty argument lists because IDA Pro defaults to an empty list, skewing our results if counted as correct.

Argument recovery is far more accurate on x86 code, where parameters are typically passed on the stack, than it is on the register-oriented x64 architecture. For x86 code generated by `gcc` and `clang`, IDA Pro correctly identifies between 64% and 81% of the argument lists on non-optimized binaries, dropping to 48% in the worst case at 03. Results for Visual Studio are slightly worse, ranging from 36% worst case to 59% in the best case. As for function starts, the standard deviation is just over 15%. On x64 code, IDA Pro recovers almost none of the argument lists, with accuracy between 0.38% and 1.87%.

Performance is significantly better for binaries with symbols, even on x64, but only for C++ code. For instance, IDA Pro's accuracy for `gcc` x64 increases to a mean of 44% for C++, peaking at 75% correct argument lists. This is because IDA Pro parses mangled function names that occur in C++ symbols, which encode signature information in the function name.

3.1.1.4 Control Flow Graph accuracy

Figure 2d presents the accuracy of basic blocks in the ICFG, the union of all function-level CFGs. We found these results to be representative of the per-function CFG accuracy. The accuracy of the ICFG is strongly correlated with instruction discovery; indeed, recursive disassemblers typically find instructions through the process of expanding the ICFG itself. Thus, the disassemblers that perform well in instruction recovery also perform well in CFG construction. For some disassemblers, such as IDA Pro, the basic block true positive rate at high optimization levels even exceeds the raw instruction recovery results (Figure 2a). This is because for the ICFG, we did not count missing `nop` instructions as false negatives.

IDA Pro consistently achieves a basic block recovery rate of between 98–100%, even at high optimization levels. Even at moderate optimization levels, the results for Hopper and Dyninst are considerably less complete, regularly dropping to 90% or less. For the remaining disassemblers, basic block recovery rates of 75% or less are typical.

All disassemblers except IDA Pro show a considerable drop in accuracy on `gcc` and `clang` for x64, compared to the x86 results. This is strongly correlated with the diminishing instruction and function detection results for these disassembler/architecture combinations (see Figures 2a–2b). This implies that when functions are missed, these disassemblers also fail to recover the instructions and basic blocks contained in the missed functions. In contrast, IDA Pro disassembles instructions even when it cannot attribute them to any function. The difference between x86/x64 and C/C++ results is less pronounced for Visual Studio binaries than for `gcc`/`clang`.

3.1.1.5 Callgraph accuracy

Like ICFG accuracy, callgraph accuracy depends strongly on the completeness of the underlying instruction analysis. As mentioned, the callgraphs returned by the tested disassemblers contain only the direct call edges, and do not deal with address-taken functions. For this reason, Figure 2e presents results for the direct component of the callgraph only. We study the impact of indirect calls on function identification accuracy in our complex case analysis instead (Section 3.1.3). The direct callgraph results in Figure 2e again show IDA Pro to be the most accurate at a consistent 99% function call resolve rate (linking function call edges to function starts), in most cases followed closely by Dyninst and Hopper. This illustrates that the lower accuracy for function starts (Figure 2b) is mainly due to indirectly called functions (such as those called via function pointers or in tail call optimizations).

3.1.2 Server Results

Table 1 shows disassembly results for the servers from our test suite. For space reasons, and because the relative accuracy of the disassemblers is the same as for SPEC, we only show results for IDA Pro, the best overall disassembler. All other results are available externally, as mentioned at the start of Section 3. We compiled all servers for both x86 and x64 with `gcc` and `clang`, using their default Makefile optimization levels.

The server tests confirm that the SPEC results from Section 3.1.1 are representative; all results lie well within the established bounds. As with SPEC, linear disassembly achieved 100% correctness. The `nginx` results warrant closer inspection; given its optimization level 01, the

Table 1: IDA Pro 6.7 disassembly results for server tests (% correct, per test case).

function start and argument information is on the low end of the accuracy spectrum. Closer analysis shows that this results from extensive use in `nginx` of indirect calls through function pointers; Section 3.1.1 shows that this negatively affects function information. Indeed, for all tested servers, the accuracy of function start detection is inversely proportional to the ratio of address-taken functions to the total number of instructions. This shows that coding style can carry through the compilation process to have a strong effect on disassembler performance.

3.1.3 Prevalence of Complex Constructs

Figure 4 shows the prevalence of complex constructs in SPEC CPU2006, which pose special disassembly challenges. We also analyzed these constructs in the server binaries, finding no significantly different results.

We did not encounter any overlapping or shared basic blocks in either the SPEC or server tests on any compiler. This is surprising, as these constructs are frequently cited in the literature [5, 17, 23]. Closer inspection showed that all the cited cases of overlapping blocks are due to constructs which we classify more specifically, namely overlapping instructions and multi-entry functions. These constructs are exceedingly rare, and occur almost exclusively in library code (discussed in Section 3.2.2). This finding fits with the examples seen in the literature, which all stem from library code, most commonly `glibc`.

No overlapping instructions occur in Linux application code, and only a handful in Windows code (with a mean of zero, and a maximum of 3 and 10 instructions for x86 and x64 Visual Studio, respectively). Multi-entry functions are somewhat more common. All cases we found consisted of functions with optional basic blocks that can execute before the main function body, and finish by jumping over the main function body prologue. Figure 4 lists such jumps as *multi-entry jumps*, and shows

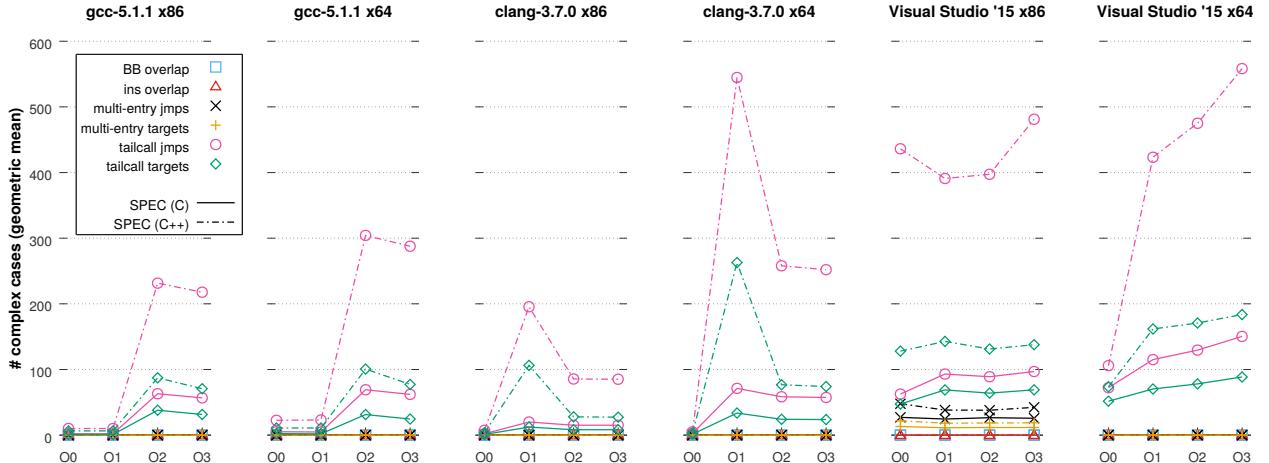

Figure 4: Prevalence of complex constructs in SPEC CPU2006 binaries.

the targeted main function bodies as *multi-entry targets*. In binaries compiled with `gcc` and `clang`, we found up to 18 multi-entry jumps for C code, and up to 64 for C++, with the highest prevalence in x64 binaries. Visual Studio produced up to 172 multi-entry jumps for C, and up to 88 for C++, the construct being most prevalent in x86 code. This kind of multi-entry function is handled well by disassemblers in practice, producing no notable decrease in disassembly accuracy compared to other functions.

Tailcalls form the most prevalent complex case, and do negatively affect function start detection if the target function is never called normally (see Section 3.1.1). The largest number of tailcalls (listed as *tailcall jumps* in Figure 4) is found in `clang` x64 C++ binaries, at a mean of 545 cases. Visual Studio produces a similar number of tailcalls. For `clang`, the number of tailcalls peaks at optimization level 01, while Visual Studio peaks at 03. For `clang` (and to a lesser extent `gcc`), higher optimization levels can lead to a decrease in tailcalls through other modifications like code merging and code elimination.

Jump tables (due to switches) are by far the most common case of inline data. They occur as inline data only on Visual Studio (`gcc` and `clang` place jump tables in the `.rodata` section). As seen in Section 3.1.1, inline data causes false positive instructions especially in linear disassembly (peaking at 0.56% false positives).

Another challenge due to jump tables is locating all case blocks belonging to the switch; these are typically reached indirectly via a jump that loads its target address from the jump table. Linear disassembly covers 100% of case blocks correctly on `gcc` and `clang` (see Section 3.1.1), and also achieves very high accuracy for Visual Studio. The best performing recursive disassemblers, most notably IDA Pro, also achieved very high coverage of switch/case blocks; coverage of these blocks is comparable to the overall instruction/basic block recov-

ery rates. This is because many recursive disassemblers have special heuristics for identifying and parsing standard jump tables.

3.1.4 Optimizing for Size

At optimization levels 00–03, no overlapping or shared basic blocks occur. A reasonable hypothesis is that compilers might more readily produce such blocks when optimizing for size (optimization level 0s) rather than for performance. To verify this, we recompiled the SPEC C and C++ benchmarks with size optimization, and repeated our disassembly tests.

Even for size-optimized binaries, we did not find any overlapping or shared blocks. Moreover, the accuracy of the instruction boundaries, callgraph and ICFG did not significantly differ from our results for 00–03. Function starts and argument lists were comparable in precision to those for performance-optimized binaries (02–03).

3.2 Shared Library Objects

This section discusses our disassembly results and complex case analysis for library code. Libraries are often highly optimized, and therefore contain more complex (handcrafted) corner cases than application code. We focus our analysis on `glibc-2.22`, the standard C library used in GNU systems, compiled in its default configuration (`gcc` with optimization level 02). This is one of the most widespread and highly optimized libraries, and is often cited as a highly complex case [5, 23].

3.2.1 Disassembly Results

Table 2 shows disassembly results for `glibc-2.22`, for all tested disassemblers that support 64-bit ELF binaries. Nearly all disassemblers display significantly lower

	Instructions	Functions	Signatures	ICFG	Callgraph
gcc-5.1.1 x64					
angr	64.4	75.6	—	70.2	87.9
BAP	65.3	79.6	—	72.4	84.8
ByteWeight	—	29.3	—	—	—

Hopper	84.3	93.3	—	90.6	93.9
IDA Pro	96.0	92.0	5.4	99.9	99.9
Linear	99.9	—	—	—	—

Table 2: Disassembly results for glibc (% correct).

accuracy on instruction boundaries than the mean for application binaries in equivalent compiler configurations. Only IDA Pro and linear disassembly are on par with their performance on application code, achieving very good accuracy without any false positives. Note that objdump achieves 99.9% accuracy instead of the usual 100% for ELF binaries. This is because unlike IDA Pro, it does not explicitly separate the overlapping instructions that occur in glibc (see Section 3.2.2).

Function start results are on par with, or even exceed the mean for application binaries; this holds true for all disassemblers. Moreover, the accuracy of function argument lists (5.4%) is much higher than one would expect from the x64 SPEC CPU2006 results (under 1% accuracy). This is because IDA Pro comes with a set of code signatures designed to recognize standard library functions that are statically linked into binaries.

For the ICFG, we see the same pattern as for instructions: all disassemblers perform worse than for application code, while IDA Pro delivers comparable accuracy. Callgraph accuracy is below the mean for most disassemblers, though IDA Pro and Dyninst perform very close to the mean, and BAP well exceeds it.

3.2.2 Complex Constructs

Overall, we found the glibc-2.22 code to be surprisingly well-behaved. Our analysis found no overlapping or shared basic blocks, and no inline data. Indeed, the glibc developers have taken special care to prevent this, explicitly placing data and jump tables in the .rodata section even when manually declared in handwritten assembly code. Prior work has analysed earlier versions of glibc, showing that inline jump tables *are* present in glibc-2.12 [23]. Moreover, inline zero-bytes used for function padding are confirmed in versions up to 2.21. This is worth noting, as older glibc versions may still be encountered in practice. Our analysis of glibc versions ranging from 2.12 to 2.22 shows consistently improving disassembler-friendliness over time.

We did find some complex constructs that do not occur in application code, the most notable being overlapping

```

[...]
```

Listing 7: Multi-entry function in glibc-2.22.

instructions. We found 31 such instructions in glibc. All of these are instructions with optional prefixes, such as the one shown in Listing 6. These overlapping instructions are defined manually in handcrafted assembly code, and typically use a conditional jump to optionally skip a lock prefix. They correspond to frequently cited complex cases in the literature [5, 23].

In addition, we found 508 tailcalls resulting from the compiler’s normal optimization; a number comparable to application binaries of similar size as glibc. We also found significantly more multi-entry functions than in the SPEC benchmarks. Most of these belong to the _nocancel family, explicitly defined in glibc, an example of which is shown in Listing 7. These functions provide optional basic blocks which can be prefixed to the main function body to choose a threadsafe variant of the function. These prefix blocks end by jumping over the prologue of the main function body, a pattern also sometimes seen in application code.

Given that all non-standard complex constructs in glibc are due to handwritten assembly, we manually analyzed all assembly code in libc++ and libstdc++. However, the amount of assembly in these libraries is very limited and revealed no new complex constructs. This suggests that the optimization constructs in glibc are typical for low-level libraries, and less common in higher-level ones such as the C++ standard libraries.

3.3 Static Linking & Linker Optimization

Static linking can reduce disassembler performance on application binaries by merging complex library code into the binary. Link-time optimization performs intermodular optimization at link-time, as opposed to more local compile-time optimizations. It is a relatively new feature that is gaining in popularity, and could worsen disassembler performance if combined with static linking, by optimizing application and library code as a whole. To study

	Instructions	Functions	Signatures	ICFG	Callgraph

SPEC/C 0s	95.5	67.8	0.2	98.4	97.7

Table 3: IDA Pro 6.7 disassembly results for static and link-time optimized SPEC C benchmarks (% correct, geometric mean).

the effects of these options, we recompiled the SPEC CPU2006 C benchmarks, statically linking them with `glibc-2.22` using `gcc`'s `-static` flag. Subsequently, we repeated the process with both static linking and link-time optimization (`gcc`'s `-flio`) enabled.

As expected, static linking merges complex cases from `glibc` into SPEC, including overlapping instructions. The effect on disassembly performance is shown in Table 3 for IDA, the overall best performing disassembler in our `glibc` tests. The impact is slight but noticeable, with an instruction accuracy drop of up to 3 percentage points compared to baseline SPEC; about the same as for `glibc`. As can be seen in Table 3, link-time optimization does not significantly decrease disassembly accuracy compared to static linking only.

Function start detection suffers from static linking mostly at lower optimization levels, dropping from a mean of 80% to just under 70% for 00; at level 03 the performance is not significantly reduced. Again, link-time optimization does not worsen the situation compared to pure static linking. For the ICFG and callgraph tests, a small accuracy drop is again seen at lower optimization levels, again with no more adverse effects due to link-time optimization. For instance, ICFG accuracy drops from close to 100% mean in baseline SPEC to just over 98% in statically linked SPEC at 00, while the results at 02 and 03 show no negative impact. We suspect that this is a result of optimized library code being linked in even at lower optimization levels. Overall, we do not expect any significant adverse impact on binary-based research as link-time optimization gains in popularity.

4 Implications of Results

This section discusses the implications of our results for three popular directions in binary-based research: (1)

Control-Flow Integrity, (2) Decompilation, and (3) Automatic bug search. A detailed comparison of our results to assumptions in the literature is given in Section 5.

4.1 Control-Flow Integrity

Control-Flow Integrity (CFI) is currently one of the most popular research directions in systems security, as shown in Table 6. Binary-level CFI typically relies on binary instrumentation to insert control flow protections into proprietary or legacy binaries [1, 10, 24, 29, 41, 45, 46, 48]. Though a wide variety of CFI solutions has been proposed, most of these have similar binary analysis requirements, due to their common aim of protecting indirect jumps, indirect calls, and return instructions. We structure our discussion around what is needed to analyze and protect each of these control edge types.

Indirect calls. Typically, protecting an indirect call requires instrumenting both the call site (the `call` instruction itself, possibly including parameters), and the call target (the called function). Finding call sites relies mainly on accurate and complete disassembly of the basic instructions. As shown in Figure 2a, these can be recovered with extremely high accuracy, even 100% accuracy for linear disassembly on `gcc` and `clang` binaries. Thus, a binary-level CFI solution is unlikely to encounter problems analyzing and instrumenting call sites.

For Visual Studio binaries, there is a chance that a small percentage of call sites may be missed. Depending on the specific CFI solution, it may be possible to detect calls from uninstrumented sites in the target function, triggering a runtime error handling mechanism (see Section 5). Since these cases are rare, it is then feasible to perform more elaborate (slow path) alternative security checks.

The main challenge is to accurately detect all possible target functions for each indirect call. As a basic prerequisite, this requires finding the complete set of indirectly called functions. As shown in Section 3.1.1 and Figure 2b, this is one of the most challenging problems in disassembly — at high optimization levels, 20% or more of all functions are routinely missed.

Moreover, fine-grained CFI systems must perform even more elaborate analysis to decide which functions are legal targets for each indirect call site. Overestimating the set of legal targets leads to attacks which redirect indirect calls to unexpected functions [12]. Matching call sites to a set of targets typically requires an accurate (I)CFG, so that control-flow and data-flow analysis can be performed to determine which function pointers are passed to each call site. Figure 2d and Sections 3.1.1–3.1.3 show that an accurate and complete ICFG is typically available, including accurate resolution of switch/jump tables in the best disassemblers. Although this type of analysis remains

extremely challenging, especially if done interprocedurally (requiring accurate indirect call resolution), it is at least not limited by the accuracy of basic blocks or direct control edges.

Additionally, fine-grained CFI systems can benefit from function signature information, to further narrow down the set of targets per call site by matching the function prototype to parameters passed at the call site [39]. Though signature information is often far from complete (Figure 2c), especially on x64, the information which is available can still be useful — even with incomplete information, the target set can be reduced, directly leading to security improvements. However, care must be taken to make the analysis as conservative as possible; if this is not done, the inaccuracy of function signature information can easily cause illegal function calls to be allowed, or worse, can cause legal calls to be inadvertently blocked.

Indirect jumps. Protecting indirect jumps requires analysis similar to the requirements for indirect calls. However, as indirect jumps are typically intraprocedural, protecting them usually does not rely on function detection. Instead, accurate switch/jump table resolution is required, which is available in disassemblers like IDA Pro (Section 3.1.3).

Return instructions. Return instructions are typically protected using a shadow stack, which requires instrumenting all call and return sites (and jumps, to handle tailcalls) [8]. Given the accurate instruction recovery possible with modern disassemblers (Figure 2a), it is possible to accurately and completely instrument these sites.

Summarizing, the main challenge for modern CFI lies in accurately and completely protecting indirect call sites. The reasons for this are twofold: (1) Function detection is one of the most inaccurate primitives (especially for indirectly called functions), even in state of the art disassemblers, and (2) It is currently very difficult to recover rich information, such as function signature information, through disassembly. This makes it extremely challenging to accurately couple indirect call sites with valid targets.

4.2 Decompilation

Instead of translating a binary into assembly instructions, decompilers lift binaries to a higher-level language, typically (pseudo-) C. Decompilers are typically built on top of a disassembler, and therefore rely heavily on the quality of the disassembly [33, 44].

As most decompilers operate at function granularity, they rely on accurate function start information. Moreover, they must translate all basic blocks belonging to a function, requiring knowledge of the function’s CFG. In effect, this requires not only accurate function start

detection, but accurate function boundary detection. As described in related work, function boundary detection is even more challenging than function start detection, as it additionally requires locating the end address of each function [4]. This is difficult, especially in optimized binaries, where tailcalls often blur the boundaries between functions (since the `jmp` instructions used in tailcalls can easily be mistaken for intraprocedural control transfers).

In addition to function detection, decompilers rely on accurate instruction disassembly, and can also greatly benefit from function signature/type information. Moreover, switch detection is required to correctly attribute all switch case blocks to their parent function. Finally, call-graph information is useful to understand the connections between decompiled functions.

The impact of inaccuracies for decompilation is not as severe as for CFI systems, since decompiled code is typically intended for use in manual reverse engineering rather than automated analysis. However, disassembly errors can still affect the decompilation process itself, especially in later passes (such as stack frame analysis or data type analysis passes) over the raw decompiled function. Such analysis phases, as well as human reverse engineers, must take into account the high probability of errors in function boundary and signature information.

4.3 Automatic Bug Search

The binary analysis requirements of automatic bug search systems depend on the type of bug being searched for, and the granularity of the search. In practice, many such systems operate at the function level, both for ease of analysis, and because it is a suitable search-granularity for common bugs, such as stack-based bugs [14, 27, 50]. Operating at the function level is also useful for interoperability with other binary analysis primitives, such as symbolic execution, which are powerful tools for semantic analysis but do not scale to full binaries [14].

Thus, like decompilation, many automatic bug search systems rely on accurate function boundary information and per-function CFGs. Fortunately, despite the relatively large inaccuracies in the input information, the output of bug detection systems tends to degrade gracefully — input inaccuracies may lead to bugs being missed, but typically do not affect the correctness of the analysis for other parts of the code. Quantifying the accuracy of the inputs (disassembly, CFG, function boundaries) helps users to determine the expected output completeness of automatic bug search systems.

5 Disassembly in the Literature

Given our disassembly results, we studied recent binary-based research to determine how well the capabilities

	# Papers	Instructions	Functions	Signatures	CFG	Callgraph

Linear	2	2	1	0	1	1
Other/Custom	8	7	2	0	6	3
Total	30	25	14	3	24	11

Table 4: Primitives/disassemblers used in the literature.

of disassemblers match the expectations in the literature. Our study covers research published between 2013 and 2015 in all top-tier systems security conferences, namely S&P (Oakland), CCS, NDSS and USENIX Security. In addition, we cover research published in these same years at RAID and ACSAC, two other major conferences which are popular targets for such research.

We found 30 papers on binary-based research published in these venues, summarized in Table 6. The rest of this section presents aggregated findings to provide a degree of anonymization for these papers.

Table 4 shows the primitives and disassemblers used in these papers. IDA Pro is by far the most popular, for all primitives; our disassembly results (Section 3) justify this choice. Despite its good accuracy, linear disassembly is among the least used, even for papers that handle only ELF binaries. This may result from the widespread belief that inline data causes far more problems than we found.

Instructions are the most often needed primitive, used by 25 of the 30 papers. It is followed by the CFG (24 papers) and function starts (14 papers). Function signature information is needed by only 3 of the analyzed papers. One paper used linear disassembly as a basis for building a CFG and callgraph, and scanning for function starts.

Table 5 provides a more detailed insight into the properties of the papers we analyzed. We distinguish between papers that target Windows PE binaries, and those that target Linux ELF. This is because some complex cases, such as inline data, are more often generated by Visual Studio, deserving closer attention in Windows papers.

Most papers that support obfuscated binaries target Windows (33% of papers versus 10% for Linux). This is because obfuscation typically occurs in malware, which is more prevalent on Windows. Though we do not consider obfuscated binaries in our tests, it is still interesting to know how many papers target such binaries. After all, these papers should pay special attention to disassembly errors and complex corner cases. Unfortunately, this is not the case; only 50% of papers that support obfuscation discuss potential errors, while 33% implement error

Property	Subproperty	All papers		Top-tier	
		#	%	#	%
Windows PE x86/x64 (16 papers, 12 top-tier)

Table 5: Properties of binary-based papers (number and percentage of papers). Numbers in parentheses indicate the total number of papers that use this primitive.

handling. This is no better than the overall number. Moreover, only 17% of these papers explicitly discuss complex cases; far below the overall rate for Windows.

Nearly all papers support optimized binaries (90% or more for both Linux and Windows, overall as well as top-tier). Stripped binaries are supported by an equally large majority of papers on Windows, and by a slightly smaller majority on Linux. Curiously, the number of top-tier papers that support stripped binaries on Linux (70%) is significantly less than the overall number (79%).

The vast majority of papers use recursive disassembly (100% on Windows and 86% on Linux), with IDA Pro being the most popular disassembler. The few papers that do use linear disassembly are based on objdump, and augment it with a layer of error correction. Interestingly, these papers claim perfect (100% accurate) or close to perfect disassembly. As shown in Section 3.1.1, this precision on Linux binaries owes entirely to the core linear disassembly, making any error correction redundant other than for a few corner cases in library code (and obfuscated code, which these papers do not consider).

A relatively small percentage of Windows papers use relocation information to find disassembly starting points. At 17%, this number is slightly higher for top-tier papers.

Discussion on disassembly errors and complex cases is somewhat lacking in the analyzed papers. For most prim-

Table 6: Set of papers discussed in the literature study.

itives on Windows, at best 50% of papers discuss what happens if the primitive is not recovered perfectly. This number applies to the top-tier papers; overall, the number is even lower. The number for Linux-based papers is slightly better, though even here only a small majority of papers devote significant attention to potential problems. One would expect more thorough discussion, especially given that between 80% and 90% of Windows papers, and around 60% of Linux papers, may suffer malignant failures given imperfect primitives. The issue is most apparent in the Windows papers that require function start information. Only 25% of the top-tier papers that require function starts consider potential errors in this information, even though Section 3.1.1 shows that function starts are quite challenging to recover accurately.

The percentage of Windows papers that discuss complex cases such as inline data varies from 31% overall to 42% for top-tier papers. Again, this is less than we would expect given the prevalence of inline jump tables generated by Visual Studio. The number for papers that target Linux is even lower, though this causes fewer issues as complex cases in ELF binaries are rare.

There is a strong correlation within all papers between discussion of errors and complex cases, and support for error handling. Papers that discuss such cases also tend to implement some mechanism for dealing with errors if they occur. Conversely, papers that do not implement error handling nearly always fail to discuss errors at all.

We identified three popular and recurring categories of error handling mechanisms.

(1) *Overestimation*: For instance, CFG and callgraph overestimation are popular in papers that build binary-level security; it minimizes the risk of accidentally prohibiting valid edges, though the precision of security policies may suffer slightly.

(2) *Underestimation*: This is used in papers where soundness is more important than completeness.

(3) *Runtime augmentation*: Some papers use static analysis to approximate a primitive, and use low-cost runtime checks to fix errors in the primitive where needed.

Overestimation is the most popular error handling strategy, used in around 30% of top-tier papers. It is followed by underestimation and runtime augmentation.

6 Discussion

Our findings show a dualism in the stance on disassembly in the literature. On the one hand, the difficulty of pure (instruction-level) disassembly is often exaggerated. The prevalence of complex constructs like overlapping basic blocks, inline data, and overlapping instructions is frequently overestimated, especially for `gcc` and `clang` [5, 23]. This leads reviewers and researchers to underestimate the effectiveness of binary-based research.

We showed that unless binaries are deliberately obfuscated, instruction recovery is extremely accurate, es-

pecially in ELF binaries generated with `gcc` or `clang`. We did not find any inline data for these binaries, even in optimized library code; even jump tables are explicitly placed in the `.rodata` section. Moreover, in Visual Studio binaries with jump tables in the code section, modern disassemblers like IDA Pro recognize and resolve them quite accurately. The rare overlapping instructions in handcrafted library code take on a limited number of forms, typically using a direct conditional jump over a prefix. These are resolved without problems by IDA Pro and Dyninst, among others. The same is true for multi-entry functions, which are also rare. Moreover, overlapping/shared basic blocks (commonly cited as particularly challenging for binary analysis), do not appear in our findings at all.

On the other hand, some primitives really do often suffer from inaccuracies. Some recursive disassemblers used for binary instrumentation (notably Dyninst) regularly miss up to 10% of basic blocks in optimized binaries, calling for special attention in systems which rely on basic block-level binary instrumentation. Additionally, function signatures in 64-bit code are extremely inaccurate; fortunately, they are also rarely used in the literature.

However, function starts *are* regularly needed, though the false negative rate regularly rises to 20% or more even for the best performing disassemblers. This is especially true in optimized binaries, or in coding styles that make extensive use of function pointers. Worse, false positive function starts are almost as common. This can lead to problems in some binary-based research, especially binary instrumentation, if care is not taken to ensure graceful failure in the event of misdetected function starts. Symbols offer a great deal of help, especially in reducing the false negative rate. Unfortunately, they are rarely available in practice.

It is surprising then, to find that only 20% to 25% (top-tier) of Windows papers that use function starts, and 33% to 50% (top-tier) of the Linux papers, devote any attention to discussing these problems. A similarly small number of papers implement error handling, even though errors can cause malignant failures in a majority of papers. While it is not impossible to base well-functioning binary-based systems on function start information (or other primitives), it is crucial that such work implement mechanisms for handling inaccuracies. Three effective classes of error handling (depending on the situation) have already been proposed in the literature: overestimation, underestimation, and runtime augmentation.

We hope our study will facilitate a better match between expectations on disassembly in future research, and the performance actually delivered by modern disassemblers. Moreover, we believe our findings can be used to better judge where problems are to be expected, and to implement effective mechanisms for dealing with them.

7 Related Work

Prior work on disassembly precision focused on complex corner cases [5, 23, 25] or obfuscated code [18, 34], showing that these can strongly reduce disassembly accuracy. We focus instead on the performance of modern disassemblers given realistic full-scale binaries without active anti-disassembly techniques.

Miller et al. center their analysis around complex cases in `glibc-2.12` [23]. Their findings largely correspond to our own, though we found no inline jump tables in `glibc-2.22`. In addition to their `glibc` analysis, Miller et al. find complex cases in SPEC CPU2006; however, this analysis focuses exclusively on statically linked binaries. We show in Section 3.3 that these cases are entirely due to embedded library code, and are extremely rare in non-statically linked applications.

Our finding that function starts are among the most challenging primitives to recover is in agreement with results by Bao et al. [4].

Paleari et al. study instruction decoders in disassemblers [25], which parse individual x86 instructions. Specific instructions that are sometimes wrongly parsed have also been outlined by the authors of Capstone [31].

Complex constructs in obfuscated code are discussed by Schwarz et al. [34], Linn et al. [21] and Kruegel et al. [18]. We show that these worst-case complex constructs are exceedingly rare in non-obfuscated code.

8 Conclusion

Our study contradicts the widespread belief that complex constructs severely limit the usefulness of binary-based research. Instead, we show that modern disassemblers achieve close to 100% instruction disassembly accuracy for compiler-generated binaries, and that constructs like inline data and overlapping code are very rare. Errors in areas where disassembly is truly lacking, such as function start recovery, are not discussed nearly as often in the literature. By analyzing discrepancies between disassembler capabilities and the literature, our work provides a foundation for guiding future research.

Abstract

Machine learning (ML) models may be deemed confidential due to their sensitive training data, commercial value, or use in security applications. Increasingly often, confidential ML models are being deployed with publicly accessible query interfaces. ML-as-a-service (“predictive analytics”) systems are an example: Some allow users to train models on potentially sensitive data and charge others for access on a pay-per-query basis.

The tension between model confidentiality and public access motivates our investigation of *model extraction attacks*. In such attacks, an adversary with black-box access, but no prior knowledge of an ML model’s parameters or training data, aims to duplicate the functionality of (i.e., “steal”) the model. Unlike in classical learning theory settings, ML-as-a-service offerings may accept partial feature vectors as inputs and include confidence values with predictions. Given these practices, we show simple, efficient attacks that extract target ML models with near-perfect fidelity for popular model classes including logistic regression, neural networks, and decision trees. We demonstrate these attacks against the online services of BigML and Amazon Machine Learning. We further show that the natural countermeasure of omitting confidence values from model outputs still admits potentially harmful model extraction attacks. Our results highlight the need for careful ML model deployment and new model extraction countermeasures.

1 Introduction

Machine learning (ML) aims to provide automated extraction of insights from data by means of a predictive model. A predictive model is a function that maps feature vectors to a categorical or real-valued output. In a supervised setting, a previously gathered data set consisting of possibly confidential feature-vector inputs (e.g., digitized health records) with corresponding output class labels (e.g., a diagnosis) serves to train a predictive model

that can generate labels on future inputs. Popular models include support vector machines (SVMs), logistic regressions, neural networks, and decision trees.

ML algorithms’ success in the lab and in practice has led to an explosion in demand. Open-source frameworks such as PredictionIO and cloud-based services offered by Amazon, Google, Microsoft, BigML, and others have arisen to broaden and simplify ML model deployment.

Cloud-based ML services often allow model owners to charge others for queries to their commercially valuable models. This pay-per-query deployment option exemplifies an increasingly common tension: The query interface of an ML model may be widely accessible, yet the model itself and the data on which it was trained may be proprietary and confidential. Models may also be privacy-sensitive because they leak information about training data [4, 23, 24]. For security applications such as spam or fraud detection [9, 29, 36, 55], an ML model’s confidentiality is critical to its utility: An adversary that can learn the model can also often evade detection [4, 36].

In this paper we explore *model extraction attacks*, which exploit the tension between query access and confidentiality in ML models. We consider an adversary that can query an ML model (a.k.a. a prediction API) to obtain predictions on input feature vectors. The model may be viewed as a black box. The adversary may or may not know the model type (logistic regression, decision tree, etc.) or the distribution over the data used to train the model. The adversary’s goal is to extract an equivalent or near-equivalent ML model, i.e., one that achieves (close to) 100% agreement on an input space of interest.

We demonstrate successful model extraction attacks against a wide variety of ML model types, including decision trees, logistic regressions, SVMs, and deep neural networks, and against production ML-as-a-service (MLaaS) providers, including Amazon and BigML.¹ In nearly all cases, our attacks yield models that are func-

¹We simulated victims by training models in our own accounts. We have disclosed our results to affected services in February 2016.

Service	Model Type	Data set	Queries	Time (s)
Amazon	Logistic Regression	Digits	650	70
	Logistic Regression	Adult	1,485	149
BigML	Decision Tree	German Credit	1,150	631
	Decision Tree	Steak Survey	4,013	2,088

Table 1: **Results of model extraction attacks on ML services.** For each target model, we report the number of prediction queries made to the ML API in an attack that extracts a 100% equivalent model. The attack time is primarily influenced by the service’s prediction latency ($\approx 100\text{ms}/\text{query}$ for Amazon and $\approx 500\text{ms}/\text{query}$ for BigML).

tionally very close to the target. In some cases, our attacks extract the exact parameters of the target (e.g., the coefficients of a linear classifier or the paths of a decision tree). For some targets employing a model type, parameters or features unknown to the attacker, we additionally show a successful preliminary attack step involving reverse-engineering these model characteristics.

Our most successful attacks rely on the information-rich outputs returned by the ML prediction APIs of all cloud-based services we investigated. Those of Google, Amazon, Microsoft, and BigML all return *high-precision confidence values in addition to class labels*. They also respond to partial queries lacking one or more features. Our setting thus differs from traditional learning-theory settings [3, 7, 8, 15, 30, 33, 36, 53] that assume only *membership queries*, outputs consisting of a class label only. For example, for logistic regression, the confidence value is a simple log-linear function $1/(1+e^{-(\mathbf{w} \cdot \mathbf{x} + \beta)})$ of the d -dimensional input vector \mathbf{x} . By querying $d+1$ random d -dimensional inputs, an attacker can with high probability solve for the unknown $d+1$ parameters \mathbf{w} and β defining the model. We emphasize that while this model extraction attack is simple and non-adaptive, it affects all of the ML services we have investigated.

Such equation-solving attacks extend to multiclass logistic regressions and neural networks, but do not work for decision trees, a popular model choice. (BigML, for example, initially offered only decision trees.) For decision trees, a confidence value reflects the number of training data points labeled correctly on an input’s path in the tree; simple equation-solving is thus inapplicable. We show how confidence values can nonetheless be exploited as pseudo-identifiers for paths in the tree, facilitating discovery of the tree’s structure. We demonstrate successful model extraction attacks that use adaptive, iterative search algorithms to discover paths in a tree.

We experimentally evaluate our attacks by training models on an array of public data sets suitable as stand-ins for proprietary ones. We validate the attacks locally using standard ML libraries, and then present case studies on BigML and Amazon. For both services, we show computationally fast attacks that use a small number of queries to extract models matching the targets on 100% of tested inputs. See Table 1 for a quantitative summary.

Having demonstrated the broad applicability of model extraction attacks to existing services, we consider the most obvious potential countermeasure ML services might adopt: Omission of confidence values, i.e., output of class labels only. This approach would place model extraction back in the membership query setting of prior work in learning theory [3, 8, 36, 53]. We demonstrate a generalization of an adaptive algorithm by Lowd and Meek [36] from binary linear classifiers to more complex model types, and also propose an attack inspired by the agnostic learning algorithm of Cohn et al. [18]. Our new attacks extract models matching targets on $>99\%$ of the input space for a variety of model classes, but need up to $100\times$ more queries than equation-solving attacks (specifically for multiclass linear regression and neural networks). While less effective than equation-solving, these attacks remain attractive for certain types of adversary. We thus discuss further ideas for countermeasures.

In summary, we explore model extraction attacks, a practical kind of learning task that, in particular, affects emerging cloud-based ML services being built by Amazon, Google, Microsoft, BigML, and others. We show:

- *Simple equation-solving model extraction attacks* that use non-adaptive, random queries to solve for the parameters of a target model. These attacks affect a wide variety of ML models that output confidence values. We show their success against Amazon’s service (using our own models as stand-ins for victims’), and also report successful reverse-engineering of the (only partially documented) model type employed by Amazon.
- *A new path-finding algorithm for extracting decision trees* that abuses confidence values as quasi-identifiers for paths. To our knowledge, this is the first example of practical “exact” decision tree learning. We demonstrate the attack’s efficacy via experiments on BigML.
- *Model extraction attacks against models that output only class labels*, the obvious countermeasure against extraction attacks that rely on confidence values. We show slower, but still potentially dangerous, attacks in this setting that build on prior work in learning theory.

We additionally make a number of observations about the implications of extraction. For example, attacks against Amazon’s system indirectly leak various summary statistics about a private training set, while extraction against kernel logistic regression models [57] recovers significant information about individual training data points.

The source code for our attacks is available online at <https://github.com/ftramer/Steal-ML>.

2 Background

For our purposes, a ML model is a function $f: \mathcal{X} \rightarrow \mathcal{Y}$. An input is a d -dimensional vector in the feature space

$\mathcal{X} = \mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_d$. Outputs lie in the range \mathcal{Y} .

We distinguish between categorical features, which assume one of a finite set of values (whose set size is the arity of the feature), and continuous features, which assume a value in a bounded subset of the real numbers. Without loss of generality, for a categorical feature of arity k , we let $\mathcal{X}_i = \mathbb{Z}_k$. For a continuous feature taking values between bounds a and b , we let $\mathcal{X}_i = [a, b] \subset \mathbb{R}$.

Inputs to a model may be pre-processed to perform feature extraction. In this case, inputs come from a space \mathcal{M} , and feature extraction involves application of a function $\text{ex}: \mathcal{M} \rightarrow \mathcal{X}$ that maps inputs into a feature space. Model application then proceeds by composition in the natural way, taking the form $f(\text{ex}(M))$. Generally, feature extraction is many-to-one. For example, M may be a piece of English language text and the extracted features counts of individual words (so-called “bag-of-words” feature extraction). Other examples are input scaling and one-hot-encoding of categorical features.

We focus primarily on classification settings in which f predicts a nominal variable ranging over a set of classes. Given c classes, we use as class labels the set \mathbb{Z}_c . If $\mathcal{Y} = \mathbb{Z}_c$, the model returns only the predicted class label. In some applications, however, additional information is often helpful, in the form of real-valued measures of confidence on the labels output by the model; these measures are called *confidence values*. The output space is then $\mathcal{Y} = [0, 1]^c$. For a given $\mathbf{x} \in \mathcal{X}$ and $i \in \mathbb{Z}_c$, we denote by $f_i(\mathbf{x})$ the i^{th} component of $f(\mathbf{x}) \in \mathcal{Y}$. The value $f_i(\mathbf{x})$ is a model-assigned probability that \mathbf{x} has associated class label i . The model’s predicted class is defined by the value $\text{argmax}_i f_i(\mathbf{x})$, i.e., the most probable label.

We associate with \mathcal{Y} a distance measure $d_{\mathcal{Y}}$. We drop the subscript \mathcal{Y} when it is clear from context. For $\mathcal{Y} = \mathbb{Z}_c$ we use 0-1 distance, meaning $d(y, y') = 0$ if $y = y'$ and $d(y, y') = 1$ otherwise. For $\mathcal{Y} = [0, 1]^c$, we use the 0-1 distance when comparing predicted classes; when comparing class probabilities directly, we instead use the total variation distance, given by $d(\mathbf{y}, \mathbf{y}') = \frac{1}{2} \sum |y[i] - y'[i]|$. In the rest of this paper, unless explicitly specified otherwise, $d_{\mathcal{Y}}$ refers to the 0-1 distance over class labels.

Training algorithms. We consider models obtained via supervised learning. These models are generated by a training algorithm \mathcal{T} that takes as input a training set $\{(\mathbf{x}_i, y_i)\}_i$, where $(\mathbf{x}_i, y_i) \in \mathcal{X} \times \mathcal{Y}$ is an input with an associated (presumptively correct) class label. The output of \mathcal{T} is a model f defined by a set of *parameters*, which are model-specific, and *hyper-parameters*, which specify the type of models \mathcal{T} generates. Hyper-parameters may be viewed as distinguished parameters, often taken from a small number of standard values; for example, the kernel-type used in an SVM, of which only a small set are used in practice, may be seen as a hyper-parameter.

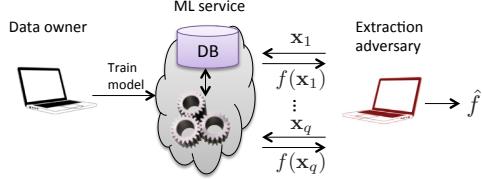

Figure 1: **Diagram of ML model extraction attacks.** A data owner has a model f trained on its data and allows others to make prediction queries. An adversary uses q prediction queries to extract an $\hat{f} \approx f$.

3 Model Extraction Attacks

An ML model extraction attack arises when an adversary obtains black-box access to some *target model* f and attempts to learn a model \hat{f} that closely approximates, or even matches, f (see Figure 1).

As mentioned previously, the restricted case in which f outputs class labels only, matches the membership query setting considered in learning theory, e.g., PAC learning [53] and other previous works [3, 7, 8, 15, 30, 33, 36]. Learning theory algorithms have seen only limited study in practice, e.g., in [36], and our investigation may be viewed as a practice-oriented exploration of this branch of research. Our initial focus, however, is on a different setting common in today’s MLaaS services, which we now explain in detail. Models trained by these services emit data-rich outputs that often include confidence values, and in which partial feature vectors may be considered valid inputs. As we show later, this setting greatly advantages adversaries.

Machine learning services. A number of companies have launched or are planning to launch cloud-based ML services. A common denominator is the ability of users to upload data sets, have the provider run training algorithms on the data, and make the resulting models generally available for prediction queries. Simple-to-use Web APIs handle the entire interaction. This service model lets users capitalize on their data without having to set up their own large-scale ML infrastructure. Details vary greatly across services. We summarize a number of them in Table 2 and now explain some of the salient features.

A model is *white-box* if a user may download a representation suitable for local use. It is *black-box* if accessible only via a prediction query interface. Amazon and Google, for example, provide black-box-only services. Google does not even specify what training algorithm their service uses, while Amazon provides only partial documentation for its feature extraction ex (see Section 5). Some services allow users to monetize trained models by charging others for prediction queries.

To use these services, a user uploads a data set and optionally applies some data pre-processing (e.g., field removal or handling of missing values). She then trains a

Service	White-box	Monetize	Confidence Scores	Logistic Regression	SVM	Neural Network	Decision Tree
Amazon [1]	x	x	✓	✓	x	x	x
Microsoft [38]	x	x	✓	✓	✓	✓	✓
BigML [11]	✓	✓	✓	✓	x	x	✓
PredictionIO [43]	✓	x	x	✓	✓	x	✓
Google [25]	x	✓	✓	✓	✓	✓	✓

Table 2: **Particularities of major MLaaS providers.** ‘White-box’ refers to the ability to download and use a trained model locally, and ‘Monetize’ means that a user may charge other users for black-box access to her models. Model support for each service is obtained from available documentation. The models listed for Google’s API are a projection based on the announced support of models in standard PMML format [25]. Details on ML models are given in Appendix A.

model by either choosing one of many supported model classes (as in BigML, Microsoft, and PredictionIO) or having the service choose an appropriate model class (as in Amazon and Google). Two services have also announced upcoming support for users to upload their own trained models (Google) and their own custom learning algorithms (PredictionIO). When training a model, users may tune various parameters of the model or training-algorithm (e.g., regularizers, tree size, learning rates) and control feature-extraction and transformation methods.

For black-box models, the service provides users with information needed to create and interpret predictions, such as the list of input features and their types. Some services also supply the model class, chosen training parameters, and training data statistics (e.g., BigML gives the range, mean, and standard deviation of each feature).

To get a prediction from a model, a user sends one or more input queries. The services we reviewed accept both synchronous requests and asynchronous ‘batch’ requests for multiple predictions. We further found varying degrees of support for ‘incomplete’ queries, in which some input features are left unspecified [46]. We will show that exploiting incomplete queries can drastically improve the success of some of our attacks. Apart from PredictionIO, all of the services we examined respond to prediction queries with not only class labels, but a variety of additional information, including *confidence scores* (typically class probabilities) for the predicted outputs.

Google and BigML allow model owners to monetize their models by charging other users for predictions. Google sets a minimum price of \$0.50 per 1,000 queries. On BigML, 1,000 queries consume at least 100 *credits*, costing \$0.10–\$5, depending on the user’s subscription.

Attack scenarios. We now describe possible motivations for adversaries to perform model extraction attacks. We then present a more detailed threat model informed by characteristics of the aforementioned ML services.

Avoiding query charges. Successful monetization of

prediction queries by the owner of an ML model f requires confidentiality of f . A malicious user may seek to launch what we call a *cross-user* model extraction attack, stealing f for subsequent free use. More subtly, in black-box-only settings (e.g., Google and Amazon), a service’s business model may involve amortizing up-front training costs by charging users for future predictions. A model extraction attack will undermine the provider’s business model if a malicious user pays less for training and extracting than for paying per-query charges.

Violating training-data privacy. Model extraction could, in turn, leak information about sensitive training data. Prior attacks such as model inversion [4, 23, 24] have shown that access to a model can be abused to infer information about training set points. Many of these attacks work better in white-box settings; model extraction may thus be a stepping stone to such privacy-abusing attacks. Looking ahead, we will see that in some cases, significant information about training data is leaked trivially by successful model extraction, because the model itself directly incorporates training set points.

Stepping stone to evasion. In settings where an ML model serves to detect adversarial behavior, such as identification of spam, malware classification, and network anomaly detection, model extraction can facilitate *evasion attacks*. An adversary may use knowledge of the ML model to avoid detection by it [4, 9, 29, 36, 55].

In all of these settings, there is an inherent assumption of secrecy of the ML model in use. We show that this assumption is broken for all ML APIs that we investigate.

Threat model in detail. Two distinct adversarial models arise in practice. An adversary may be able to make *direct* queries, providing an arbitrary input \mathbf{x} to a model f and obtaining the output $f(\mathbf{x})$. Or the adversary may be able to make only *indirect* queries, i.e., queries on points in input space \mathcal{M} yielding outputs $f(\text{ex}(\mathcal{M}))$. The feature extraction mechanism ex may be unknown to the adversary. In Section 5, we show how ML APIs can further be exploited to “learn” feature extraction mechanisms. Both direct and indirect access to f arise in ML services. (Direct query interfaces arise when clients are expected to perform feature extraction locally.) In either case, the output value can be a class label, a confidence value vector, or some data structure revealing various levels of information, depending on the exposed API.

We model the adversary, denoted by \mathcal{A} , as a randomized algorithm. The adversary’s goal is to use as few queries as possible to f in order to efficiently compute an approximation \hat{f} that closely matches f . We formalize “closely matching” using two different error measures:

- *Test error* R_{test} : This is the average error over a test set D , given by $R_{\text{test}}(f, \hat{f}) = \sum_{(\mathbf{x}, y) \in D} d(f(\mathbf{x}), \hat{f}(\mathbf{x}))/|D|$.

A low test error implies that \hat{f} matches f well for inputs distributed like the training data samples.²

- *Uniform error* R_{unif} : For a set U of vectors uniformly chosen in \mathcal{X} , let $R_{\text{unif}}(f, \hat{f}) = \sum_{\mathbf{x} \in U} d(f(\mathbf{x}), \hat{f}(\mathbf{x}))/|U|$. Thus R_{unif} estimates the fraction of the full feature space on which f and \hat{f} disagree. (In our experiments, we found $|U| = 10,000$ was sufficiently large to obtain stable error estimates for the models we analyzed.)

We define the extraction *accuracy* under test and uniform error as $1 - R_{\text{test}}(f, \hat{f})$ and $1 - R_{\text{unif}}(f, \hat{f})$. Here we implicitly refer to accuracy under 0-1 distance. When assessing how close the class probabilities output by \hat{f} are to those of f (with the total-variation distance) we use the notations $R_{\text{test}}^{\text{TV}}(f, \hat{f})$ and $R_{\text{unif}}^{\text{TV}}(f, \hat{f})$.

An adversary may know any of a number of pieces of information about a target f : What training algorithm \mathcal{T} generated f , the hyper-parameters used with \mathcal{T} , the feature extraction function ex , etc. We will investigate a variety of settings in this work corresponding to different APIs seen in practice. We assume that \mathcal{A} has no more information about a model’s training data, than what is provided by an ML API (e.g., summary statistics). For simplicity, we focus on *proper* model extraction: If \mathcal{A} believes that f belongs to some model class, then \mathcal{A} ’s goal is to extract a model \hat{f} from the *same* class. We discuss some intuition in favor of proper extraction in Appendix D, and leave a broader treatment of *improper* extraction strategies as an interesting open problem.

4 Extraction with Confidence Values

We begin our study of extraction attacks by focusing on prediction APIs that return confidence values. As per Section 2, the output of a query to f thus falls in a range $[0, 1]^c$ where c is the number of classes. To motivate this, we recall that most ML APIs reveal confidence values for models that support them (see Table 2). This includes logistic regressions (LR), neural networks, and decision trees, defined formally in Appendix A. We first introduce a generic *equation-solving* attack that applies to all logistic models (LR and neural networks). In Section 4.2, we present two novel *path-finding* attacks on decision trees.

4.1 Equation-Solving Attacks

Many ML models we consider directly compute class probabilities as a continuous function of the input \mathbf{x} and real-valued model parameters. In this case, an API that reveals these class probabilities provides an adversary \mathcal{A} with samples $(\mathbf{x}, f(\mathbf{x}))$ that can be viewed as equations in the unknown model parameters. For a large class of

²Note that for some D , it is possible that \hat{f} predicts true labels better than f , yet $R_{\text{test}}(f, \hat{f})$ is large, because \hat{f} does not closely match f .

Data set	Synthetic	# records	# classes	# features

Table 3: Data sets used for extraction attacks. We train two models on the Adult data, with targets ‘Income’ and ‘Race’. SVMs and binary logistic regressions are trained on data sets with 2 classes. Multiclass regressions and neural networks are trained on multiclass data sets. For decision trees, we use a set of public models shown in Table 5.

models, these equation systems can be efficiently solved, thus recovering f (or some good approximation of it).

Our approach for evaluating attacks will primarily be experimental. We use a suite of synthetic or publicly available data sets to serve as stand-ins for proprietary data that might be the target of an extraction attack. Table 3 displays the data sets used in this section, which we obtained from various sources: the synthetic ones we generated; the others are taken from public surveys (*Steak Survey* [26] and *GSS Survey* [49]), from *scikit* [42] (*Digits*) or from the UCI ML library [35]. More details about these data sets are in Appendix B.

Before training, we remove rows with missing values, apply *one-hot-encoding* to categorical features, and scale all numeric features to the range $[-1, 1]$. We train our models over a randomly chosen subset of 70% of the data, and keep the rest for evaluation (i.e., to calculate R_{test}). We discuss the impact of different pre-processing and feature extraction steps in Section 5, when we evaluate equation-solving attacks on production ML services.

4.1.1 Binary logistic regression

As a simple starting point, we consider the case of logistic regression (LR). A LR model performs binary classification ($c = 2$), by estimating the probability of a binary response, based on a number of independent features. LR is one of the most popular binary classifiers, due to its simplicity and efficiency. It is widely used in many scientific fields (e.g., medical and social sciences) and is supported by all the ML services we reviewed.

Formally, a LR model is defined by parameters $\mathbf{w} \in \mathbb{R}^d$, $\beta \in \mathbb{R}$, and outputs a probability $f_1(\mathbf{x}) = \sigma(\mathbf{w} \cdot \mathbf{x} + \beta)$, where $\sigma(t) = 1/(1 + e^{-t})$. LR is a linear classifier: it defines a *hyperplane* in the feature space \mathcal{X} (defined by $\mathbf{w} \cdot \mathbf{x} + \beta = 0$), that separates the two classes.

Given an oracle sample $(\mathbf{x}, f(\mathbf{x}))$, we get a *linear* equation $\mathbf{w} \cdot \mathbf{x} + \beta = \sigma^{-1}(f_1(\mathbf{x}))$. Thus, $d + 1$ samples are both necessary and sufficient (if the queried \mathbf{x} are linearly independent) to recover \mathbf{w} and β . Note that the required

samples are chosen non-adaptively, and can thus be obtained from a single batch request to the ML service.

We stress that while this extraction attack is rather straightforward, it directly applies, with possibly devastating consequences, to all cloud-based ML services we considered. As an example, recall that some services (e.g., BigML and Google) let model owners monetize black-box access to their models. Any user who wishes to make more than $d + 1$ queries to a model would then minimize the prediction cost by first running a cross-user model extraction attack, and then using the extracted model for personal use, free of charge. As mentioned in Section 3, attackers with a final goal of model-inversion or evasion may also have incentives to first extract the model. Moreover, for services with black-box-only access (e.g., Amazon or Google), a user may abuse the service’s resources to train a model over a large data set D (i.e., $|D| \gg d$), and extract it after only $d + 1$ predictions. Crucially, the extraction cost is independent of $|D|$. This could undermine a service’s business model, should prediction fees be used to amortize the high cost of training.

For each binary data set shown in Table 3, we train a LR model and extract it given $d + 1$ predictions. In all cases, we achieve $R_{\text{test}} = R_{\text{unif}} = 0$. If we compare the probabilities output by f and \hat{f} , $R_{\text{test}}^{\text{TV}}$ and $R_{\text{unif}}^{\text{TV}}$ are lower than 10^{-9} . For these models, the attack requires only 41 queries on average, and 113 at most. On Google’s platform for example, an extraction attack would cost less than \$0.10, and subvert any further model monetization.

4.1.2 Multiclass LRs and Multilayer Perceptrons

We now show that such equation-solving attacks broadly extend to all model classes with a ‘logistic’ layer, including multiclass ($c > 2$) LR and deeper neural networks. We define these models formally in Appendix A.

A multiclass logistic regression (MLR) combines c binary models, each with parameters \mathbf{w}_i, β_i , to form a multiclass model. MLRs are available in all ML services we reviewed. We consider two types of MLR models: softmax and one-vs-rest (OvR), that differ in how the c binary models are trained and combined: A softmax model fits a joint multinomial distribution to all training samples, while a OvR model trains a separate binary LR for each class, and then normalizes the class probabilities.

A MLR model f is defined by parameters $\mathbf{w} \in \mathbb{R}^{cd}$, $\beta \in \mathbb{R}^c$. Each sample $(\mathbf{x}, f(\mathbf{x}))$ gives c equations in \mathbf{w} and β . The equation system is non-linear however, and has no analytic solution. For softmax models for instance, the equations take the form $e^{\mathbf{w}_i \cdot \mathbf{x} + \beta_i} / (\sum_{j=0}^{c-1} e^{\mathbf{w}_j \cdot \mathbf{x} + \beta_j}) = f_i(\mathbf{x})$. A common method for solving such a system is by minimizing an appropriate loss function, such as the logistic loss. With a regularization term, the loss function is *strongly convex*, and the optimization thus con-

Model	Unknowns	Queries	$1 - R_{\text{test}}$	$1 - R_{\text{unif}}$	Time (s)
Softmax	530	265	99.96%	99.75%	2.6
		530	100.00%	100.00%	3.1
OvR	530	265	99.98%	99.98%	2.8
		530	100.00%	100.00%	3.5
MLP	2,225	1,112	98.17%	94.32%	155
		2,225	98.68%	97.23%	168
		4,450	99.89%	99.82%	195
		11,125	99.96%	99.99%	89

Table 4: Success of equation-solving attacks. Models to extract were trained on the Adult data set with multiclass target ‘Race’. For each model, we report the number of unknown model parameters, the number of queries used, and the running time of the equation solver. The attack on the MLP with 11,125 queries converged after 490 epochs.

verges to a *global minimum* (i.e., a function \hat{f} that predicts the same probabilities as f for all available samples). A similar optimization (over class labels rather than probabilities) is actually used for training logistic models. Any MLR implementation can thus easily be adapted for model extraction with equation-solving.

This approach naturally extends to deeper neural networks. We consider multilayer perceptrons (MLP), that first apply a non-linear transform to all inputs (the hidden layer), followed by a softmax regression in the transformed space. MLPs are becoming increasingly popular due to the continued success of deep learning methods; the advent of cloud-based ML services is likely to further boost their adoption. For our attacks, MLPs and MLRs mainly differ in the number of unknowns in the system to solve. For perceptrons with one hidden layer, we have $\mathbf{w} \in \mathbb{R}^{dh+hc}$, $\beta \in \mathbb{R}^{h+c}$, where h is the number of hidden nodes ($h = 20$ in our experiments). Another difference is that the loss function for MLPs is not strongly convex. The optimization may thus converge to a local minimum, i.e., a model \hat{f} that does not exactly match f ’s behavior.

To illustrate our attack’s success, we train a softmax regression, a OvR regression and a MLP on the Adult data set with target ‘Race’ ($c = 5$). For the non-linear equation systems we obtain, we do not know a priori how many samples we need to find a solution (in contrast to linear systems where $d + 1$ samples are necessary and sufficient). We thus explore various query budgets of the form $\alpha \cdot k$, where k is the number of unknown model parameters, and α is a budget scaling factor. For MLRs, we solve the equation system with BFGS [41] in scikit [42]. For MLPs, we use theano [51] to run stochastic gradient descent for 1,000 epochs. Our experiments were performed on a commodity laptop (2-core Intel CPU @3.1GHz, 16GB RAM, no GPU acceleration).

Table 4 shows the extraction success for each model, as we vary α from 0.5 to at most 5. For MLR models (softmax and OvR), the attack is extremely efficient, requiring around one query per unknown parameter of f (each query yields $c = 5$ equations). For MLPs, the system to solve is more complex, with about 4 times more

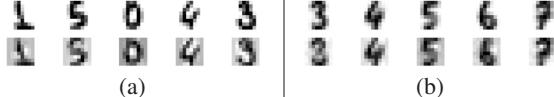

Figure 2: **Training data leakage in KLR models.** (a) Displays 5 of 20 training samples used as representers in a KLR model (top) and 5 of 20 extracted representers (bottom). (b) For a second model, shows the average of all 1,257 representers that the model classifies as a 3, 4, 5, 6 or 7 (top) and 5 of 10 extracted representers (bottom).

unknowns. With a sufficiently over-determined system, we converge to a model \hat{f} that very closely approximates f . As for LR models, queries are chosen non-adaptively, so \mathcal{A} may submit a single ‘batch request’ to the API.

We further evaluated our attacks over all multiclass data sets from Table 3. For MLR models with $k = c \cdot (d + 1)$ parameters (c is the number of classes), k queries were sufficient to achieve perfect extraction ($R_{\text{test}} = R_{\text{unif}} = 0$, $R_{\text{test}}^{\text{TV}}$ and $R_{\text{unif}}^{\text{TV}}$ below 10^{-7}). We use 260 samples on average, and 650 for the largest model (Digits). For MLPs with 20 hidden nodes, we achieved >99.9% accuracy with 5,410 samples on average and 11,125 at most (Adult). With 54,100 queries on average, we extracted a \hat{f} with 100% accuracy over tested inputs. As for binary LRs, we thus find that cross-user model extraction attacks for these model classes can be extremely efficient.

4.1.3 Training Data Leakage for Kernel LR

We now move to a less mainstream model class, *kernel logistic regression* [57], that illustrates how extraction attacks can leak private training data, when a model’s outputs are directly computed as a function of that data.

Kernel methods are commonly used to efficiently extend support vector machines (SVM) to nonlinear classifiers [14], but similar techniques can be applied to logistic regression [57]. Compared to kernel SVMs, kernel logistic regressions (KLR) have the advantage of computing class probabilities, and of naturally extending to multiclass problems. Yet, KLRs have not reached the popularity of kernel SVMs or standard LRs, and are not provided by any MLaaS provider at the time. We note that KLRs could easily be constructed in any ML library that supports both kernel functions and LR models.

A KLR model is a softmax model, where we replace the linear components $\mathbf{w}_i \cdot \mathbf{x} + \beta_i$ by a mapping $\sum_{r=1}^s \alpha_{i,r} K(\mathbf{x}, \mathbf{x}_r) + \beta_i$. Here, K is a kernel function, and the *representers* $\mathbf{x}_1, \dots, \mathbf{x}_s$ are a chosen subset of the training points [57]. More details are in Appendix A.

Each sample $(\mathbf{x}, f(\mathbf{x}))$ from a KLR model yields c equations over the parameters $\boldsymbol{\alpha} \in \mathbb{R}^{sc}$, $\boldsymbol{\beta} \in \mathbb{R}^c$ and the representers $\mathbf{x}_1, \dots, \mathbf{x}_s$. Thus, by querying the model, \mathcal{A} obtains a non-linear equation system, the solution of which leaks training data. This assumes that \mathcal{A} knows the exact number s of representers sampled from the data.

However, we can relax this assumption: First, note that f ’s outputs are unchanged by adding ‘extra’ representers, with weights $\alpha = 0$. Thus, over-estimating s still results in a consistent system of equations, of which a solution is the model f , augmented with unused representers. We will also show experimentally that training data may leak even if \mathcal{A} extracts a model \hat{f} with $s' \ll s$ representers.

We build two KLR models with a *radial-basis function* (RBF) kernel for a data set of handwritten digits. We select 20 random digits as representers for the first model, and all 1,257 training points for the second. We extract the first model, assuming knowledge of s , by solving a system of 50,000 equations in 1,490 unknowns. We use the same approach as for MLPs, i.e., logistic-loss minimization using gradient descent. We initialize the extracted representers to uniformly random vectors in \mathcal{X} , as we assume \mathcal{A} does not know the training data distribution. In Figure 2a, we plot 5 of the model’s representers from the training data, and the 5 closest (in l_1 norm) extracted representers. The attack clearly leaks information on individual training points. We measure the attack’s robustness to uncertainty about s , by attacking the second model with only 10 local representers (10,000 equations in 750 unknowns). Figure 2b shows the *average* image of training points classified as a 3, 4, 5, 6 or 7 by the target model f , along with 5 extracted representers of \hat{f} . Surprisingly maybe, the attack seems to be leaking the ‘average representor’ of each class in the training data.

4.1.4 Model Inversion Attacks on Extracted Models

Access to a model may enable inference of privacy-damaging information, particularly about the training set [4, 23, 24]. The *model inversion attack* explored by Fredrikson et al. [23] uses access to a classifier f to find the input \mathbf{x}_{opt} that maximizes the class probability for class i , i.e., $\mathbf{x}_{\text{opt}} = \text{argmax}_{\mathbf{x} \in \mathcal{X}} f_i(\mathbf{x})$. This was shown to allow recovery of recognizable images of training set members’ faces when f is a facial recognition model.

Their attacks work best in a *white-box* setting, where the attacker knows f and its parameters. Yet, the authors also note that in a black-box setting, remote queries to a prediction API, combined with numerical approximation techniques, enable successful, albeit much less efficient, attacks. Furthermore, their black-box attacks inherently require f to be queried *adaptively*. They leave as an open question making black-box attacks more efficient.

We explore composing an attack that first attempts to *extract* a model $\hat{f} \approx f$, and then uses it with the [23] white-box inversion attack. Our extraction techniques replace adaptive queries with a non-adaptive “batch” query to f , followed by local computation. We show that extraction plus inversion can require fewer queries and less time than performing black-box inversion directly.

As a case study, we use the softmax model from [23], trained over the AT&T Faces data [5]. The data set consists of images of faces (92×112 pixels) of 40 people. The black-box attack from [23] needs about 20,600 queries to reconstruct a recognizable face for a single training set individual. Reconstructing the faces of all 40 individuals would require around 800,000 online queries.

The trained softmax model is much larger than those considered in Section 4.1, with 412,160 unknowns ($d = 10,304$ and $c = 40$). We solve an under-determined system with 41,216 equations (using gradient descent with 200 epochs), and recover a model \hat{f} achieving $R_{\text{test}}^{\text{TV}}, R_{\text{unif}}^{\text{TV}}$ in the order of 10^{-3} . Note that the number of model parameters to extract is linear in the number of people c , whose faces we hope to recover. By using \hat{f} in white-box model inversion attacks, we obtain results that are visually indistinguishable from the ones obtained using the true f . Given the extracted model \hat{f} , we can recover all 40 faces using white-box attacks, incurring around $20 \times$ fewer remote queries to f than with 40 black-box attacks.

For black-box attacks, the authors of [23] estimate a query latency of 70 milliseconds (a little less than in our own measurements of ML services, see Table 1). Thus, it takes 24 minutes to recover a single face (the inversion attack runs in seconds), and 16 hours to recover all 40 images. In contrast, solving the large equation system underlying our model-extraction attack took 10 hours. The 41,216 online queries would take under one hour if executed sequentially and even less with a batch query. The cost of the 40 local white-box attacks is negligible.

Thus, if the goal is to reconstruct faces for all 40 training individuals, performing model inversion over a previously extracted model results in an attack that is both faster and requires $20 \times$ fewer online queries.

4.2 Decision Tree Path-Finding Attacks

Contrary to logistic models, decision trees do not compute class probabilities as a continuous function of their input. Rather, decision trees partition the input space into discrete regions, each of which is assigned a label and confidence score. We propose a new *path-finding* attack, that exploits API particularities to extract the ‘decisions’ taken by a tree when classifying an input.

Prior work on decision tree extraction [7, 12, 33] has focused on trees with Boolean features and outputs. While of theoretical importance, such trees have limited practical use. Kushilevitz and Mansour [33] showed that Boolean trees can be extracted using membership queries (arbitrary queries for class labels), but their algorithm does not extend to more general trees. Here, we propose attacks that exploit ML API specificities, and that apply to decision tree models used in MLaaS platforms.

Our tree model, defined formally in Appendix A, al-

lows for binary and multi-ary splits over categorical features, and binary splits over numeric features. Each leaf of the tree is labeled with a class label and a confidence score. We note that our attacks also apply (often with better results) to *regression trees*. In regression trees, each leaf is labeled with a real-valued output and confidence.

The key idea behind our attack is to use the rich information provided by APIs on a prediction query, as a *pseudo-identifier* for the *path* that the input traversed in the tree. By varying the value of each input feature, we then find the predicates to be satisfied, for an input to follow a given path in the tree. We will also exploit the ability to query *incomplete inputs*, in which each feature x_i is chosen from a space $\mathcal{X}_i \cup \{\perp\}$, where \perp encodes the absence of a value. One way of handling such inputs ([11, 46]) is to label each node in the tree with an output value. On an input, we traverse the tree until we reach a leaf or an internal node with a split over a missing feature, and output that value of that leaf or node.

We formalize these notions by defining *oracles* that \mathcal{A} can query to obtain an identifier for the leaf or internal node reached by an input. In practice, we instantiate these oracles using prediction API peculiarities.

Definition 1 (Identity Oracles). *Let each node v of a tree T be assigned some identifier id_v . A leaf-identity oracle \mathcal{O} takes as input a query $\mathbf{x} \in \mathcal{X}$ and returns the identifier of the leaf of the tree T that is reached on input \mathbf{x} .*

A node-identity oracle \mathcal{O}_{\perp} takes as input a query $\mathbf{x} \in \mathcal{X}_1 \cup \{\perp\} \times \cdots \times \mathcal{X}_d \cup \{\perp\}$ and returns the identifier of the node or leaf of T at which the tree computation halts.

4.2.1 Extraction Algorithms

We now present our path-finding attack (Algorithm 1), that assumes a leaf-identity oracle that returns *unique* identifiers for each leaf. We will relax the uniqueness assumption further on. The attack starts with a random input \mathbf{x} and gets the leaf id from the oracle. We then search for all constraints on \mathbf{x} that have to be satisfied to remain in that leaf, using procedures LINE_SEARCH (for continuous features) and CAT_SPLIT (for categorical features) described below. From this information, we then create new queries for unvisited leaves. Once all leaves have been found, the algorithm returns, for each leaf, the corresponding constraints on \mathbf{x} . We analyze the algorithm’s correctness and complexity in Appendix C.

We illustrate our algorithm with a toy example of a tree over continuous feature *Size* and categorical feature *Color* (see Figure 3). The current query is $\mathbf{x} = \{\text{Size} = 50, \text{Color} = R\}$ and $\mathcal{O}(\mathbf{x}) = \text{id}_2$. Our goal is two-fold: (1) Find the *predicates* that \mathbf{x} has to satisfy to end up in leaf id_2 (i.e., $\text{Size} \in (40, 60]$, $\text{Color} = R$), and (2) create new inputs \mathbf{x}' to explore other paths in the tree.

Algorithm 1 The path-finding algorithm. The notation $\text{id} \leftarrow \mathcal{O}(\mathbf{x})$ means querying the leaf-identity oracle \mathcal{O} with an input \mathbf{x} and obtaining a response id . By $\mathbf{x}[i] \Rightarrow v$ we denote the query \mathbf{x}' obtained from \mathbf{x} by replacing the value of x_i by v .

```

1:  $\mathbf{x}_{\text{init}} \leftarrow \{x_1, \dots, x_d\}$                                 ▷ random initial query
2:  $Q \leftarrow \{\mathbf{x}_{\text{init}}\}$                                          ▷ Set of unprocessed queries
3:  $P \leftarrow \{\}$                                                  ▷ Set of explored leaves with their predicates
4: while  $Q$  not empty do
5:    $\mathbf{x} \leftarrow Q.\text{POP}()$ 
6:    $\text{id} \leftarrow \mathcal{O}(\mathbf{x})$                                      ▷ Call to the leaf identity oracle
7:   if  $\text{id} \in P$  then                                         ▷ Check if leaf already visited
8:     continue
9:   end if
10:  for  $1 \leq i \leq d$  do                                         ▷ Test all features
11:    if IS_CONTINUOUS( $i$ ) then
12:      for  $(\alpha, \beta) \in \text{LINE\_SEARCH}(\mathbf{x}, i, \varepsilon)$  do
13:        if  $x_i \in (\alpha, \beta)$  then
14:           $P[\text{id}].\text{ADD}('x_i \in (\alpha, \beta)')$            ▷ Current interval
15:        else
16:           $Q.\text{PUSH}(\mathbf{x}[i] \Rightarrow \beta)$                   ▷ New leaf to visit
17:        end if
18:      end for
19:    else
20:       $S, V \leftarrow \text{CATEGORY\_SPLIT}(\mathbf{x}, i, \text{id})$ 
21:       $P[\text{id}].\text{ADD}('x_i \in S')$                       ▷ Values for current leaf
22:      for  $v \in V$  do
23:         $Q.\text{PUSH}(\mathbf{x}[i] \Rightarrow v)$                       ▷ New leaves to visit
24:      end for
25:    end if
26:  end for
27: end while

```

The LINE_SEARCH procedure (line 12) tests *continuous features*. We start from bounds on the range of a feature $X_i = [a, b]$. In our example, we have $Size \in [0, 100]$. We set the value of $Size$ in \mathbf{x} to 0 and 100, query \mathcal{O} , and obtain id_1 and id_5 . As the ids do not match, a split on $Size$ occurs on the path to id_2 . With a binary search over feature $Size$ (and all other features in \mathbf{x} fixed), we find all intervals that lead to different leaves, i.e., $[0, 40], (40, 60], (60, 100]$. From these intervals, we find the predicate for the current leaf (i.e., $Size \in (40, 60]$) and build queries to explore new tree paths. To ensure termination of the line search, we specify some *precision* ε . If a split is on a threshold t , we find the value \tilde{t} that is the unique multiple of ε in the range $(t - \varepsilon, t]$. For values x_i with granularity ε , splitting on \tilde{t} is then equivalent to splitting on t .

The CATEGORY_SPLIT procedure (line 20) finds splits on *categorical features*. In our example, we vary the value of *Color* in \mathbf{x} and query \mathcal{O} to get a leaf id for each value. We then build a set S of values that lead to the current leaf, i.e., $S = \{\text{R}\}$, and a set V of values to set in \mathbf{x} to explore other leaves (one representative per leaf). In our example, we could have $V = \{\text{B}, \text{G}, \text{Y}\}$ or $V = \{\text{B}, \text{G}, \text{O}\}$.

Using these two procedures, we thus find the predicates defining the path to leaf id_2 , and generate new queries \mathbf{x}' for unvisited leaves of the tree.

A top-down approach. We propose an empirically more efficient *top-down* algorithm that exploits queries over partial inputs. It extracts the tree ‘layer by layer’,

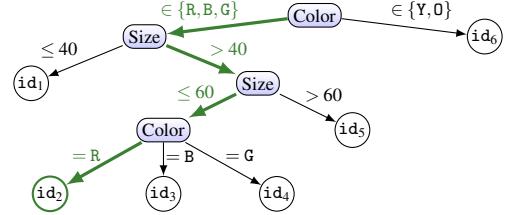

Figure 3: Decision tree over features Color and Size. Shows the path (thick green) to leaf id_2 on input $\mathbf{x} = \{Size = 50, Color = R\}$.

Table 5: Data sets used for decision tree extraction. Trained trees for these data sets are available in BigML’s public gallery. The last two data sets are used to train regression trees.

starting at the root: We start with an empty query (all features set to \perp) and get the root’s id by querying \mathcal{O}_\perp . We then set each feature in turn and query \mathcal{O} again. For exactly one feature (the root’s splitting feature), the input will reach a different node. With similar procedures as described previously, we extract the root’s splitting criterion, and recursively search lower layers of the tree.

Duplicate identities. As we verify empirically, our attacks are resilient to some nodes or leaves sharing the same id . We can modify line 7 in Algorithm 1 to detect id duplicates, by checking not only whether a leaf with the current id was already visited, but also whether the current query violates that leaf’s predicates. The main issue with duplicate ids comes from the LINE_SEARCH and CATEGORY_SPLIT procedures: if two queries \mathbf{x} and \mathbf{x}' differ in a single feature and reach different leaves with the same id , the split on that feature will be missed.

4.2.2 Attack Evaluation

Our tree model (see Appendix A) is the one used by BigML. Other ML services use similar tree models. For our experiments, we downloaded eight public decision trees from BigML (see Table 5), and queried them locally using available API bindings. More details on these models are in Appendix B. We show *online* extraction attacks on black-box models from BigML in Section 5.

To emulate black-box model access, we first issue online queries to BigML, to determine the information contained in the service’s responses. We then simulate black-box access locally, by discarding any extra information returned by the local API. Specifically, we make use of the following fields in query responses:

Model	Leaves	Unique IDs	Depth	Without incomplete queries			With incomplete queries		
				$1 - R_{\text{test}}$	$1 - R_{\text{unif}}$	Queries	$1 - R_{\text{test}}$	$1 - R_{\text{unif}}$	Queries
IRS Tax Patterns	318	318	8	100.00%	100.00%	101,057	100.00%	100.00%	29,609

Email Importance	109	55	17	99.13%	99.90%	12,888	99.81%	99.99%	4,081
Email Spam	219	78	29	87.20%	100.00%	42,324	99.70%	100.00%	21,808
German Credit	26	25	11	100.00%	100.00%	1,722	100.00%	100.00%	1,150
Medical Cover	49	49	11	100.00%	100.00%	5,966	100.00%	100.00%	1,788
Bitcoin Price	155	155	9	100.00%	100.00%	31,956	100.00%	100.00%	7,390

Table 6: Performance of extraction attacks on public models from BigML. For each model, we report the number of leaves in the tree, the number of unique identifiers for those leaves, and the maximal tree depth. The chosen granularity ϵ for continuous features is 10^{-3} .

- **Prediction.** This entry contains the predicted class label (classification) or real-valued output (regression).
- **Confidence.** For classification and regression trees, BigML computes confidence scores based on a confidence interval for predictions at each node [11]. The prediction and confidence value constitute a node’s id.
- **Fields.** Responses to black-box queries contain a ‘fields’ property, that lists all features that appear either in the input query or on the path traversed in the tree. If a partial query x reaches an internal node v , this entry tells us which feature v splits on (the feature is in the ‘fields’ entry, but not in the input x). We make use of this property for the top-down attack variant.

Table 6 displays the results of our attacks. For each tree, we give its number of leaves, the number of unique leaf ids, and the tree depth. We display the success rate for Algorithm 1 and for the “top-down” variant with incomplete queries. Querying partial inputs vastly improves our attack: we require far less queries (except for the Steak Survey model, where Algorithm 1 only visits a fraction of all leaves and thus achieves low success) and achieve higher accuracy for trees with duplicate leaf ids. As expected, both attacks achieve perfect extraction when all leaves have unique ids. While this is not always the case for classification trees, it is far more likely for regression trees, where both the label and confidence score take real values. Surprisingly maybe, the top-down approach also fully extracts some trees with a large number of duplicate leaf ids. The attacks are also efficient: The top-down approach takes less than 10 seconds to extract a tree, and Algorithm 1 takes less than 6 minutes for the largest tree. For online attacks on ML services, discussed next, this cost is trumped by the delay for the inherently adaptive prediction queries that are issued.

5 Online Model Extraction Attacks

In this section, we showcase *online* model extraction attacks against two ML services: BigML and Amazon. For BigML, we focus on extracting models set up by a user, who wishes to charge for predictions. For Amazon, our goal is to extract a model trained by ourselves, to which we only get black-box access. Our attacks only use ex-

Model	OHE	Binning	Queries	Time (s)	Price (\$)
Circles	-	Yes	278	28	0.03
Digits	-	No	650	70	0.07
Iris	-	Yes	644	68	0.07
Adult	Yes	Yes	1,485	149	0.15

Table 7: Results of model extraction attacks on Amazon. OHE stands for one-hot-encoding. The reported query count is the number used to find quantile bins (at a granularity of 10^{-3}), plus those queries used for equation-solving. Amazon charges \$0.0001 per prediction [1].

posed APIs, and do not in any way attempt to bypass the services’ authentication or access-control mechanisms. We only attack models trained in our own accounts.

5.1 Case Study 1: BigML

BigML currently only allows monetization of decision trees [11]. We train a tree on the *German Credit* data, and set it up as a black-box model. The tree has 26 leaves, two of which share the same label and confidence score. From another account, we extract the model using the two attacks from Section 4.2. We first find the tree’s number of features, their type and their range, from BigML’s public gallery. Our attacks (Algorithm 1 and the top-down variant) extract an exact description of the tree’s paths, using respectively 1,722 and 1,150 queries. Both attacks’ duration (1,030 seconds and 631 seconds) is dominated by query latency (≈ 500 ms/query). The monetary cost of the attack depends on the per-prediction-fee set by the model owner. In any case, a user who wishes to make more than 1,150 predictions has economic incentives to run an extraction attack.

5.2 Case Study 2: Amazon Web Services

Amazon uses logistic regression for classification, and provides black-box-only access to trained models [1]. By default, Amazon uses two feature extraction techniques: (1) Categorical features are *one-hot-encoded*, i.e., the input space $\mathcal{M}_i = \mathbb{Z}_k$ is mapped to k binary features encoding the input value. (2) *Quantile binning* is used for numeric features. The training data values are split into k -quantiles (k equally-sized bins), and the input space $\mathcal{M}_i = [a, b]$ is mapped to k binary features encoding the bin that a value falls into. Note that $|\mathcal{X}| > |\mathcal{M}|$,

i.e., ex increases the number of features. If \mathcal{A} reverse-engineers ex , she can query the service on samples M in input space, compute $\mathbf{x} = \text{ex}(M)$ locally, and extract f in feature-space using equation-solving.

We apply this approach to models trained by Amazon. Our results are summarized in Table 7. We first train a model with no categorical features, and quantile binning disabled (this is a manually tunable parameter), over the Digits data set. The attack is then identical to the one considered in Section 4.1.2: using 650 queries to Amazon, we extract a model that achieves $R_{\text{test}} = R_{\text{unif}} = 0$.

We now consider models with feature extraction enabled. We assume that \mathcal{A} knows the input space \mathcal{M} , but not the training data distribution. For one-hot-encoding, knowledge of \mathcal{M} suffices to apply the same encoding locally. For quantile binning however, applying ex locally requires knowledge of the training data quantiles. To reverse-engineer the binning transformation, we use line-searches similar to those we used for decision trees: For each numeric feature, we search the feature’s range in input space for thresholds (up to a granularity ϵ) where f ’s output changes. This indicates our value landed in an adjacent bin, with a different learned regression coefficient. Note that learning the bin boundaries may be interesting in its own right, as it leaks information about the training data distribution. Having found the bin boundaries, we can apply both one-hot-encoding and binning locally, and extract f over its feature space. As we are restricted to queries over \mathcal{M} , we cannot define an arbitrary system of equations over \mathcal{X} . Building a well-determined and consistent system can be difficult, as the encoding ex generates sparse inputs over \mathcal{X} . However, Amazon facilitates this process with the way it handles queries with *missing features*: if a feature is omitted from a query, all corresponding features in \mathcal{X} are set to 0. For a linear model for instance, we can trivially re-construct the model by issuing queries with a single feature specified, such as to obtain equations with a single unknown in \mathcal{X} .

We trained models for the Circles, Iris and Adult data sets, with Amazon’s default feature-extraction settings. Table 7 shows the results of our attacks, for the reverse-engineering of ex and extraction of f . For binary models (Circles and Adult), we use $d + 1$ queries to solve a linear equation-system over \mathcal{X} . For models with $c > 2$ classes, we use $c \cdot (d + 1)$ queries. In all cases, the extracted model matches f on 100% of tested inputs. To optimize the query complexity, the queries we use to find quantile bins are re-used for equation-solving. As line searches require adaptive queries, we do not use batch predictions. However, even for the Digits model, we resorted to using real-time predictions, because of the service’s significant overhead in evaluating batches. For attacks that require a large number of non-adaptive queries, we expect batch predictions to be faster than real-time predictions.

5.3 Discussion

Additional feature extractors. In some ML services we considered, users may enable further feature extractors. A common transformation is feature scaling or normalization. If \mathcal{A} has access to training data statistics (as provided by BigML for instance), applying the transformation locally is trivial. More generally, for models with a linear input layer (i.e., logistic regressions, linear SVMs, MLPs) the scaling or normalization can be seen as being applied to the learned weights, rather than the input features. We can thus view the composition $f \circ \text{ex}$ as a model f' that operates over the ‘un-scaled’ input space \mathcal{M} and extract f' directly using equation-solving.

Further extractors include text analysis (e.g., bag-of-words or n-gram models) and Cartesian products (grouping many features into one). We have not analyzed these in this work, but we believe that they could also be easily reverse-engineered, especially given some training data statistics and the ability to make incomplete queries.

Learning unknown model classes or hyper-parameters. For our online attacks, we obtained information about the model class of f , the enabled feature extraction ex , and other hyper-parameters, directly from the ML service or its documentation. More generally, if \mathcal{A} does not have full certainty about certain model characteristics, it may be able to narrow down a guess to a small range. Model hyper-parameters for instance (such as the free parameter of an RBF kernel) are typically chosen through cross-validation over a default range of values.

Given a set of attack strategies with varying assumptions, \mathcal{A} can use a generic *extract-and-test* approach: each attack is applied in turn, and evaluated by computing R_{test} or R_{unif} over a chosen set of points. The adversary succeeds if any of the strategies achieves a low error. Note that \mathcal{A} needs to interact with the model f only once, to obtain responses for a chosen set of extraction samples and test samples, that can be re-used for each strategy.

Our attacks on Amazon’s service followed this approach: We first formulated guesses for model characteristics left unspecified by the documentation (e.g., we found no mention of one-hot-encoding, or of how missing inputs are handled). We then evaluated our assumptions with successive extraction attempts. Our results indicate that Amazon uses softmax regression and does not create binary predictors for missing values. Interestingly, BigML takes the ‘opposite’ approach (i.e., BigML uses OvR regression and adds predictors for missing values).

6 Extraction Given Class Labels Only

The successful attacks given in Sections 4 and 5 show the danger of revealing confidence values. While current

ML services have been designed to reveal rich information, our attacks may suggest that returning only labels would be safer. Here we explore model extraction in a setting with no confidence scores. We will discuss further countermeasures in Section 7. We primarily focus on settings where \mathcal{A} can make *direct* queries to an API, i.e., queries for arbitrary inputs $\mathbf{x} \in \mathcal{X}$. We briefly discuss *indirect* queries in the context of linear classifiers.

The Lowd-Meek attack. We start with the prior work of Lowd and Meek [36]. They present an attack on any linear classifier, assuming black-box oracle access with membership queries that return just the predicted class label. A linear classifier is defined by a vector $\mathbf{w} \in \mathbb{R}^d$ and a constant $\beta \in \mathbb{R}$, and classifies an instance \mathbf{x} as *positive* if $\mathbf{w} \cdot \mathbf{x} + \beta > 0$ and *negative* otherwise. SVMs with linear kernels and binary LRs are examples of linear classifiers. Their attack uses line searches to find points arbitrarily close to f 's decision boundary (points for which $\mathbf{w} \cdot \mathbf{x} + \beta \approx 0$), and extracts \mathbf{w} and β from these samples.

This attack only works for linear binary models. We describe a straightforward extension to some non-linear models, such as polynomial kernel SVMs. Extracting a polynomial kernel SVM can be reduced to extracting a linear SVM in the transformed feature space. Indeed, for any kernel $K_{\text{poly}}(\mathbf{x}, \mathbf{x}') = (\mathbf{x}^T \cdot \mathbf{x}' + 1)^d$, we can derive a projection function $\phi(\cdot)$, so that $K_{\text{poly}}(\mathbf{x}, \mathbf{x}') = \phi(\mathbf{x})^T \cdot \phi(\mathbf{x}')$. This transforms the kernel SVM into a linear one, since the decision boundary now becomes $\mathbf{w}^F \cdot \phi(\mathbf{x}) + \beta = 0$ where $\mathbf{w}^F = \sum_{i=1}^t \alpha_i \phi(\mathbf{x}_i)$. We can use the Lowd-Meek attack to extract \mathbf{w}^F and β as long as $\phi(\mathbf{x})$ and its inverse are feasible to compute; this is unfortunately not the case for the more common RBF kernels.³

The retraining approach. In addition to evaluating the Lowd-Meek attack against ML APIs, we introduce a number of other approaches based on the broad strategy of re-training a model locally, given input-output examples. Informally, our hope is that by extracting a model that achieves low *training error* over the queried samples, we would effectively approximate the target model's decision boundaries. We consider three re-training strategies, described below. We apply these to the model classes that we previously extracted using equation-solving attacks, as well as to SVMs.⁴

- (1) **Retraining with uniform queries.** This baseline strategy simply consists in sampling m points $\mathbf{x}_i \in \mathcal{X}$ uniformly at random, querying the oracle, and training a model \hat{f} on these samples.

³We did explore using approximations of ϕ , but found that the adaptive re-training techniques discussed in this section perform better.

⁴We do not expect retraining attacks to work well for decision trees, because of the greedy approach taken by learning algorithms. We have not evaluated extraction of trees, given class labels only, in this work.

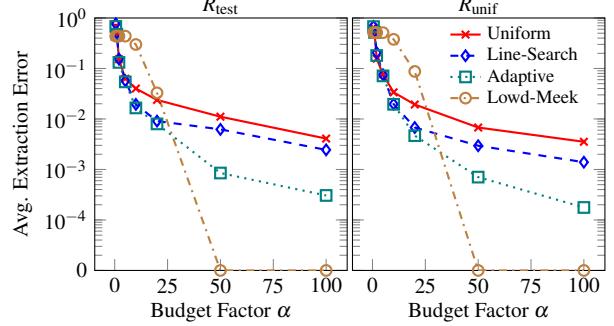

Figure 4: **Average error of extracted linear models.** Results are for different extraction strategies applied to models trained on all binary data sets from Table 3. The left shows R_{test} and the right shows R_{unif} .

- (2) **Line-search retraining.** This strategy can be seen as a model-agnostic generalization of the Lowd-Meek attack. It issues m adaptive queries to the oracle using line search techniques, to find samples close to the decision boundaries of f . A model \hat{f} is then trained on the m queried samples.
- (3) **Adaptive retraining.** This strategy applies techniques from active learning [18, 47]. For some number r of rounds and a query budget m , it first queries the oracle on $\frac{m}{r}$ uniform points, and trains a model \hat{f} . Over a total of r rounds, it then selects $\frac{m}{r}$ new points, along the decision boundary of \hat{f} (intuitively, these are points \hat{f} is *least certain* about), and sends those to the oracle before retraining \hat{f} .

6.1 Linear Binary Models

We first explore how well the various approaches work in settings where the Lowd-Meek attack can be applied. We evaluate their attack and our three retraining strategies for logistic regression models trained over the binary data sets shown in Table 3. These models have $d+1$ parameters, and we vary the query budget as $\alpha \cdot (d+1)$, for $0.5 \leq \alpha \leq 100$. Figure 4 displays the average errors R_{test} and R_{unif} over all models, as a function of α .

The retraining strategies that search for points near the decision boundary clearly perform better than simple uniform retraining. The adaptive strategy is the most efficient of our three strategies. For relatively low budgets, it even outperforms the Lowd-Meek attack. However, for budgets large enough to run line searches in each dimension, the Lowd-Meek attack is clearly the most efficient.

For the models we trained, about 2,050 queries on average, and 5,650 at most, are needed to run the Lowd-Meek attack effectively. This is 50× more queries than what we needed for equation-solving attacks. With 827 queries on average, adaptive retraining yields a model \hat{f} that matches f on over 99% of tested inputs. Thus, even if an ML API only provides class labels, efficient extrac-

tion attacks on linear models remain possible.

We further consider a setting where feature-extraction (specifically one-hot-encoding of categorical features) is applied by the ML service, rather than by the user. \mathcal{A} is then limited to indirect queries in input space. Lowd and Meek [36] note that their extraction attack does not work in this setting, as \mathcal{A} can not run line searches directly over \mathcal{X} . In contrast, for the linear models we trained, we observed no major difference in extraction accuracy for the adaptive-retraining strategy, when limited to queries over \mathcal{M} . We leave an in-depth study of model extraction with indirect queries, and class labels only, for future work.

6.2 Multiclass LR Models

The Lowd-Meek attack is not applicable in multiclass ($c > 2$) settings, even when the decision boundary is a combination of linear boundaries (as in multiclass regression) [39, 50]. We thus focus on evaluating the three retraining attacks we introduced, for the type of ML models we expect to find in real-world applications.

We focus on softmax models here, as softmax and one-vs-rest models have identical output behaviors when only class labels are provided: in both cases, the class label for an input \mathbf{x} is given by $\text{argmax}_i(\mathbf{w}_i \cdot \mathbf{x} + \beta_i)$. From an extractor’s perspective, it is thus irrelevant whether the target was trained using a softmax or OvR approach.

We evaluate our attacks on softmax models trained on the multiclass data sets shown in Table 3. We again vary the query budget as a factor α of the number of model parameters, namely $\alpha \cdot c \cdot (d + 1)$. Results are displayed in Figure 5. We observe that the adaptive strategy clearly performs best and that the line-search strategy does not improve over uniform retraining, possibly because the line-searches have to be split across multiple decision-boundaries. We further note that all strategies achieve lower R_{test} than R_{unif} . It thus appears that for the models we trained, points from the test set are on average ‘far’ from the decision boundaries of f (i.e., the trained models separate the different classes with large margins).

For all models, $100 \cdot c \cdot (d + 1)$ queries resulted in extraction accuracy above 99.9%. This represents 26,000 queries on average, and 65,000 at the most (Digits data set). Our equation-solving attacks achieved similar or better results with $100 \times$ less queries. Yet, for scenarios with high monetary incentives (e.g., intrusion detector evasion), extraction attacks on MLR models may be attractive, even if APIs only provide class labels.

6.3 Neural Networks

We now turn to attacks on more complex deep neural networks. We expect these to be harder to retrain than multiclass regressions, as deep networks have more pa-

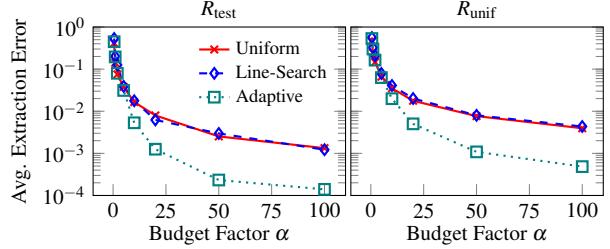

Figure 5: Average error of extracted softmax models. Results are for three retraining strategies applied to models trained on all multiclass data sets from Table 3. The left shows R_{test} and the right shows R_{unif} .

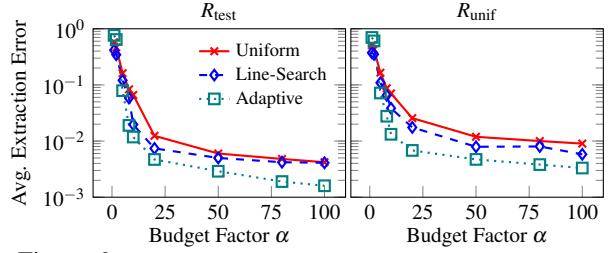

Figure 6: Average error of extracted RBF kernel SVMs. Results are for three retraining strategies applied to models trained on all binary data sets from Table 3. The left shows R_{test} and the right shows R_{unif} .

rameters and non-linear decision-boundaries. Therefore, we may need to find a large number of points close to a decision boundary in order to extract it accurately.

We evaluated our attacks on the multiclass models from Table 3. For the tested query budgets, line-search and adaptive retraining gave little benefit over uniform retraining. For a budget of $100 \cdot k$, where k is the number of model parameters, we get $R_{\text{test}} = 99.16\%$ and $R_{\text{unif}} = 98.24\%$, using 108,200 queries per model on average. Our attacks might improve for higher budgets but it is unclear whether they would then provide any monetary advantage over using ML APIs in an honest way.

6.4 RBF Kernel SVMs

Another class of nonlinear models that we consider are support-vector machines (SVMs) with radial-basis function (RBF) kernels. A kernel SVM first maps inputs into a higher-dimensional space, and then finds the hyperplane that maximally separates the two classes. As mentioned in Section 6, SVMs with polynomial kernels can be extracted using the Lowd-Meek attack in the transformed feature space. For RBF kernels, this is not possible because the transformed space has infinite dimension.

SVMs do not provide class probability estimates. Our only applicable attack is thus retraining. As for linear models, we vary the query budget as $\alpha \cdot (d + 1)$, where d is the input dimension. We further use the *extract-and-test* approach from Section 5 to find the value of the RBF kernel’s *hyper-parameter*. Results of our attacks are in

Figure 6. Again, we see that adaptive retraining performs best, even though the decision boundary to extract is non-linear (in input space) here. Kernel SVMs models are overall harder to retrain than models with linear decision boundaries. Yet, for our largest budgets (2,050 queries on average), we do extract models with over 99% accuracy, which may suffice in certain adversarial settings.

7 Extraction Countermeasures

We have shown in Sections 4 and 5 that adversarial clients can effectively extract ML models given access to rich prediction APIs. Given that this undermines the financial models targeted by some ML cloud services, and potentially leaks confidential training data, we believe researchers should seek countermeasures.

In Section 6, we analyzed the most obvious defense against our attacks: prediction API minimization. The constraint here is that the resulting API must still be useful in (honest) applications. For example, it is simple to change APIs to not return confidences and not respond to incomplete queries, assuming applications can get by without it. This will prevent many of our attacks, most notably the ones described in Section 4 as well as the feature discovery techniques used in our Amazon case study (Section 5). Yet, we showed that even if we strip an API to only provide class labels, successful attacks remain possible (Section 6), albeit at a much higher query cost.

We discuss further potential countermeasures below.

Rounding confidences. Applications might need confidences, but only at lower granularity. A possible defense is to round confidence scores to some fixed precision [23]. We note that ML APIs already work with some finite precision when answering queries. For instance, BigML reports confidences with 5 decimal places, and Amazon provides values with 16 significant digits.

To understand the effects of limiting precision further, we re-evaluate equation-solving and decision tree path-finding attacks with confidence scores rounded to a fixed decimal place. For equation-solving attacks, rounding the class probabilities means that the solution to the obtained equation-system might not be the target f , but some truncated version of it. For decision trees, rounding confidence scores increases the chance of node id collisions, and thus decreases our attacks’ success rate.

Figure 7 shows the results of experiments on softmax models, with class probabilities rounded to 2–5 decimals. We plot only R_{test} , the results for R_{unif} being similar. We observe that class probabilities rounded to 4 or 5 decimal places (as done already in BigML) have no effect on the attack’s success. When rounding further to 3 and 2 decimal places, the attack is weakened, but still vastly outperforms adaptive retraining using class labels only.

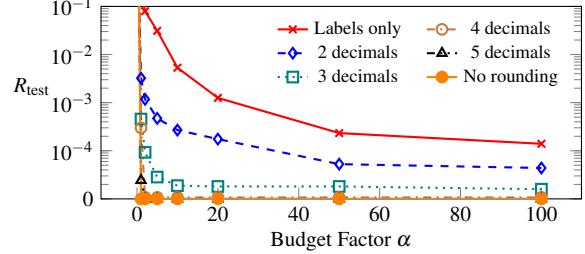

Figure 7: **Effect of rounding on model extraction.** Shows the average test error of equation-solving attacks on softmax models trained on the benchmark suite (Table 3), as we vary the number of significant digits in reported class probabilities. Extraction with no rounding and with class labels only (adaptive retraining) are added for comparison.

For regression trees, rounding has no effect on our attacks. Indeed, for the models we considered, the output itself is unique in each leaf (we could also round outputs, but the impact on utility may be more critical). For classification trees, we re-evaluated our top-down attack, with confidence scores rounded to fewer than 5 decimal places. The attacks on the ‘IRS Tax Patterns’ and ‘Email Importance’ models are the most resilient, and suffer no success degradation before scores are rounded to 2 decimal places. For the other models, rounding confidences to 3 or 4 decimal places severely undermines our attack.

Differential privacy. Differential privacy (DP) [22] and its variants [34] have been explored as mechanisms for protecting, in particular, the privacy of ML training data [54]. DP learning has been applied to regressions [17, 56], SVMs [44], decision trees [31] and neural networks [48]. As some of our extraction attacks leak training data information (Section 4.1.3), one may ask whether DP can prevent extraction, or at least reduce the severity of the privacy violations that extraction enables.

Consider naive application of DP to protect individual training data elements. This should, in theory, decrease the ability of an adversary \mathcal{A} to learn information about training set elements, when given access to prediction queries. One would not expect, however, that this prevents model extraction, as DP is not defined to do so: consider a trivially useless learning algorithm for binary logistic regression, that discards the training data and sets \mathbf{w} and β to 0. This algorithm is differentially private, yet \mathbf{w} and β can easily be recovered using equation-solving.

A more appropriate strategy would be to apply DP directly to the model parameters, which would amount to saying that a query should not allow \mathcal{A} to distinguish between closely neighboring model parameters. How exactly this would work and what privacy budgets would be required is left as an open question by our work.

Ensemble methods. Ensemble methods such as random forests return as prediction an aggregation of pre-

dictions by a number of individual models. While we have not experimented with ensemble methods as targets, we suspect that they may be more resilient to extraction attacks, in the sense that attackers will only be able to obtain relatively coarse approximations of the target function. Nevertheless, ensemble methods may still be vulnerable to other attacks such as model evasion [55].

8 Related Work

Our work is related to the extensive literature on learning theory, such as PAC learning [53] and its variants [3, 8]. Indeed, extraction can be viewed as a type of learning, in which an unknown instance of a known hypothesis class (model type) is providing labels (without error). This is often called learning with membership queries [3]. Our setting differs from these in two ways. The first is conceptual: in PAC learning one builds algorithms to learn a concept — the terminology belies the motivation of formalizing learning from data. In model extraction, an attacker is literally given a function oracle that it seeks to illicitly determine. The second difference is more pragmatic: prediction APIs reveal richer information than assumed in prior learning theory work, and we exploit that.

Algorithms for learning with membership queries have been proposed for Boolean functions [7, 15, 30, 33] and various binary classifiers [36, 39, 50]. The latter line of work, initiated by Lowd and Meek [36], studies strategies for model evasion, in the context of spam or fraud detectors [9, 29, 36, 37, 55]. Intuitively, model extraction seems harder than evasion, and this is corroborated by results from theory [36, 39, 50] and practice [36, 55].

Evasion attacks fall into the larger field of *adversarial machine learning*, that studies machine learning in general adversarial settings [6, 29]. In that context, a number of authors have considered strategies and defenses for *poisoning* attacks, that consist in injecting maliciously crafted samples into a model’s train or test data, so as to decrease the learned model’s accuracy [10, 21, 32, 40, 45].

In a non-malicious setting, improper model extraction techniques have been applied for interpreting [2, 19, 52] and compressing [16, 27] complex neural networks.

9 Conclusion

We demonstrated how the flexible prediction APIs exposed by current ML-as-a-service providers enable new model extraction attacks that could subvert model monetization, violate training-data privacy, and facilitate model evasion. Through local experiments and online attacks on two major providers, BigML and Amazon, we illustrated the efficiency and broad applicability of attacks that exploit common API features, such as the

availability of confidence scores or the ability to query arbitrary partial inputs. We presented a generic *equation-solving* attack for models with a logistic output layer and a novel *path-finding* algorithm for decision trees.

We further explored potential countermeasures to these attacks, the most obvious being a restriction on the information provided by ML APIs. Building upon prior work from learning-theory, we showed how an attacker that only obtains class labels for adaptively chosen inputs, may launch less effective, yet potentially harmful, *retraining attacks*. Evaluating these attacks, as well as more refined countermeasures, on production-grade ML services is an interesting avenue for future work.

Acknowledgments. We thank Martín Abadi and the anonymous reviewers for their comments. This work was supported by NSF grants 1330599, 1330308, and 1546033, as well as a generous gift from Microsoft.

A Some Details on Models

SVMs. Support vector machines (SVMs) perform binary classification ($c = 2$) by defining a maximally separating hyperplane in d -dimensional feature space. A linear SVM is a function $f(\mathbf{x}) = \text{sign}(\mathbf{w} \cdot \mathbf{x} + \beta)$ where ‘sign’ outputs 0 for all negative inputs and 1 otherwise. Linear SVMs are not suitable for non-linearly separable data. Here one uses instead kernel techniques [14].

A kernel is a function $K: \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$. Typical kernels include the quadratic kernel $K_{\text{quad}}(\mathbf{x}, \mathbf{x}') = (\mathbf{x}^T \cdot \mathbf{x}' + 1)^2$ and the Gaussian radial basis function (RBF) kernel $K_{\text{rbf}}(\mathbf{x}, \mathbf{x}') = e^{-\gamma \|\mathbf{x} - \mathbf{x}'\|^2}$, parameterized by a value $\gamma \in \mathbb{R}$. A kernel's projection function is a map ϕ defined by $K(\mathbf{x}, \mathbf{x}') = \phi(\mathbf{x}) \cdot \phi(\mathbf{x}')$. We do not use ϕ explicitly, indeed for RBF kernels this produces an infinite-dimension vector. Instead, classification is defined using a “kernel trick”: $f(\mathbf{x}) = \text{sign}([\sum_{i=1}^t \alpha_i K(\mathbf{x}, \mathbf{x}_i)] + \beta)$ where β is again a learned threshold, $\alpha_1, \dots, \alpha_t$ are learned weights, and $\mathbf{x}_1, \dots, \mathbf{x}_t$ are feature vectors of inputs from a training set. The \mathbf{x}_i for which $\alpha_i \neq 0$ are called support vectors. Note that for non-zero α_i , it is the case that $\alpha_i < 0$ if the training-set label of \mathbf{x}_i was zero and $\alpha_i > 0$ otherwise.

Logistic regression. SVMs do not directly generalize to multiclass settings $c > 2$, nor do they output class probabilities. Logistic regression (LR) is a popular classifier that does. A binary LR model is defined as $f_1(\mathbf{x}) = \sigma(\mathbf{w} \cdot \mathbf{x} + \beta) = 1/(1 + e^{-(\mathbf{w} \cdot \mathbf{x} + \beta)})$ and $f_0(\mathbf{x}) = 1 - f_1(\mathbf{x})$. A class label is chosen as 1 iff $f_1(\mathbf{x}) > 0.5$.

When $c > 2$, one fixes c weight vectors $\mathbf{w}_0, \dots, \mathbf{w}_{c-1}$ each in \mathbb{R}^d , thresholds $\beta_0, \dots, \beta_{c-1}$ in \mathbb{R} and defines $f_i(\mathbf{x}) = e^{\mathbf{w}_i \cdot \mathbf{x} + \beta_i} / (\sum_{j=0}^{c-1} e^{\mathbf{w}_j \cdot \mathbf{x} + \beta_j})$ for $i \in \mathbb{Z}_c$. The class label is taken to be $\text{argmax}_i f_i(\mathbf{x})$. Multiclass regression is referred to as multinomial or softmax regression. An alternative approach to softmax regression is to build a binary model $\sigma(\mathbf{w}_i \cdot \mathbf{x} + \beta_i)$ per class in a *one-vs-rest* fashion and then set $f_i(\mathbf{x}) = \sigma(\mathbf{w}_i \cdot \mathbf{x} + \beta_i) / \sum_j \sigma(\mathbf{w}_j \cdot \mathbf{x} + \beta_j)$.

These are log-linear models, and may not be suitable for data that is not linearly separable in \mathcal{X} . Again, one may use kernel techniques to deal with more complex data relationships (c.f., [57]). Then, one replaces $\mathbf{w}_i \cdot \mathbf{x} + \beta_i$ with $\sum_{r=1}^t \alpha_{i,r} K(\mathbf{x}, \mathbf{x}_r) + \beta_i$. As written, this uses the entire set of training data points $\mathbf{x}_1, \dots, \mathbf{x}_t$ as so-called representors (here analogous to support vectors). Unlike with SVMs, where most training data set points will never end up as support vectors, here all training set points are potentially representors. In practice one uses a size $s < t$ random subset of training data [57].

Deep neural networks. A popular way of extending softmax regression to handle data that is non linearly separable in \mathcal{X} is to first apply one or more non-linear transformations to the input data. The goal of these *hidden layers* is to map the input data into a (typically) lower-dimensional space in which the classes are separable by the softmax layer. We focus here on fully connected networks, also known as multilayer perceptrons, with a single hidden layer. The hidden layer consists of a number h of *hidden nodes*, with associated weight vectors $\mathbf{w}_0^{(1)}, \dots, \mathbf{w}_{h-1}^{(1)}$ in \mathbb{R}^d and thresholds $\beta_0^{(1)}, \dots, \beta_{h-1}^{(1)}$ in \mathbb{R} . The i -th hidden unit applies a non linear transformation $h_i(\mathbf{x}) = g(\mathbf{w}_i^{(1)} \cdot \mathbf{x} + \beta_i^{(1)})$, where g is an activation function such as \tanh or σ . The vector $h(\mathbf{x}) \in \mathbb{R}^h$ is then

input into a softmax output layer with weight vectors $\mathbf{w}_0^{(2)}, \dots, \mathbf{w}_{c-1}^{(2)}$ in \mathbb{R}^h and thresholds $\beta_0^{(2)}, \dots, \beta_{c-1}^{(2)}$ in \mathbb{R} .

Decision trees. A decision tree T is a labeled tree. Each internal node v is labeled by a feature index $i \in \{1, \dots, d\}$ and a *splitting function* $\rho : \mathcal{X}_i \rightarrow \mathbb{Z}_{k_v}$, where $k_v \geq 2$ denotes the number of outgoing edges of v .

On an input $\mathbf{x} = (x_1, x_2, \dots, x_d)$, a tree T defines a computation as follows, starting at the root. When we reach a node v , labeled by $\{i, \rho\}$, we proceed to the child of v indexed by $\rho(x_i)$. We consider three types of splitting functions ρ that are typically used in practice ([11]):

- (1) The feature x_i is categorical with $\mathcal{X}_i = \mathbb{Z}_k$. Let $\{S, T\}$ be some partition of \mathbb{Z}_k . Then $k_v = 2$ and $\rho(x_i) = 0$ if $x_i \in S$ and $\rho(x_i) = 1$ if $x_i \in T$. This is a binary split on a categorical feature.
- (2) The feature x_i is categorical with $\mathcal{X}_i = \mathbb{Z}_k$. We have $k_v = k$ and $\rho(x_i) = x_i$. This corresponds to a k -ary split on a categorical feature of arity k .
- (3) The feature x_i is continuous with $\mathcal{X}_i = [a, b]$. Let $a < t < b$ be a *threshold*. Then $k_v = 2$ and $\rho(x_i) = 0$ if $x_i \leq t$ and $\rho(x_i) = 1$ if $x_i > t$. This is a binary split on a continuous feature with threshold t .

When we reach a leaf, we terminate and output that leaf’s value. This value can be a class label, or a class label and confidence score. This defines a function $f : \mathcal{X} \rightarrow \mathcal{Y}$.

B Details on Data Sets

Here we give some more information about the data sets we used in this work. Refer back to Table 3 and Table 5.

Synthetic data sets. We used 4 synthetic data sets from scikit [42]. The first two data sets are classic examples of non-linearly separable data, consisting of two concentric Circles, or two interleaving Moons. The next two synthetic data sets, Blobs and 5-Class, consist of Gaussian clusters of points assigned to either 3 or 5 classes.

Public data sets. We gathered a varied set of data sets representative of the type of data we would expect ML service users to use to train logistic and SVM based models. These include famous data sets used for supervised learning, obtained from the UCI ML repository (*Adult*, *Iris*, *Breast Cancer*, *Mushrooms*, *Diabetes*). We also consider the *Steak* and *GSS* data sets used in prior work on model inversion [23]. Finally, we add a data set of digits available in scikit, to visually illustrate training data leakage in kernelized logistic models (c.f. Section 4.1.3).

Public data sets and models from BigML. For experiments on decision trees, we chose a varied set of models publicly available on BigML’s platform. These models were trained by real MLaaS users and they cover a wide range of application scenarios, thus providing a realistic benchmark for the evaluation of our extraction attacks.

The *IRS* model predicts a US state, based on administrative tax records. The *Steak* and *GSS* models respectively predict a person’s preferred steak preparation and happiness level, from survey and demographic data. These two models were also considered in [23]. The *Email Importance* model predicts whether Gmail classifies an email as ‘important’ or not, given message metadata. The *Email Spam* model classifies emails as spam, given the presence of certain words in its content. The German Credit data set was taken from the UCI library [35] and classifies a user’s loan risk. Finally, two regression models respectively predict *Medical Charges* in the US based on state demographics, and the *Bitcoin Market Price* from daily opening and closing values.

C Analysis of the Path-Finding Algorithm

In this section, we analyze the correctness and complexity of the decision tree extraction algorithm in Algorithm 1. We assume that all leaves are assigned a unique id by the oracle \mathcal{O} , and that no continuous feature is split into intervals of width smaller than ε . We may use id to refer directly to the leaf with identity id .

Correctness. Termination of the algorithm follows immediately from the fact that new queries are only added to Q when a new leaf is visited. As the number of leaves in the tree is bounded, the algorithm must terminate.

We prove by contradiction that all leaves are eventually visited. Let the *depth* of a node v , denote the length of the path from v to the root (the root has depth 0). For two leaves id, id' , let A be their deepest common ancestor (A is the deepest node appearing on both the paths of id and id'). We denote the depth of A as $\Delta(\text{id}, \text{id}')$.

Suppose Algorithm 1 terminates without visiting all leaves, and let (id, id') be a pair of leaves with maximal $\Delta(\text{id}, \text{id}')$, such that id was visited but id' was not. Let x_i be the feature that their deepest common ancestor A splits on. When id is visited, the algorithm calls `LINE_SEARCH` or `CATEGORY_SPLIT` on feature x_i . As all leaf ids are unique and there are no intervals smaller than ε , we will discover a leaf in each sub-tree rooted at A , including the one that contains id' . Thus, we visit a leaf id'' for which $\Delta(\text{id}'', \text{id}') > \Delta(\text{id}, \text{id}')$, a contradiction.

Complexity. Let m denote the number of leaves in the tree. Each leaf is visited exactly once, and for each leaf we check all d features. Suppose continuous features have range $[0, b]$, and categorical features have arity k . For continuous features, finding one threshold takes at most $\log_2(\frac{b}{\varepsilon})$ queries. As the total number of splits on one feature is at most m (i.e., all nodes split on the same feature), finding all thresholds uses at most $m \cdot \log_2(\frac{b}{\varepsilon})$ queries. Testing a categorical feature uses k queries. The total query complexity is $O(m \cdot (d_{\text{cat}} \cdot k + d_{\text{cont}} \cdot m \cdot \log_2(\frac{b}{\varepsilon}))$, where d_{cat} and d_{cont} represent respectively the number of categorical and continuous features.

For the special case of boolean trees, the complexity is $O(m \cdot d)$. In comparison, the algorithm of [33], that uses membership queries only, has a complexity polynomial in d and 2^δ , where δ is the tree depth. For degenerate trees, 2^δ can be exponential in m , implying that the assumption of unique leaf identities (obtained from confidence scores for instance) provides an exponential speed-up over the best-known approach with class labels only. The algorithm from [33] can be extended to regression trees, with a complexity polynomial in the size of the output range \mathcal{Y} . Again, under the assumption of unique leaf identities (which could be obtained solely from the output values) we obtain a much more efficient algorithm, with a complexity independent of the output range.

The Top-Down Approach. The correctness and complexity of the top-down algorithm from Section 4.2 (which uses incomplete queries), follow from a similar analysis. The main difference is that we assume that all nodes have a unique id , rather than only the leaves.

D A Note on Improper Extraction

To extract a model f , without knowledge of the model class, a simple strategy is to extract a multilayer perceptron \hat{f} with a large enough hidden layer. Indeed, feed-forward networks with a single hidden layer can, in principle, closely approximate any continuous function over a bounded subset of \mathbb{R}^d [20, 28].

However, this strategy intuitively does not appear to be optimal. Even if we know that we can find a multilayer perceptron \hat{f} that closely matches f , \hat{f} might have a far more complex representation (more parameters) than f . Thus, tailoring the extraction to the ‘simpler’ model class of the target f appears more efficient. In learning theory, the problem of finding a succinct representation of some target model f is known as *Occam Learning* [13].

Our experiments indicate that such generic improper extraction indeed appears sub-optimal, in the context of equation-solving attacks. We train a softmax regression over the Adult data set with target “Race”. The model f is defined by 530 real-valued parameters. As shown in Section 4.1.2, using only 530 queries, we extract a model \hat{f} from the *same* model class, that closely matches f (\hat{f} and f predict the same labels on 100% of tested inputs, and produce class probabilities that differ by less than 10^{-7} in TV distance). We also extracted the same model, assuming a multilayer perceptron target class. Even with 1,000 hidden nodes (this model has 111,005 parameters), and 10 \times more queries (5,300), the extracted model \hat{f} is a weaker approximation of f (99.5% accuracy for class labels and TV distance of 10^{-2} for class probabilities).

Oblivious Multi-Party Machine Learning on Trusted Processors

Olga Ohrimenko, Felix Schuster, Cédric Fournet, Aastha Mehta*, Sebastian Nowozin
Kapil Vaswani, Manuel Costa
Microsoft Research

Abstract

Privacy-preserving multi-party machine learning allows multiple organizations to perform collaborative data analytics while guaranteeing the privacy of their individual datasets. Using trusted SGX-processors for this task yields high performance, but requires a careful selection, adaptation, and implementation of machine-learning algorithms to provably prevent the exploitation of any side channels induced by data-dependent access patterns.

We propose data-oblivious machine learning algorithms for support vector machines, matrix factorization, neural networks, decision trees, and k-means clustering. We show that our efficient implementation based on Intel Skylake processors scales up to large, realistic datasets, with overheads several orders of magnitude lower than with previous approaches based on advanced cryptographic multi-party computation schemes.

1 Introduction

In many application domains, multiple parties would benefit from pooling their private datasets, training precise machine-learning models on the aggregate data, and sharing the benefits of using these models. For example, multiple hospitals might share patient data to train a model that helps in diagnosing a disease; having more data allows the machine learning algorithm to produce a better model, benefiting all the parties. As another example, multiple companies often collect complementary data about customers; sharing such data would allow machine learning algorithms to make joint predictions about customers based on a set of features that would not otherwise be available to any of the companies. This scenario also applies to individuals. For example, some systems learn an individual’s preferences to make accurate recommendations [9]; while users would like to keep their data private, they want to reap the rewards of correlating their preferences with those of other users.

Secure multi-party computation [17, 24, 44] and fully homomorphic encryption [23] are powerful cryptographic tools that can be used for privacy preserving machine learning. However, recent work [38, 47, 48, 54] reports large runtime overheads, which limits their prac-

tical adoption for compute-intensive analyses of large datasets. We propose an alternative privacy-preserving multi-party machine learning system based on trusted SGX processors [45]. In our system, multiple parties agree on a joint machine learning task to be executed on their aggregate data, and on an SGX-enabled data center to run the task. Although they do not trust one another, they can each review the corresponding machine-learning code, deploy the code into a processor-protected memory region (called an enclave), upload their encrypted data just for this task, perform remote attestation, securely upload their encryption keys into the enclave, run the machine learning code, and finally download the encrypted machine learning model. The model may also be kept within the enclave for secure evaluation by all the parties, subject to their agreed access control policies. Figure 1 provides an overview of our system.

While we rely on the processor to guarantee that only the machine learning code inside the enclave has direct access to the data, achieving privacy still requires a careful selection, adaptation, and implementation of machine-learning algorithms, in order to prevent the exploitation of any side channels induced by disk, network, and memory access patterns, which may otherwise leak a surprisingly large amount of data [39, 49, 70]. The robust property we want from these algorithms is *data-obliviousness*: the sequence of memory references, disk accesses, and network accesses that they perform should not depend on secret data. We propose data-oblivious machine learning algorithms for support vector machines (SVM), matrix factorization, neural networks, decision trees, and k-means clustering. Our data-oblivious algorithms are based on careful elimination of data-dependent accesses (SVM, neural networks and k-means), novel algorithmic techniques (matrix factorization) and deployment of platform specific hardware features (decision trees). We provide strong, provable confidentiality guarantees, similar to those achieved by purely cryptographic solutions: we ensure that an attacker that observes the sequence of I/O operations, including their addresses and their encrypted contents, cannot distinguish between two datasets of the same size that yield results of the same size.

We implemented and ran our algorithms on off-the-shelf Intel Skylake processors, using several large ma-

*Work done while at Microsoft Research; affiliated with Max Planck Institute for Software Systems (MPI-SWS), Germany.

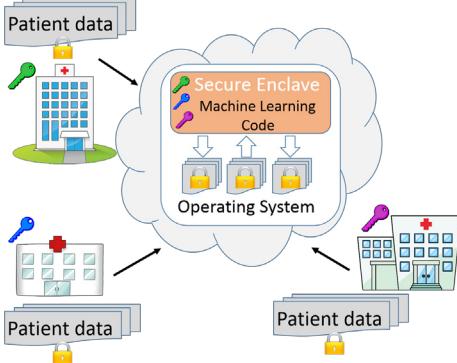

Figure 1: Sample privacy-preserving multi-party machine learning system. Multiple hospitals encrypt patient datasets, each with a different key. The hospitals deploy an agreed-upon machine learning algorithm in an enclave in a cloud data center and share their data keys with the enclave. The enclave processes the aggregate datasets and outputs an encrypted machine learning model.

chine learning datasets. Our results show that our approach scales to realistic datasets, with overheads that are several orders of magnitude better than with previous approaches based on advanced cryptographic multi-party computation schemes. On the other hand, our approach trusts the processor to protect the confidentiality of its internal state, whereas these cryptographic approaches do not rely on this assumption.

2 Preliminaries

Intel SGX SGX [45] is a set of new x86 instructions that applications can use to create protected memory regions within their address space. These regions, called enclaves, are isolated from any other code in the system, including operating system and hypervisor. The processor monitors all memory accesses to the enclaves: only code running in an enclave can access data in the enclave. When inside the physical processor package (in the processor’s caches), the enclave memory is available in plaintext, but it is encrypted and integrity protected when written to system memory (RAM). External code can only invoke code inside the enclave at statically-defined entry points. SGX also supports attestation and sealing [2]: code inside an enclave can get messages signed using a per-processor private key along with a digest of the enclave. This enables other entities to verify that these messages originated from a genuine enclave with a specific code and data configuration.

Using SGX instructions, applications can set up fine-grained trusted execution environments even in (potentially) hostile or compromised hosts, but application developers who write code that runs inside enclaves are still responsible for maintaining confidentiality of secrets managed by the enclave. In this paper, we focus on guaranteeing that the machine learning algorithms that we

load into enclaves do not leak information through memory, disk, or network access patterns.

Adversary Model We assume the machine learning computation runs in an SGX-enabled cloud data center that provides a convenient ‘neutral ground’ to run the computation on datasets provided by multiple parties. The parties do not trust one another, and they are also suspicious about the cloud provider. From the point of view of each party (or any subset of parties), the adversary models all the other parties and the cloud provider.

The adversary may control all the hardware in the cloud data center, except the processor chips used in the computation. In particular, the adversary controls the network cards, disks, and other chips in the motherboards. She may record, replay, and modify network packets or files. The adversary may also read or modify data after it left the processor chip using physical probing, direct memory access (DMA), or similar techniques.

The adversary may also control all the software in the data center, including the operating system and hypervisor. For instance, the adversary may change the page tables so that any enclave memory access results in a page fault. This active adversary is general enough to model privileged malware running in the operating or hypervisor layers, as well as malicious cloud administrators who may try to access the data by logging into hosts and inspecting disks and memory.

We assume that the adversary is unable to physically open and manipulate the SGX processor chips that run the machine learning computation. Denial-of-service and side-channel attacks based on power and timing analysis are outside our scope. We consider the implementation of the machine learning algorithms to be benign: the code will never intentionally try to leak secrets from enclaves. We assume that all parties agree on the machine learning code that gets access to their datasets, after inspecting the code or using automated verification [60] to ascertain its trustworthiness. We assume that all parties get access to the output of the machine learning algorithm, and focus on securing its implementation—limiting the amount of information released by its correct output [19] is outside the scope of this paper.

Security Guarantees We are interested in designing algorithms with strong provable security guarantees. The attacker described above should not gain any side information about sensitive data inputs. More precisely, for each machine learning algorithm, we specify *public parameters* that are allowed to be disclosed (such as the input sizes and the number of iterations to perform) and we treat all other inputs as private. We then say that an algorithm is *data-oblivious* if an attacker that interacts with it and observes its interaction with memory, disk and network learns nothing except possibly those public

parameters. We define this interaction as a trace execution τ of I/O events, each recording an access type (read or write), an address, and some contents, controlled by the adversary for all read accesses. Crucially, this trace leaks accurate information about access to code as well as data; for example, a conditional jump within an enclave may reveal the condition value by leaking the next code address [70].

We express our security properties using a simulation-based technique: for each run of an algorithm given some input that yields a trace τ , we show that there exists a *simulator program* given *only* the public parameters that simulates the interaction of the original algorithm with the memory by producing a trace τ' indistinguishable from τ . Intuitively, if the algorithm leaked any information depending on private data, then the simulator (that does not have the data) would not be able to adapt its behavior accordingly. Beside the public parameters, the simulator may be given the result of the algorithm (e.g., the machine learning model) in scenarios where the result is revealed to the parties running the algorithm. We rely on indistinguishability (rather than simple trace equivalence $\tau' = \tau$) to account for randomized algorithms, and in particular for encryption. For instance, any private contents in write events will be freshly encrypted and thus (under some suitable semantic-encryption security assumption) will appear to be independently random in both τ and τ' , rather than equal. More precisely, we define indistinguishability as usual in cryptography, using a game between a system that runs the algorithm (or the simulator) and a computationally bounded adversary that selects the inputs, interacts with the system, observes the trace, and attempts to guess whether it interacts with the algorithm or the simulator. The algorithm is data-oblivious when such adversaries guess correctly with probability at most $\frac{1}{2}$ plus a negligible advantage.

3 Data-Oblivious Primitives

Our algorithms rely on a library of general-purpose oblivious primitives. We describe them first and then show how we use them in machine learning algorithms.

Oblivious assignments and comparisons These primitives can be used to conditionally assign or compare integer, floating point, or 256-bit vector variables. They are implemented in x86-64 assembly, operating solely on registers whose content is loaded from and stored to memory using deterministic memory accesses. The registers are private to the processor; their contents are not accessible to code outside the enclave. As such, evaluations that involve registers only are not recorded in the trace τ , hence, any register-to-register data manipulation is data-oblivious by default.

We choose `omove()` and `ogreater()` as two representative oblivious primitives. In conjunction, they enable

Non-oblivious	Oblivious
<pre>int max(int x, int y) { if (x > y) return x; else return y; }</pre>	<pre>int max(int x, int y) { bool getx = ogreater(x, y); return omove(getx, x, y); }</pre>

Figure 2: **Left:** C++ function determining the maximum of two integers using a non-oblivious if-else statement; **right:** oblivious variant of the function using oblivious primitives.

the straightforward, oblivious implementation of the `max()` function, as shown in Figure 2. In the oblivious version of `max()`, `ogreater()` evaluates the guard $x > y$ and `omove()` selects either x or y , depending on that guard. In our library, similar to related work [53], both primitives are implemented with conditional instructions `cmovz` and `setg`. For example, in simplified form, `omove()` and `ogreater()` for 64-bit integers comprise the following instructions:

ogreater()	omove()
<pre>mov rcx, x mov rdx, y cmp rcx, rdx setg al retn</pre>	<pre>mov rcx, cond mov rdx, x mov rax, y test rcx, rcx cmovz rax, rdx retn</pre>

On top of such primitives for native C++ types, our library implements more complex primitives for user-defined types. For example, most of our oblivious algorithms rely on `omoveEx()`, an extended version of the basic `omove()`, which can be used to conditionally assign any type of variable; depending on the size of the given type, `omoveEx()` iteratively uses the 64-bit integer or 256-bit vector version of `omove()`.

Oblivious array accesses Scanning entire arrays is a commonly used technique to make data-dependent memory accesses oblivious. In the simplest case, we use `omoveEx()` iteratively to access each element when actually just a single element is to be loaded or stored.¹ However, our adversary model implies that, for enclave code, the attacker can only observe memory accesses at cache-line granularity. Accordingly, the x least significant bits² of memory addresses are not recorded in a trace τ . It is hence sufficient to scan arrays at cache-line granularity rather than element or byte granularity. We implement accordingly optimized array access primitives that leverage AVX2 vector instructions [31]. In particular, the `vpgatherdd` instruction can load each of the eight 32-bit (4-byte) components of a 256-bit vector

¹Dummy writes without actual effect are made to all but one element in case of a store. Modern processors treat such writes in the same way as real writes and mark corresponding cache lines as dirty.

²The value of x depends on the actual hardware implementation; for Skylake processors, where cache lines are 64 bytes long, $x = 6$.

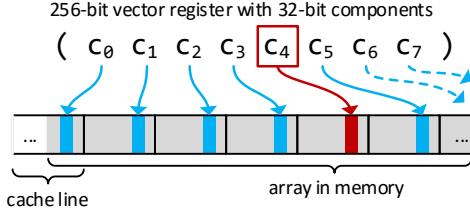

Figure 3: Optimized array scanning using the `vpgatherdd` instruction; here, the value of interest is read into C_4 . The other components perform dummy reads.

register from a different memory offset. Hence, by loading each component from a different cache line, 4 bytes can be read obliviously from an aligned 512-byte array with a single instruction as depicted in Figure 3 (i.e., a 4-byte read is hidden among 8 cache lines accessed via `vpgatherdd`). On top of this, the `oget()` primitive is created, which obliviously reads an element from an unaligned array of arbitrary form and size. `oget()` iteratively applies the `vpgatherdd` instruction in the described way while avoiding out-of-bounds reads. Depending on the dynamic layout of the caches, `oget()` can significantly speed-up oblivious array lookups (see Section 6.6). The construction of `oget()` is conservative in the sense that it assumes (i) that the processor may load vector components in arbitrary, possibly parallel order³ and (ii) that this order is recorded precisely in τ . For cases where (i) or (ii) do not apply, e.g., for software-only attackers, a further optimized version of `oget()` is described in Appendix B.

Oblivious sorting We implement oblivious sorting by passing its elements through a network of carefully arranged compare-and-swap functions. Given an input size n , the network layout is fixed and, hence, the memory accesses fed to the functions in each layer of the network depend only on n and not the content of the array (as opposed to, e.g., quicksort). Hence, its memory trace can be easily simulated using public parameter n and fixed element size. Though there exists an optimal sorting network due to Ajtai *et al.* [1], it incurs high constants. As a result, a Batcher’s sorting network [7] with running time of $O(n(\log n)^2)$ is preferred in practice. Our library includes a generic implementation of Batcher’s sort for shuffling the data as well as re-ordering input instances to allow for efficient (algorithm-specific) access later on. The sorting network takes as input an array of user-defined type and an oblivious compare-and-swap function for this type. The oblivious compare-and-swap usually relies on the `ogreater()` and `omoveEx()` primitives described above.

³The implementation of the `vpgatherdd` instruction is microarchitecture-specific and undocumented.

4 Machine Learning Algorithms

We describe five machine learning algorithms: four training and one prediction method, and their data-oblivious counter-parts. The algorithms vary in the complexity of access patterns, from randomly sampling the training data to input-dependent accesses to the corresponding model. Hence, we propose algorithm-specific mitigation techniques that build on the oblivious primitives from the last section.

4.1 K-Means

The goal of k-means clustering is to partition input data points into k clusters such that each point is assigned to the cluster closest to it. Data points are vectors in the Euclidean space \mathbb{R}^d . To implement clustering, we chose a popular and efficient Lloyd’s algorithm [40, 41, 43].

During its execution, k-means maintains a list of k points that represent the current cluster centroids: for $i = 1..k$, the i th point is the mean of all points currently assigned to the i th cluster. Starting from random centroids, the algorithm iteratively reassigns points between clusters: (1) for each point, it compares its distances to the current k centroids, and assigns it to the closest cluster; (2) once all points have been processed, it recomputes the centroids based on the new assignment. The algorithm ends after a fixed number of iterations, or once the clustering is stable, that is, in case points no longer change their cluster assignments. Depending on the application, k-means returns either the centroids or the assignment of data points to clusters.

Although the algorithm data flow is largely independent of the actual points and clusters, its naive implementation may still leak much information in the conditional update in (1)—enabling for instance an attacker to infer some point coordinates from the final assignment, or vice-versa—and in the recomputation (2)—leaking, for instance, intermediate cluster sizes and assignments.

In the following, we treat the number of points (n), clusters (k), dimension (d) and iterations (T) as public. We consider efficient, streaming implementations with, for each iteration, an outer loop traversing all points once, and successive inner loops on all centroids for the steps (1) and (2) above. For each centroid, in addition to the d coordinates, we locally maintain its current cluster size (in $0..n$). To perform both (1) and (2) in a single pass, we maintain both the current and the next centroids, and we delay the division of coordinates by the cluster size in the latter. Thus, for a given point, inner loop (1) for $i = 1..k$ maintains the (square of the) current minimal distance δ_{min} and its centroid index i_{min} . And inner loop (2) performs k conditional updates on the next centroids, depending on $i = i_{min}$. Finally, a single pass over centroids recomputes their coordinates. An important detail is to uniformly handle the special case of empty clus-

ters; another to select the initial centroids, for instance by sampling random points from the shuffled dataset.

In our adapted algorithm, the “privacy overhead” primarily consists of oblivious assignments to loop variables in (1), held in registers, and to the next centroids, held in the cache. In particular, instead of updating statistics for only the centroid that the point belongs to, we make dummy updates to each centroid (using our `omoveEx()` primitive). In the computation of new centroids, we use a combination of `ogreater()` and `omoveEx()` to handle the case of empty clusters. These changes do not affect the algorithm’s time complexity: in the RAM model the operations above can still be done in $O(T(nkd + kd)) = O(Tnkd)$ operations.

Theorem 1. *The adapted k-means algorithm runs in time $O(Tnkd)$ and is data-oblivious, as there exists a simulator for k-means that depends only on T , n , d , and k .*

Proof. The simulator can be trivially constructed as follows: given T , n , d and k , it chooses n random points from \mathbb{R}^d and simply runs the algorithm above for k centroids and T iterations. \square

It is easy to see that the subroutine for finding the closest centroid in the training algorithm can be also used to predict the trained cluster that an input point belongs to.

4.2 Supervised Learning Methods

In supervised machine learning problems, we are given a dataset $D = \{(x_i, y_i)\}_{i=1..n}$ of instances, where $x_i \in \mathcal{X}$ is an observation and $y_i \in \mathcal{Y}$ is a desired prediction. The goal then is to learn a predictive model $f: \mathcal{X} \rightarrow \mathcal{Y}$ such that $f(x_i) \approx y_i$ and the model generalizes to unseen instances $x \in \mathcal{X}$. Many machine learning methods learn such a model by minimizing an *empirical risk* objective function together with a regularization term [65]:

$$\min_w \Omega(w) + \frac{1}{n} \sum_{i=1}^n L(y_i, f_w(x_i)). \quad (1)$$

We will show secure implementations of support vector machines (SVM) and neural networks, which are of the form (1). Other popular methods such as linear regression and logistic regression are also instances of (1).

Most algorithms to minimize (1) operate iteratively on small subsets of the data at a time. When sampling these subsets, one common requirement for correctness is that the algorithm should have access to a distribution of samples with an unbiased estimate of the expected value of the original distribution. We make an important observation that an unbiased estimate of the expected value of a population can be computed from a subset of independent and identically distributed instances as well as from a subset of *pairwise-distinct* instances.

Thus, we can achieve correctness and security by adapting the learning algorithm as follows. Repeatedly, (1) securely shuffle all instances at random, using Batcher’s sort, for example, or an oblivious shuffle [50]; (2) run the learning algorithm on the instances *sequentially*, rather than randomly, either individually or in small batches. Thus, the cost of shuffling is amortized over all n instances. Next, we illustrate this scheme for support vector machines and neural networks.

4.3 Support Vector Machines (SVM)

Support Vector Machines are a popular machine learning model for classification problems. The original formulation [12] applies to problems with two classes. Formally, SVM specializes (1) by using the linear model $f_w(x) = \langle w, x \rangle$, the regularization $\Omega(w) = \frac{\lambda}{2} \|w\|^2$ for $\lambda > 0$, and the loss function $L(y_i, f_w(x_i)) = \max\{0, 1 - y_i f_w(x_i)\}$.

The SVM method is important historically and in practice for at least four separate reasons: *first*, it is easy to use and tune and it performs well in practice; *second*, it is derived from the principle of structural risk minimization [65] and comes with excellent theoretical guarantees in the form of generalization bounds; *third*, it was the first method to be turned into a non-linear classifier through application of the kernel trick [12, 56], *fourth*, the SVM has inspired a large number of generalizations, for example to the multi-class case [67], regression [61], and general pattern recognition problems [63].

Here we only consider the linear (primal) case with two classes, but our methods would readily extend to multiple classes or support vector regression problems. There are many methods to solve the SVM objective and for its simplicity we adapt the state-of-the-art *Pegasos* method [58]. The algorithm proceeds in iterations $t = 1..T$ and, at each iteration, works on small subsets of l training instances at a time, $A^{(t)}$. It updates a sequence of weight vectors $w^{(1)}, w^{(2)}, \dots, w^{(T)}$ converging to the optimal minimizer of the objective function (1).

Let us now consider in detail our implementation of the algorithm, and the changes that make it data-oblivious. We present the pseudo-code in Algorithm 1 where our changes are highlighted in blue, and indented to the right. As explained in Section 4.2, SVM samples input data during training. Instead, we obliviously (or privately) shuffle the data and process it sequentially. The original algorithm updates the model using instances that are mispredicted by the current model, $A_+^{(t)}$ in Line 5 of the pseudo-code. As this would reveal the state of the current model to the attacker, we make sure that the computation depends on every instance of $A^{(t)}$. In particular, we generate a modified set of instances in $B^{(t)}$ which has the original (x, y) instance if x is mispredicted and $(x, 0)$ otherwise, assigning either 0 or y using our `ogreater()` and `omove()` primitives (see Figure 2).

Algorithm 1 SVM Original with changes (starting with \triangleright) and additional steps required for the Oblivious Version indicated in blue.

```

1: INPUT:  $I = \{(x_i, y_i)\}_{i=1,\dots,n}$ ,  $\lambda, T, l$ 
2: INITIALIZE: Choose  $w^{(0)}$  s.t.  $\|w^{(0)}\| \leq 1/\sqrt{\lambda}$ 
3:   Shuffle  $I$ 
4: FOR  $t = 1, 2, \dots, T \times n/l$ 
5:   Choose  $A^{(t)} \subseteq I$  s.t.  $|A^{(t)}| = l$ 
      $\triangleright$  Set  $A^{(t)}$  to  $t$ th batch of  $l$  instances
6:   Set  $A_+^{(t)} = \{(x, y) \in A^{(t)} : y\langle w^t, x \rangle < 1\}$ 
      $\triangleright B^{(t)} = \{(x, \mathbf{1}[y\langle w^t, x \rangle < 1]y) : \forall (x, y) \in A^{(t)}\}$ 
7:   Set  $\eta = 1/\lambda t$ 
8:   Set  $v = \sum_{(x,y) \in A_+^{(t)}} yx$             $\triangleright v = \sum_{(x,z) \in B^{(t)}} zx$ 
9:   Set  $v = (1 - \eta \lambda)w^{(t)} + \frac{\eta}{l}v$ 
10:  Set  $c = 1 < \frac{1}{\sqrt{\lambda}}\|w\|$ 
11:  Set  $w^{(t+1)} = \min\left\{1, \frac{1}{\sqrt{\lambda}}\|w\|\right\}v$ 
      $\triangleright$  Set  $w^{(t+1)} = \left(c + (1 - c) \times \frac{1}{\sqrt{\lambda}\|w\|}\right)v$ 
12: OUTPUT  $w^{(t+1)}$ 

```

The second change is due to a Euclidean projection in Line 11, where v is multiplied by the minimum of the two values. In the oblivious version, we ensure that both values participate in the update of the model, again using our oblivious primitives. The modifications above are simple and, if the data is shuffled offline, asymptotically do not add overhead as the algorithm has to perform prediction for every value in the sample. Otherwise, the overhead of sorting is amortized as T is usually set to at least one.

Theorem 2. *The SVM algorithm described above runs in time $O(n(\log n)^2)$ and is data-oblivious, as there exists a simulator for SVM that depends only on T, n, d, λ and l , where d is the number of features in each input instance.*

The simulator can be constructed by composing a simulator for oblivious sorting and one that follows the steps of Algorithm 1.

We note that the oblivious computation of a label in the training algorithm ($\langle w, x \rangle$ in Line 6 in Algorithm 1) can be used also for the prediction phase of SVM.

4.4 Neural Networks

Feedforward neural networks are classic models for pattern recognition that process an observation using a sequence of learned non-linear transformations [10]. Recently, deep neural networks made significant progress on difficult pattern recognition applications in speech, vision, and natural language understanding and the collective set of methods and models is known as *deep learning* [26].

Formally, a feedforward neural network is a sequence of transformations $f(x) = f_t(\dots f_2(f_1(x)))$, where each transformation f_i is described by a fixed family of transformations and a parameter w_i to identify one particular element in that family. *Learning* a neural network means to find suitable parameters by minimization of the learning objective (1).

To minimize (1) efficiently in the context of neural networks, we use stochastic gradient methods (SGD) on small subsets of training data [26]. In particular, for $l \ll n$, say $l = 32$, we compute a *parameter gradient* on a subset $S \subset \{1, 2, \dots, n\}$, $|S| = l$ of the data as

$$\nabla_w \Omega(w) + \frac{1}{l} \sum_{i \in S} \nabla_w L(y_i, f(x_i)). \quad (2)$$

The expression above is an unbiased estimate of the gradient of (1) and we can use it to update the parameters via gradient descent. By repeating this update for many subsets S we can find parameters that approximately minimize the objective. Instead, as for SVM, we use disjoint subsets that are contiguous within the set of all (obliviously or privately) shuffled instances and iterate T times.

Because most neural networks densely process each input instance, memory access patterns during training and testing do not depend on the particular data instance. There are two exceptions. First, the initialization of a vector with $|\mathcal{Y}|$ ground truth labels depends on the true label y_i of the instance (recall that \mathcal{Y} is the set of possible prediction classes or labels). In particular, the y_i th entry is set, for example, to 1 and all other entries to 0. We initialize the label vector and hide the true label of the instance by using our oblivious comparison and move operations. The second exception is due to special functions that occur in certain f_i , for example in tanh-activation layers. Since special functions are relatively expensive, they are usually evaluated using piecewise approximations. Such conditional computation may leak parameter values and, in our adapted algorithm, we instead compute the approximation obliviously using a sequence of oblivious move operations. Neither of these changes affects the complexity of the algorithm.

The prediction counterpart of NN, similar to the k-means and SVM algorithms, is a subroutine of the training algorithm. Hence, our changes can be also used to make an oblivious prediction given a trained network.

4.5 Decision Tree Evaluation

Decision trees are common machine learning models for classification and regression tasks [15, 51, 52]. In these models, a tree is traversed from root to leaf node by performing a simple test on a given instance, at each interior node of the tree. Once a leaf node is reached, a simple model stored at this node, for example a constant value, is used as prediction.

Decision trees remain popular because they are *non-parametric*: the size of the decision tree can grow with more training data, providing increasingly accurate models. Ensembles of decision trees, for example in the form of *random forests* [14] offer improved predictive performance by averaging the predictions of many individual tree models [16]. Decision trees illustrate a class of data structures whose usage is highly instance-specific: when evaluating the model, the path traversed from root to leaf node reveals a large amount of information on both the instance and the tree itself. To enable the evaluation of decision trees without leaking side information, we adapt the evaluation algorithm of an existing library for random forests to make it data oblivious. We keep modifications of the existing implementation at a minimum, relying on the primitives of Section 3 wherever possible. Our target tree evaluation algorithm operates on one instance $x \in \mathbb{R}^d$ at a time. In particular, the trees are such that, at each interior node, a simple *decision stump* is performed:

$$\phi(x; j, t) = \begin{cases} \text{left}, & \text{if } x(j) \leq t, \\ \text{right}, & \text{otherwise,} \end{cases} \quad (3)$$

where $j \in \{1, \dots, d\}$ and $t \in \mathbb{R}$ are learned parameters stored at the interior tree node.

In order to conceal the path taken through a tree, we modify the algorithm such that each tree layer is stored as an array of nodes. During evaluation of an instance x , the tree is traversed by making exactly one oblivious lookup in each of these arrays. At each node, the lookup $x(j)$ and corresponding floating point comparison are done using our oblivious primitives. In case a leaf is found early, that is before the last layer of the tree was reached, its ID is stored obliviously and the algorithm proceeds with dummy accesses for the remaining layers of the tree. The predictions of all trees in a random forest are accumulated obliviously in an array; the final output is the prediction with the largest weight.

Together, the described modifications guarantee data-obliviousness both for instances and for trees (of the same size, up to padding). The algorithmic overhead is linear in the number of nodes n in a tree, i.e., $O(n)$ for a fixed d ; we omit the corresponding formal development.

4.6 Matrix Factorization

Matrix factorization methods [55] are a popular set of techniques for constructing recommender systems [32]. Given *users* and *items* to be rated, we take as input the observed ratings for a fraction of user-item pairs, either as explicit scores (“five stars”) or implicit user feedback. As a running example, we consider a system to recommend movies to viewers based on their experience.

Matrix factorization embeds users and items into a latent vector space, such that the inner product of a user vector with an item vector produces an estimate of the

rating a user would assign to the item. We can then use this expected rating to propose novel items to the user. While the individual preference dimensions in the user and item vectors are not assigned fixed meanings, empirically they often correspond to interpretable properties of the items. For example, a latent dimension may correspond to the level of action the movie contains.

Matrix factorization methods are remarkably effective [9] because they learn to transfer preference information across users and items by discovering dimensions of preferences shared by all users and items.

Let n be the number of users and m the number of items in the system. We may represent all (known and unknown) ratings as a matrix $R \in \mathbb{R}^{n \times m}$. The input consists of M ratings $r_{i,j}$ with $i \in 1..n$ and $j \in 1..m$, given by users to the items they have seen (using the movies analogy). The output consists of $U \in \mathbb{R}^{n \times d}$ and $V \in \mathbb{R}^{m \times d}$ such that $R \approx UV^\top$; these two matrices may then be used to predict unknown ratings $r_{i,j}$ as inner products $\langle u_i, v_j \rangle$. Following [48], we refer to u_i and v_j as user and item profiles, respectively.

The computation of U and V is performed by minimizing regularized least squares on the known ratings:

$$\min \frac{1}{M} \sum (r_{i,j} - \langle u_i, v_j \rangle)^2 + \lambda \sum \|u_i\|_2^2 + \mu \sum \|v_j\|_2^2 \quad (4)$$

where λ and μ determine the extent of regularization. The function above is not jointly convex in U and V , but becomes strictly convex in U for a fixed V , and strictly convex in V for a fixed U .

We implement matrix factorization using a gradient descent, as in prior work on oblivious methods [47, 48]. More efficient methods are now available to solve (4), such as the so-called *damped Wiberg method*, as shown in an extensive empirical evaluation [30], but they all involve more advanced linear algebra, so we leave their privacy-preserving implementation for future work.

Gradient descent This method iteratively updates U and V based on the current prediction error on the input ratings. The error is computed as $e_{i,j} = r_{i,j} - \langle u_i, v_j \rangle$, and u_i and v_j are updated in the opposite direction of the gradient as follows:

$$u_i^{(t+1)} \leftarrow u_i^{(t)} + \gamma \left[\sum_j e_{i,j} v_j^{(t)} - \lambda u_i^{(t)} \right] \quad (5)$$

$$v_j^{(t+1)} \leftarrow v_j^{(t)} + \gamma \left[\sum_i e_{i,j} u_i^{(t)} - \mu v_j^{(t)} \right] \quad (6)$$

The descent continues as long as the error (4) decreases, or for a fixed number of iterations (T). Each iteration can be efficiently computed by updating U and V sequentially. To update each user profile u_i , we may for instance use an auxiliary linked list of user ratings and pointers to the corresponding movie profiles in V .

The gradient descent above runs in time $\Theta(TM)$ in the RAM model, since all ratings are used at each iteration. For a fixed number of iterations, the access pattern of the algorithm does not depend on the actual values of the input ratings. However, it still reveals much sensitive information about which user-item pairs appear in the input ratings. For example, assuming they indicate which users have seen which movies, it trivially reveals the popularity of each movie, and the intersection of movie profiles between users, during the gradient update (see [46] for privacy implications of leaking movie ratings).

Our data-oblivious algorithm We design an algorithm whose observable behaviour depends only on public parameters n, m, M and T , and, hence, it can be simulated and does not reveal R . (We assume that d, λ, μ , and γ are public and do not depend on the input data.)

The high level idea is to use data structures that interleave user and movie profiles. This interleaving allows us to perform an update by sequentially reading and updating these profiles in-place. Once all profiles have been updated, some additional processing is required to interleave them for the next iteration but, with some care, this can also be implemented by sequential traversals of our data structures. (An illustration of the algorithm can be found in the Appendix.)

Our algorithm preserves the symmetry between users and items. It maintains data structures \mathbf{U} and \mathbf{V} that correspond to expanded versions of the matrices U and V . Intuitively, every user profile in \mathbf{U} is followed by the movie profiles required to update it (that is, the profiles for all movies rated by this user), and symmetrically every movie profile in \mathbf{V} is followed by its user profiles. We use superscript notation $\mathbf{U}^{(t)}$ and $\mathbf{V}^{(t)}$ to distinguish these data structures between iterations.

\mathbf{U} stores n *user tuples* that embed the user profiles of the original U , and M *rating tuples* that contain both movie profiles and their ratings. All tuples have the same size; they each include a *user id*, a *movie id*, a *rating*, and a vector of d values. User tuples are of the form $(i, 0, 0, u_i)$ with $i \in 1..n$; Rating tuples are of the form $(i, j, r_{i,j}, v_j)$. Hence, for each rating for j , we have a copy of v_j in a rating tuple. \mathbf{V} symmetrically stores m *item tuples*, of the form $(0, j, 0, v_j)$, and M *rating tuples*, of the form $(i, j, r_{i,j}, u_i)$.

The precise ordering of tuples within \mathbf{U} (and \mathbf{V}) is explained shortly but, as long as the tuples of \mathbf{U} are grouped by user ids (i), and the user tuple precedes its rating tuples, we can compute each $u_i^{(t+1)}$ according to Equation (5) by traversing $\mathbf{U}^{(t)}$ once, in order. After an initial *Setup*, each iteration actually consists of three data-oblivious phases:

- Update the user profiles u_i within $\mathbf{U}^{(t)}$ using Equation (5); let $\tilde{\mathbf{U}}$ be the updated data structure;

- Extract $U^{(t+1)}$ from $\tilde{\mathbf{U}}$;
- Copy $U^{(t+1)}$ into the rating tuples of $\tilde{\mathbf{V}}$ to obtain $\mathbf{V}^{(t+1)}$ for the next iteration.

(We omit symmetric steps producing $\tilde{\mathbf{V}}$, $\mathbf{V}^{(t+1)}$, and $\mathbf{U}^{(t+1)}$.) The extraction step is necessary to compute the prediction error and prepare \mathbf{U} and \mathbf{V} for the next iteration. Without tweaking the tuple ordering, the only efficient way of doing so would be to sort $\tilde{\mathbf{U}}$ lexicographically (by j , then i) so that the updated user profiles appear in the first n tuples (the approach taken in [48]). Oblivious sorting at each iteration is expensive, however, and would take $O((M+n)(\log(M+n))^2)$ oblivious compare-and-swap of pairs of $d+3$ elements.

Instead, we carefully place the user tuples in $\tilde{\mathbf{U}}$ so that they can be extracted in a single scan, outputting profiles *at a fixed rate*: one user profile every $(M+n)/n$ tuples, on average. Intuitively, this is achieved by interleaving the tuples of users with many ratings with those of users with few ratings—Section 4.7 explains how we efficiently compute such a tuple ordering.

Setup phase: We first initialize the user and vector profiles, and fill \mathbf{U} and \mathbf{V} using the input ratings.

(1) We build a sequence $L_{\mathbf{U}}$ (and symmetrically $L_{\mathbf{V}}$) that, for every user, contains a pair of the user id i and the count w_i of the movies he has rated. To this end, we extract the user ids from the input ratings (discarding the other fields); we sort them; we rewrite them sequentially, so that each entry is extended with a partial count and a flag indicating whether the next user id changes; and we sort them again, this time by flag then user id, to obtain $L_{\mathbf{U}}$ as the top n entries. (Directly outputting $L_{\mathbf{U}}$ during the sequential scan would reveal the counts.) For instance, after the first sorting and rewriting, the entries may be of the form $(1, 1, \perp), (1, 2, \perp), (1, 3, \top), (2, 1, \perp), \dots$

(2) We expand $L_{\mathbf{U}}$ (and symmetrically $L_{\mathbf{V}}$) into a sequence $I_{\mathbf{U}}$ of size $M+n$ that includes, for every user i with w_i ratings, one tuple $(i, 0, \perp, k, \ell)$ for each $k = 0..w_i$, such that the values ℓ are ordered by the interleaving explained in Section 4.7.

(3) We construct \mathbf{U} with empty user and rating profiles, as follows. Our goal is to order the input ratings according to $L_{\mathbf{U}}$. To this end, we extend each input rating with a user-rating sequence number $k = 1..w_i$, thereby producing M tuples $(i, j, r_{i,j}, k, \perp)$, and we append those to $I_{\mathbf{U}}$. We sort those tuples by i then k then $r_{i,j}$, so that $(i, 0, \perp, k, \ell)$ is directly followed by $(i, j, r_{i,j}, k, \perp)$ for $k = 1..w_i$; we sequentially rewrite those tuples so that they become $(_, _, _, _, _)$ directly followed by $(i, j, r_{i,j}, k, \ell)$; we sort again by ℓ ; and we discard the last M dummy tuples $(_, _, _, _, _)$.

(4) We generate initial values for the user and item profiles by scanning \mathbf{U} and filling in u_i and v_j using two pseudo-random functions (PRFs): one for u_i s and one

for v_j s. For each, user tuple $(i, 0, 0, u_i)$, we use the first PRF on inputs $(i-1)d+1, \dots, id$ to generate d random numbers that we normalize and write to u_i . For each, rating tuple $(i, j, r_{i,j}, v_j)$, we use the second PRF on inputs $(j-1)d+1, \dots, jd$ to generate d random numbers that we also normalize and write to v_j . We then use the same two PRFs for \mathbf{V} : the first one for rating tuples and the second one for item tuples.

Update phase: We compute updated user profiles (and symmetrically item profiles) in a single scan, reading each tuple of \mathbf{U} (and symmetrically \mathbf{V}) and (always) rewriting its vector—that is, its last d values, storing u_i for user tuples and v_j for rating tuples.

We use 4 loop variables u , δ , u° , and δ° each holding a \mathbb{R}^d vector, to record partially-updated profiles for the current user and for user i° . We first explain how u and δ are updated for the current user (i). During the scan, upon reading a user tuple $(i, 0, 0, u_i)$, as is always the case for the first tuple, we set u to u_i and δ to $u_i(1 - \lambda\gamma)$ and we overwrite u_i (to hide the fact that we scanned a user tuple). Upon reading a rating tuple $(i, j, r_{i,j}, v_j)$ for the current user i , we update δ to $\gamma v_j(r_{i,j} - \langle u, v_j \rangle) + \delta$ and overwrite v_j with δ . Hence, the last rating tuple (before the next user tuple) now stores the updated profile $u_i^{(t+1)}$ for the current user i .

We now bring our attention to i° , u° , and δ° . Recall that our interleaving of users in \mathbf{U} splits the rating tuples for some users. In such cases, if there are ratings left to scan, the running value δ written to v_j (before scanning the next user) may not yet contain the updated user profile. Accordingly, we use i° , u° , and δ° to save the state of the ‘split’ user while we process the next user, and restore it later as we scan the next rating tuple of the form $(i^\circ, j, r_{i^\circ,j}, v_j)$. In the full version of the paper we prove that a single state copy suffices during the expansion of $L_{\mathbf{U}}$ as we split at most one user at a time.

Extraction phase: The update leaves some of the values $u_i^{(t+1)}$ scattered within $\tilde{\mathbf{U}}$ (and similarly for $v_j^{(t+1)}$ within $\tilde{\mathbf{V}}$). Similar to the update phase we can extract all profiles by maintaining a state i° and u° for only one user. We extract U while scanning $\tilde{\mathbf{U}}$. In particular, after reading the last tuple of every chunk of size $(M+n)/n$ in $\tilde{\mathbf{U}}$ we always append an entry to U . This entry is either i° and u° or the content of the last tuple i and u . Meanwhile, after reading every tuple of $\tilde{\mathbf{U}}$ we write back either the same entry or the profile that was written to U last. This step ensures that user tuples contain the updated $u^{(t+1)}$. We also update i° and u° on every tuple: either performing a dummy update or changing the state to the next (split) user.

This step relies on a preliminary re-ordering and interleaving of users, such that the i th chunk of tuples always contains (a copy of) a user profile, and all n user profiles

can be collected (details of the expansion properties that are used here are described in the following section and in the full version of the paper).

Copying phase: We finally propagate the updated user profiles $U^{(t+1)}$ to the rating tuples in $\tilde{\mathbf{V}}$, which still carry (multiple copies of) the user profiles $U^{(t)}$. We update $\tilde{\mathbf{V}}$ sequentially in chunks of size n , that is, we first update the first n rows of \mathbf{V} , then rows $n+1$ to $2n$ and so on until all \mathbf{V} is updated, each time copying from the same n user profiles of $U^{(t+1)}$, as follows. (The exact chunk size is irrelevant, but n is asymptotically optimal.)

Recall that each rating tuple of $\tilde{\mathbf{V}}$ is of the form $(i, j, r_{i,j}, u_i^\ell, \ell)$ where $i \neq 0$ and ℓ indicates the interleaved position of the tuple in \mathbf{V} . To each chunk of $\tilde{\mathbf{V}}$, we append the profiles of $U^{(t+1)}$ extended with dummy values, of the form $(i, 0, -, u_i^{(t+1)}, -)$; we sort those $2n$ tuples by i then j , so that each tuple from $U^{(t+1)}$ immediately precedes tuples from (the chunk of) $\tilde{\mathbf{V}}$ whose user profile must be updated by $u_i^{(t+1)}$; we perform all updates by a linear rewriting; we sort again by ℓ ; and we keep the first n tuples. Finally, $\mathbf{V}^{(t+1)}$ is just the concatenation of those updated chunks.

Theorem 3. *Our matrix factorization algorithm runs in time $O((M+\tilde{n})(\log(M+\tilde{n}))^2 + T(M+\tilde{n})(\log \tilde{n})^2)$ where $\tilde{n} = \max(n,m)$. It is data-oblivious, as there exists a simulator that depends only on T, M, n, m , and d and produces the same trace.*

Proof Outline. The Setup phase is the most expensive, as it involves oblivious sorting on all the input ratings at once, with a $O((M+\tilde{n})(\log(M+\tilde{n}))^2)$ run time. The update phase runs in time $O(M+n+m)$ since it requires a single scan of \mathbf{U} and \mathbf{V} . The extraction phase similarly runs in time $O(M+n+m)$. The copying phase runs in time $O((M+m)(\log n)^2 + (M+n)(\log m)^2)$ due to $(M+m)/n$ sorts of U of size n and $(M+n)/m$ sorts of V of size m . Since all phases except Setup run T times, the total run time is

$$O((M+\tilde{n})\log^2(M+\tilde{n}) + T(M+\tilde{n})\log^2\tilde{n}).$$

A simulator can be built from the public parameters mentioned in the beginning of the algorithm. It executes every step of the algorithm: it creates the interleaving data structures that depend only on n, m, M and d and updates them using the steps of the Setup once and runs the Update, Extraction and Copy phases for T iterations. As part of Setup, it invokes the simulator of the sequence expansion algorithm described in the full version of the paper. \square

4.7 Equally-Interleaved Expansion

We finally present our method for arranging tuples of \mathbf{U} and \mathbf{V} in Matrix Factorization. We believe this method is

applicable to other data processing scenarios. For example, Arasu and Kaushik [4] use a similar, careful arrangement of tuples to obliviously answer database queries.

Definition 1. A weighted list L is a sequence of pairs (i, w_i) with n elements i and integer weights $w_i \geq 1$.

An expansion I of L is a sequence of elements of length $\sum^n w_i$ such that every element i occurs exactly w_i times.

Definition 2. Let $\alpha = \sum w_i / n$ be the average weight of L and the j th chunk of I be the sub-sequence of $\lceil \alpha \rceil$ elements $I_{\lfloor (j-1)\alpha + 1 \rfloor}, \dots, I_{\lceil j\alpha \rceil}$.

I equally interleaves L when all its elements can be collected by selecting one element from each chunk.

For example, for $L = (a, 4), (b, 1), (c, 1)$, every chunk has $\alpha = 2$ elements. The expansion $I = a, b, a, c, a, a$ equally interleaves L , as its elements a , b , and c can be chosen from its third, first, and second chunks, respectively. The expansion $I' = a, a, a, a, b, c$ does not.

We propose an efficient method for generating equal interleavings. Since it is used as an oblivious building block, we ensure that it accesses L , I and intermediate data structures in a manner that depends only on n and $M = \sum w_i$, not on the individual weights. (In matrix factorization, M is the total number of input ratings.) We adopt the terminology of Arasu and Kaushik [4], even if our definitions and algorithm are different. (In comparison, our expansions do not involve padding, as we do not require that copies of the same element are adjacent).

Given a weighted list L , we say that element i is heavy when $w_i \geq \alpha$, and light otherwise. The main idea is to put at most one light element in every chunk, filling the rest with heavy elements. We proceed in two steps: (1) we reorder L so that each heavy element is followed by light elements that compensate for it; (2) we sequentially produce chunks containing copies of one or two elements.

Step 1: Assume L is sorted by decreasing weights ($w_i \geq w_{i+1}$ for $i \in [1, n - 1]$), and b is its last heavy element ($w_b \geq \alpha > w_{b+1}$). Let δ_i be the sum of differences defined as $\sum_{j \in [1, i]} (w_j - \alpha)$ for heavy elements and $\sum_{j \in [b+1, i]} (\alpha - w_j)$ for light elements. Let S be L (obliviously) sorted by δ_j , breaking ties in favor of higher element indices. This does not yet guarantee that light elements appear after the heavy element they compensate for. To this end, we scan S starting from its last element (which is always the lightest), swapping any light element followed by a heavy element (so that, eventually, the first element is the heaviest).

Step 2: We produce I sequentially, using two loop variables: k , the latest heavy element read so far; and w , the remaining number of copies of k to place in I . We repeatedly read an element from the re-ordered list and produce a chunk of elements. For the first element k_1 , we produce α copies of k_1 , and we set $k = k_1$ and

$w = w_{k_1} - \alpha$. For each light element k_i , we produce w_{k_i} copies of k_i and $\alpha - w_{k_i}$ copies of k , and we decrement w by $\alpha - w_{k_i}$. For each heavy element k_i , we produce w copies of k and $\alpha - w$ copies of k_i , and we set $k = k_i$ and $w = w_{k_i} - (\alpha - w)$.

Continuing with our example sequence L above, a is heavy, b and c are light, and we have $\delta_a = 2$, $\delta_b = 1$, and $\delta_c = 2$. Sorting L by δ yields $(b, 1), (a, 4), (c, 1)$. Swapping heavy and light elements yields $(a, 4), (b, 1), (c, 1)$ and we produce the expansion $I = a, a, b, a, c, a$.

In the full version of the paper we prove that the algorithm is oblivious, always succeeds and runs in time $O(n(\log n)^2 + \sum w)$.

5 Protocols

For completeness, we give an overview of the protocols we use for running multi-party machine learning algorithms in a cloud equipped with SGX processors. Our protocols are standard, and similar to those used in prior work for outsourcing computations [29, 57]. For simplicity, we describe protocols involving a single enclave.

We assume that each party agrees on the machine-learning code, its public parameters, and the identities of all other parties (based, for example, on their public keys for signature). One of the parties sends this collection of code and static data to the cloud data center, where an (untrusted) code-loader allocates resources and creates an enclave with that code and data.

Each party independently establishes a secure channel with the enclave, authenticating themselves (e.g., using signatures) and using remote attestation [2] to check the integrity of the code and static data loaded into the enclave. They may independently interact with the cloud provider to confirm that this SGX processor is part of that data center. Each party securely uploads its private data to the enclave, using for instance AES-GCM for confidentiality and integrity protection. Each party uses a separate, locally-generated secret key to encrypt its own input data set, and uses its secure channel to share that key with the enclave. The agreed-upon machine learning code may also be optionally encrypted but we expect that in the common case this code will be public.

After communicating with all parties, and getting the keys for all the data sets, the enclave code runs the target algorithm on the whole data set, and outputs a machine learning model encrypted and integrity protected with a fresh symmetric key. We note that denial-of-service attacks are outside the threat model for this paper—the parties or the data centre may cause the computation to fail before completion. Conversely, any attempt to tamper with the enclave memory (including its code and data) would be caught as it is read by the SGX processor, and hence the job completion guarantees the integrity of the whole run. Finally, the system needs to guarantee that all

parties get access to the output. To achieve this, the enclave sends the encrypted output to every party over their secure authenticated channel, and waits for each of them to acknowledge its receipt and integrity. It then publishes the output key, sending it to all parties, as well as to any reliable third-party (to ensure its fair availability).

6 Evaluation

This section describes our experiments to evaluate the overhead of running our machine learning algorithms with privacy guarantees. We ran oblivious and non-oblivious versions of the algorithms that decrypt and process the data inside SGX enclaves, using off-the-shelf Intel Skylake processors. Our results show that, in all cases, the overhead of encryption and SGX protection was low. The oblivious version of algorithms with irregular data structures, such as matrix factorization and decision trees, adds substantial overhead, but we find that it is still several orders of magnitude better than previous work based on advanced cryptography.

6.1 Datasets

We use standard machine learning datasets from the *UCI Machine Learning Repository*.⁴ We evaluate matrix factorization on the MovieLens dataset [28]. Table 1 summarizes our datasets and configuration parameters.

The *Nursery* dataset describes the outcomes of the Slovenian nursery admission process for 12,960 applications in the 1980s. Given eight socio-economic attributes about the child and parents, the task is to classify the record into one out of five possible classes. We use the 0/1 encoding of the attributes as we evaluate the records on binary decision trees. Hence, each record in the dataset is represented using 27 features.

The *MNIST* dataset is a set of 70,000 digitized grayscale images of 28-by-28 pixels recording handwritten digits written by 500 different writers. The task is to classify each image into one of ten possible classes.

The *SUSY* dataset comprises 5,000,000 instances produced by Monte Carlo simulations of particle physics processes. The task is to classify, based on 18 observed features, whether the particles originate from a process producing supersymmetric (*SUSY*) particles or not.

The *MovieLens* datasets contain movie ratings (1–5); 100K ratings given by 943 users to 1682 movies.

The datasets were chosen either because they were used in prior work on secure ML (e.g., *Nursery* in [13], *MovieLens* in [47, 48]) or because they are one of the largest in the UCI repository (e.g., *SUSY*), or because they represent common benchmarks for particular algorithms (e.g., *MNIST* for neural networks).

Our learning algorithms are iterative—the accuracy (and execution time) of the model depends on the number

of iterations. In our experiments, we fixed the number of iterations a priori to a value that typically results in convergence: 10 for k-means, 5 for neural network, 10 for SVM, and 20 for matrix factorization.

6.2 Setup

The experiments were conducted on a single machine with quad-core Intel Skylake processor, 8GB RAM, and 256GB solid state drive running Windows 10 enterprise. This processor limits the amount of platform memory that can be reserved for enclaves to 94MB (out of a total of 128MB of protected memory). Each benchmark is compiled using the Microsoft C/C++ compiler version 17.00 with the O2 flag (optimize for speed) and linked against the Intel SGX SDK for Windows version 1.1.30214.81. We encrypted and integrity protected the input datasets with AES-GCM; we used a hardware-accelerated implementation of AES-GCM based on the Intel AES-NI instructions. We ran non-oblivious and oblivious versions of our algorithms that decrypt and process the binary data inside SGX enclaves. We compare the run times with a baseline that processes the data in plaintext and does not use SGX protection. Table 1 summarizes the relative run time for all the algorithms (we report averages over five runs). Next we analyze the results for each algorithm.

6.3 K-Means

We have implemented a streaming version of the k-means clustering algorithm to overcome space constraints of enclaves. Our implementation partitions the inputs into batches of a specified size, copies each batch into enclave memory, decrypts it and processes each point within the batch.

Table 1 shows the overheads for partitions of size 1MB. The non-oblivious and oblivious versions have overheads of 91% and 199% over baseline (6.8 seconds). The overhead for the non-oblivious version is due to the cost of copying encrypted data into the enclave and decrypting it.

We observe similar overheads for longer executions. The overheads decrease with the number of clusters (34% with 30 clusters and 11% with 50 clusters for non-oblivious version) and (154% for 30 clusters and 138% for 50 clusters for oblivious version) as the cost of input decryption is amortized over cluster computation. By comparison, recent work [38] based on cryptographic primitives reports 5 to 6 orders of magnitude slowdown for k-means.

6.4 Neural Networks

We have implemented a streaming version of the algorithm for training a convolution neural network (CNN) on top of an existing library [20]. Table 1 shows the overheads of training the network for the MNIST dataset.

⁴<https://archive.ics.uci.edu/ml/>

Algorithm	SGX+enc.	SGX+enc.+obl.	Dataset	Parameters	Input size	# Instances
K-Means	1.91	2.99	MNIST	$k=10, d=784$	128MB	70K
CNN	1.01	1.03	SUSY	$k=2, d=18$	307MB	2.25M
SVM	1.07	1.08	MovieLens	$n=943, m=1,682$	2MB	100K
Matrix fact.	1.07	115.00	Nursery	$k=5, d=27$	358KB	6.4K
Decision trees	1.22	31.10				

Table 1: Relative run times for all algorithms with SGX protection + encryption, and SGX protection + encryption + data obliviousness, compared with a baseline that processes the data in plaintext without SGX protection. Parameters of the datasets used for each algorithm are provided on the right, where d is the number of features, k is the number of classes, n is the number of users and m is the number of movies in the MovieLens dataset.

The low overheads ($< 0.3\%$) reflect the observation that the training algorithm is predominantly data oblivious, hence running obliviously does not increase execution time while achieving the same accuracy. We are aware that state-of-the-art implementations use data-dependent optimizations such as max pooling and adding noise; finding oblivious algorithms that support these optimizations with good performance remains an open problem.

6.5 SVM

As described in Section 4.2, the correctness of supervised learning methods requires that the input data instances be independent and identically distributed. Our oblivious SVM implementation achieves this by accessing a batch of l data instances uniformly at random during each iteration. We implement random access by copying the partition containing the instance into enclave memory, decrypting the partition and then accessing the data instance. In the experiments we set data partitions to be of size 2KB and $l = 20$. In addition, we use conditional move instructions to make data accesses within the training algorithm oblivious. These modifications allow us to process datasets much larger than enclave memory. Our evaluation (Table 1) shows that random access adds a 7% overhead to the non-oblivious SVM algorithm, whereas the additional overhead of the oblivious algorithm is marginal.

6.6 Decision Tree Evaluation

For the Nursery dataset, we use an offline-trained ensemble of 32 sparse decision trees (182KB) with 295–367 nodes/leaves each and depths ranging from 14 to 16 layers. For this dataset, as shown in Table 1, our oblivious classifier running inside an enclave has an average overhead of 31.1x over the baseline (255ms vs. 10ms). The oblivious implementation of the algorithm employs the `oget()` primitive (see Section 3) for all data-dependent array lookups. Without this optimization, using `omoveEx()` for the element-granular scanning of arrays instead, the overhead is much higher (142.27x on average). We observe that our oblivious implementation scales well to even very large trees. For example, for an

ensemble of 32 decision trees (16,860KB) with 30,497–32,663 nodes/leaves and 35–45 layers each,⁵ the average overhead is 63.16x over the baseline.

In comparison, prior work based on homomorphic encryption [13] uses much smaller decision trees (four nodes on four layers for the Nursery dataset), has higher overheads and communication costs, and scales poorly with increasing depth. Our experiments show that smaller depth trees have much lower accuracy (82% for depth 4 and 84% for depth 5). In contrast, our classifier for the Nursery dataset achieves an accuracy of 98.7%.

6.7 Matrix Factorization

We measure the performance of our gradient descent on the MovieLens dataset. We implemented both the baseline algorithm and the oblivious algorithm of Section 4.6. As for k-means, we stream the input data (once) into the enclave to initialize the data structures, then we operate on them in-place. We also implemented the oblivious method of Nikolaenko *et al.* [48] to compare its overhead with ours (see Section 7 for the asymptotic comparison). We did not use garbled circuits, and merely implemented their algorithm natively on Skylake CPUs.

In each experiment, we set the dimension of user and vector profiles to $d = 10$, following previous implementations in [47, 48]. We experimented with fixed numbers of iterations $T = 1, 10, 20$. With higher number of iterations the prediction rate of the model improves. For example, when using 90K instances for training, the mean squared error of prediction on 10K test dataset drops from 12.94 after 1 iteration, to 4.04 after 20 iterations, to 1.06 after 100 iterations (with $\lambda = \mu = \gamma = 0.0001$).

Table 1 reports the overheads for the MovieLens-100K dataset. The oblivious version takes 49s, versus 0.43s for the baseline, reflecting the cost of multiple oblivious sorting for each of the $T = 20$ iterations. With smaller number of iterations, the running times are 8.2s versus 0.03s for $T = 1$, and 27s versus 0.21s for $T = 10$. (As a sanity check, a naive oblivious algorithm that accesses

⁵The numbers correspond to a random forest trained on the standard *Covertype* dataset from the UCI repository.

T	This work	Previous work
1	8	14 (1.7x)
10	27	67 (2.4x)
20	49	123 (2.5x)

Table 2: Comparison of running times (in seconds) of oblivious matrix factorization methods on the MovieLens dataset: our work is the method in Section 4.6 and previous work is our implementation of an algorithm in [48] *without* garbled circuits. T is the number of algorithm iterations.

all entries in U and V to hide its random accesses runs in 1850s for $T = 10$.)

Table 2 compares the overheads of our oblivious algorithm and the one of [48]. As expected, our method outperforms theirs as the number of iterations grows, inasmuch as it sorts smaller data structures.

Comparison with cryptographic evaluations: We are aware of two prior evaluations of oblivious matrix factorization [47, 48]. Both solutions are based on garbled circuits, and exploit their parallelism. Both only perform one iteration ($T = 1$). Nikolaenko *et al.* (in 2013) report a run time of 2.9 hours for 15K ratings (extracted from 100K MovieLens dataset) using two machines with 16 cores each. Nayak *et al.* (in 2015) report a run time of 2048s for 32K ratings, using 32 processors.

6.8 Security Evaluation

We experimentally confirmed the data-obliviousness of all enclave code for each of our algorithms, as follows. We ran each algorithm in a simulated SGX environment⁶ and used Intel’s Pin framework [42] to collect runtime traces that record all memory accesses of enclave code, not only including our core algorithms, but also all standard libraries and SGX framework code. For each algorithm, we collected traces for a range of different inputs of the same size and compared code and data accesses at cache-line granularity, simulating the powerful attacker from Section 2. While we initially discovered deviations in the traces due to implementation errors in our oblivious primitives and algorithmic modifications, we can report that the final versions of all implementations produce uniform traces that depend only on the input size.

7 Related Work

Secure multi-party machine learning General cryptographic approaches to secure multi-party computation

⁶For debugging purposes, the Intel SGX SDK allows for the creation of simulated SGX enclaves. Those simulated enclaves have largely the same memory layout as regular SGX enclaves, but are not isolated from the rest of the system. In simulation mode, SGX instructions are emulated in software inside and outside the enclave with a high level of abstraction.

are based on garbled circuits, secret sharing and encryption with homomorphic properties. Lindell and Pinkas [36] survey these techniques with respect to data mining tasks including machine learning. It is worth noting that beside mathematical assumptions, some of the above approaches also rely on (a subset of) computing parties being honest when running the protocol as well as non-colluding.

Garbled circuits [71] provide a mechanism for multiple parties to compute any function on their joint inputs without having to reveal the inputs to each other. Solutions based on garbled circuits have been tailored for several specific machine learning tasks including matrix factorization [48], and training of a decision tree [6, 35]. GraphSC [47] and ObliVM [38] are two recent programming frameworks for secure computation using garbled circuits. The former framework offers a paradigm for parallel computation (e.g., MapReduce) and the latter uses a combination of ORAM and garbled circuits.

Training of an SVM kernel [34] and construction of a decision tree [18] have been proposed based on secret-sharing and oblivious transfer.

Homomorphic encryption lets multiple parties encrypt their data and request the server to compute a joint function by performing computations directly on the ciphertexts. Bost *et al.* [13] study classification over encrypted data in the model where the server performs classification by operating on semi-homomorphic encrypted data; whenever the server needs to perform operations not supported by the encryption, it engages in a protocol with a party that can decrypt the data and perform the necessary computation. Solutions based on fully-homomorphic encryption have been proposed for training several ML algorithms [27, 69] and for classifying decision trees [68].

Shokri and Shmatikov [59] describe a method for multiple parties to compute a deep neural network on joint inputs. This method does not rely on cryptographic primitives. It assumes that the parties train their own model and do not share the data with each other, but exchange intermediate parameters during training. Our model is different as parties in our solution do not perform any computation and do not learn anything about the training process; after the training they can either obtain the model, if they agreed to, or use it for querying in a black-box manner.

Privacy implications of revealing the output of a machine learning algorithm, i.e., the model, is orthogonal to the focus of this paper; we refer the reader to Fredriksson *et al.* [21, 22] on this topic. As a remedy, differential privacy guarantees for the output of several machine learning algorithms have been studied by Blum *et al.* [11].

Data-oblivious techniques Oblivious RAM (ORAM) [25] is a general protection technique against

side-channels on memory accesses. Though recent advances in this space [62] have significantly decreased the ORAM overhead, there are cases where the default solution does not always meet system requirements. First, many ORAM solutions offer a tradeoff between the size of the private memory and the overhead they incur. In current CPUs, registers act as an equivalent of processor’s private memory, however their number is limited, e.g., even for the latest x86 generations, less than 2KB can be stored in all general purpose and SIMD registers combined. Second, ORAM does not hide the number of accesses. That is, if this number depends on a sensitive input (e.g., number of movies rated by each user) then fake accesses need to be generated to hide the real number of accesses. Finally, ORAM is ideal for programs that make few accesses in a large dataset. For algorithms that process data multiple times, customized solutions often perform better (e.g., MapReduce [47, 49]). Machine learning algorithms fall in the latter category as they need all input instances to train and use the model.

Raccoon [53] and GhostRider [37] propose general compiler techniques for protecting memory accesses of a program. Some of the techniques they deploy are ORAM and execution of both branches of if-else statements. However, general techniques are less effective in cases where an algorithm accesses data in a structured way that can be exploited for greater efficiency. For example, compiling matrix factorization using these techniques is not trivial as the interleaving of the accesses between internal data structures has to be also protected. (The interleaving depends on sensitive information such as rating counts per user and per movie which have to be taken into account.)

Asymptotical comparison of individual algorithms
 We now compare the asymptotic performance of our data-oblivious algorithms to prior work. We evaluate the overhead of obtaining oblivious properties only. That is, we do not consider the cost of their secure implementation on SGX (our approach) or using garbled circuits in [38, 47, 48] (though the latter is known to add large run time overheads).

ObliVM [38] uses a streaming version of MapReduce to perform oblivious *k-means* which is then compiled to garbled circuits. The algorithm relies on oblivious sorting to update the centroids at each iteration, resulting in the running time of $O(T(nkd + dn(\log n)^2))$ (ignoring conversion to garbled circuits). Since our algorithm takes $O(Tnkd)$ time, the asymptotical comparison between the two depends on the relation between values k and $O((\log n)^2)$. Moreover, oblivious sorting incurs high constants and our experiments confirmed that our simple method was more efficient.

The algorithmic changes required to make *SVM* and *Neural Networks* oblivious can be captured with automated tools for compiling code into its oblivious counterpart. Instead of an oblivious shuffle or sort between the iterations, these methods would place input instances into an ORAM and then sample them by accessing the ORAM. Since all n instances are accessed at each iteration, the asymptotical cost of the two solutions remains the same. However, such tools either use a backend that would require careful adaption for the constrained SGX environment (for example, GhostRider [37] defines its own source language and ObliVM [38] translates code into circuits) or they are not as optimized as our approach (for example, Raccoon [53] always executes both code paths of a secret-dependent conditional statement and its described array scanning technique is less fine-tuned for the x86 architecture than ours).

Our simple data-oblivious *decision tree* algorithm is adequate for ad hoc tree evaluations, and scales up to reasonably large forests. With larger irregular data structures, algorithms based instead on oblivious data structures [38, 66] may be more effective as they store data in elaborate randomized data structures that avoid streaming over all the tree leaves. Though their asymptotical performance dominates our approach — $O((\log n)^2)$ vs. $O(n)$, assuming height of the tree of $O(\log n)$ — as pointed out in [53] ORAM-based solutions improve over the plain scanning of arrays only for larger n due to the involved constants. Moreover, private memory of size $O(\log n)$ is assumed in [66] while as mentioned earlier, private memory for SGX is limited to registers. Oblivious tree can be implemented also via ORAM with constant private memory size [33], incurring $O((\log n)^3 / \log \log n)$ overhead.

Finally, oblivious *matrix factorization* for garbled circuits, rather than SGX processors, was considered in [48] and [47]. Nikolaenko *et al.* [48] also rely on a data structure that combines both user and movie profiles: They maintain a global matrix of size $M + n + m$ with M rows for the ratings, n rows for the users, and m rows for the movies. Their updates are performed in several sequential passes, and synchronized using a sorting network on the whole data structure. Hence, their algorithm runs in time $O(T(M + n + m)(\log(M + n + m))^2)$, dominated by the cost of sorting the rows of the matrix at every iteration. GraphSC [47] implements matrix factorization using an oblivious parallel graph processing paradigm. However, this method also relies on oblivious sorting of $M + n + m$ profiles, hence, asymptotically it incurs the same cost. In comparison, our approach sorts on that scale only during Setup and, besides, those costly operations only sort user ids and ratings—not the larger profiles in \mathbb{R}^d . Then, asymptotically, our iterations are more efficient due to a smaller logarithmic factor as we

sort fewer tuples at a time: $O(T(M + \tilde{n})(\log \tilde{n})^2)$ where $\tilde{n} = \max(n, m)$. As we showed in the evaluation section our method also outperforms [48] in practice.

Similar to prior oblivious matrix factorization techniques [47, 48], our method is easily parallelizable. First, an oblivious sort that runs in time $O(n(\log n)^2)$ sequentially can run in time $O((\log n)^2)$ with n parallel processes. Besides, each row in our data structures \mathbf{U} and \mathbf{V} can be processed independently, and aggregated in time $\log(M + \tilde{n})$, as in the method described in [47]. Even with parallel processing, our method is more efficient, because the depth of the computation stays logarithmic in \tilde{n} for our method and M in theirs [47, 48].

Secure hardware TrustedDB [5], Cipherbase [3], and Monomi [64] use different forms of trusted hardware to process database queries with privacy. Haven [8] runs unmodified Windows applications in SGX enclaves, and VC3 [57] proposes a cloud data analytics framework based on SGX. None of these systems provides protection from side-channel attacks. These systems were evaluated using SGX emulators. In contrast, we are the first to evaluate implementations of machine learning algorithms on real SGX processors.

8 Conclusions

We presented a new practical system for privacy-preserving multi-party machine learning. We propose data-oblivious algorithms for support vector machines, matrix factorization, decision trees, neural networks, and k-means. Our algorithms provide strong privacy guarantees: they prevent exploitation of side channels induced by memory, disk, and network accesses. Experiments with an efficient implementation based on Intel SGX Skylake processors show that our system provides good performance on realistic datasets.

A Illustration of Oblivious Matrix Factorization from Section 4.6

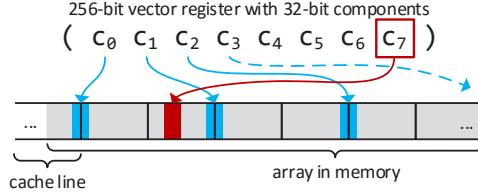

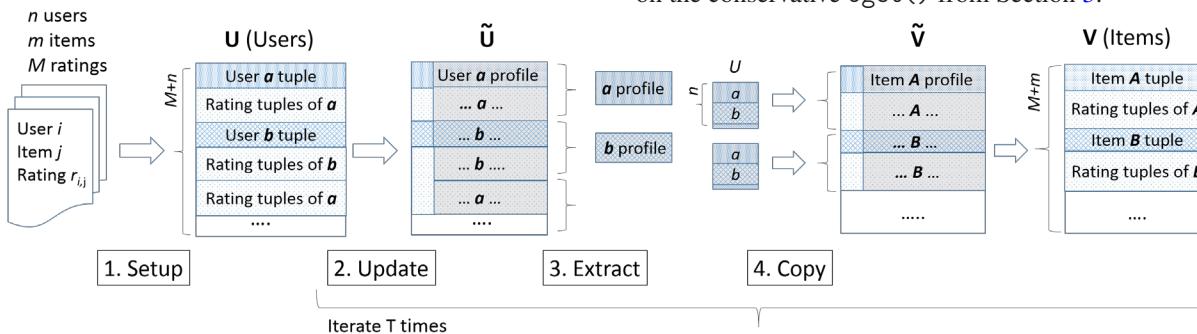

Figure 4: Optimized array scanning using the 256-bit vector instruction vpgatherdd

B Optimized Array Scanning

The `oget()` primitive can be further optimized using `vpgatherdd` as follows. We make sure that a certain number of components of the vector register load values that span *two* cache lines. (This can be done by loading two bytes from one cache line and two bytes from the next one, recall that each component loads 4 bytes.) Hence, up to 16 cache lines can potentially be touched with a single instruction.

We assign components to cache lines in a careful manner. The first few components request addresses within dummy cache lines or cache lines that contain the values of interest (whose addresses should be kept secret). The values of interest are loaded into the remaining components. The concept is depicted in Figure 4 where components C_0 and C_2 - C_6 request dummy cache lines, C_1 requests the cache lines that contain the desired value which is loaded into C_7 . In this configuration, four bytes are read obliviously from a memory region of size $7 \cdot 2 \cdot 64$ bytes = 896 bytes with a single `vpgatherdd` instruction. The method easily generalizes when more bytes (e.g., 8 bytes using C_6 and C_7) are to be read.

This technique can significantly increase throughput (up to 2x in some micro-benchmarks outside enclaves on recent Intel Skylake processors). However, it requires that `vpgatherdd` appears as a truly atomic operation or, at least, that the hardware loads dummy components before secret ones (and those are then loaded from the cache). Though this may be true in a software-only attacker model, it is not the case in the powerful threat model in Section 2. Hence, our implementation relies on the conservative `oget()` from Section 3.

Thoth: Comprehensive Policy Compliance in Data Retrieval Systems

Max Planck Institute for Software Systems (MPI-SWS)

Abstract

Data retrieval systems process data from many sources, each subject to its own data use policy. Ensuring compliance with these policies despite bugs, misconfiguration, or operator error in a large, complex, and fast evolving system is a major challenge. Thoth provides an efficient, kernel-level compliance layer for data use policies. Declarative policies are attached to the systems' input and output files, key-value tuples, and network connections, and specify the data's integrity and confidentiality requirements. Thoth tracks the flow of data through the system, and enforces policy regardless of bugs, misconfigurations, compromises in application code, or actions by unprivileged operators. Thoth requires minimal changes to an existing system and has modest overhead, as we show using a prototype Thoth-enabled data retrieval system based on the popular Apache Lucene.

1 Introduction

Online data retrieval systems typically serve a searchable corpus of documents, web pages, blogs, personal emails, online social network (OSN) profiles and posts, along with real-time microblogs, stock and news tickers. Examples include large providers like Amazon, Facebook, eBay, Google, and Microsoft, and also numerous smaller, domain-specific sharing, trading and networking sites run by organizations, enterprises, and governments.

Each data item served or used by a retrieval system may have its own usage policy. For instance, email is private to its sender/receiver(s), OSN data and blogs limited to friends, and corporate documents limited to employees. External data stream providers may restrict the use of (meta)data, and require expiration. The provider's privacy policy may require that a user's query and click stream be used only for personalization. Lastly, providers must comply with local laws, which may require them, for instance, to filter certain data items within a given jurisdiction.

Ensuring compliance with applicable policies is labor-intensive and error-prone [36]. The policy actually in effect for a data item may depend on checks and settings in

many components and several layers of a system, making it difficult to audit and reason about. Moreover, any bug, misconfiguration, or compromise in a large and evolving application codebase could violate a policy. The problem affects both large providers with complex, fast evolving systems and smaller providers with limited IT budgets. Indeed, reports of data losses abound [14, 1, 44, 11, 13]. The stakes are high: providers stand to lose customer confidence, business and reputation, and may face fines. Hence, developing technical mechanisms to enforce policies in data retrieval systems is important. In fact, the Grok system combines lightweight static analysis with heuristics to annotate source code to check for policy violations in Bing's back-end [36].

Existing policy compliance systems for data retrieval, including Grok, usually target *column-specific policies*—policies that apply uniformly to all data of a specific type, e.g., the policy “no IP address can be used for advertising.” However, no existing work covers the equally important *individual policies* that are specific to individual data items or to a given client's data items. For example, Alice's blog posts, but not Bob's, may be subject to the policy “visible only to Alice's friends”. Similarly, the expiration time of every item in a news ticker may be different. In fact, all policies mentioned a couple of paragraphs ago are individual policies. It is this (significant and important) missing part of policy enforcement that we wish to address in this paper. Specifically, we present Thoth, a policy compliance layer integrated into the Linux kernel to enforce both individual and column-specific policies efficiently.

We briefly describe the key insights in Thoth's design. First, by design, Thoth separates policies from application code. A policy specifying confidentiality and integrity requirements may be associated with any data conduit, i.e, a file, key-value tuple, named pipe or network connection, and is enforced on all application code that accesses the conduit's data or data derived from that data. Thoth provides a declarative language for specifying policies. The language itself is novel; in addition to standard access (read/write) policies, it also allows specifying data declassification policies by stipulating how

access policies may change along a data flow.

Second, unlike column-specific policies, individual policies may not be very amenable to static analysis because a given program variable may contain data with very different individual policies over time at the same program point and, hence, the abstraction of static analysis may lose precision quickly. So, Thoth uses dynamic analysis. It intercepts I/O in the kernel, tracks the flow of data at the granularity of conduits and processes (similar to Flume [28]), and enforces policies at process boundaries. This incurs a runtime overhead but we show that the overhead is not too high. With an optimized prototype implementation, we measure an overhead of 0.7% on indexing and 3.6% on query throughput in the widely used search engine Apache Lucene. While this overhead may be too high for large-scale data retrieval systems, we believe that it can be optimized further and that it is already suitable for domain-specific, medium-scale data retrieval systems run by organizations, enterprises and governments. Moreover, application code requires very few changes to run with Thoth (50 lines in a codebase of 300,000 LoC in our experiments).

Third, the complexity of a data retrieval system often necessitates some declassification to maintain functionality. For instance, a search process that consults an index computed over a corpus containing the private data of more than one individual cannot produce any readable results without declassification. To handle this and similar situations, we introduce a new form of declassification called *typed declassification*, which allows the declassification of data in specific forms (types). To accommodate the aforementioned search process, all source data policies allow declassification into a list of search results (document names). Hence, the search process can function as usual. At the same time, the possibility of data leaks is limited to a very narrow channel: To leak information from a private file, the search process' code must maliciously encode the information in a list of valid document names. Given that the provider has a genuine interest in preventing data breaches and that the search process is an internal component that is unlikely to be compromised in a casual external attack, the chance of having such malicious code in the search process is low. Thus, typed declassification is a pragmatic design point in the security-functionality trade-off for our threat model. Note that typed declassification needs content-dependent policies, which our policy language supports.

To summarize, the contributions of this work are: (1) A policy language that can express individual access and declassification policies declaratively (Section 2); (2) the design of a kernel-level monitor to enforce policies by I/O interception and lightweight taint propagation (Section 3); (3) application of the design to medium-scale data retrieval systems, specifically

Apache's Lucene (Sections 2; 5); and (4) an optimized prototype implementation and experimental evaluation to measure overheads (Sections 4, 6).

2 Thoth policies

Thoth is a kernel-level policy compliance layer that helps data retrieval system providers enforce confidentiality and integrity policies on the data they collect and serve. In Thoth, the *provider* attaches policies to data sources (documents and live streams, posts and profiles, user click history, etc.) based on the privacy preferences of clients, external (e.g., legal) and internal usage requirements. Thoth *tracks data flows* by intercepting all IPC and I/O in the kernel, and it propagates source policies along these flows. It enforces policy conditions when data leaves the system, or when a declassification happens. The policy attached to a data source is a *complete, one point description* of all privacy and integrity rules in effect for that source.

Thoth policies are specified in a new, expressive declarative language, separate from application code. In this section, we describe this policy language briefly, discuss example policies that clients, data sources, and the provider might wish to enforce in a data retrieval system, and give a glimpse of how to express these policies in Thoth's policy language. More policy examples are included in Appendix A. Section 3 explains how Thoth enforces these policies. We note that our policy language and enforcement are general and apply beyond data retrieval systems.

Policy language overview A Thoth policy can be attached to any *conduit*—a file, key-value tuple, named pipe or network socket that stores data or carries data in transit. The policy on a conduit protects the confidentiality and integrity of the data in the conduit and is specified in two layers. The first layer, an *access control policy*, specifies which principals may **read** and **update** the conduit and under what conditions (e.g., only before or only after a certain date). A second layer protects data *derived* from the conduit by restricting the policies of conduits downstream in the data pipeline. This layer can **declassify** data by allowing the access policies downstream to be relaxed progressively, as more and more declassification conditions are met. The second layer that specifies declassification by controlling downstream policies is the language's key novelty.¹ Another noteworthy feature is that we allow policy evaluation to depend on a conduit's state—both its data and its metadata. This allows expressing content-dependent policies and, in particular, a kind of declassification that we call *typed declassification*.

¹Our full language also supports provenance policies in the second layer by allowing control over upstream policies. Due to lack of space, we omit provenance policies here.

Arithmetic/string	Conduit	Content
add(x,y,z) $x=y+z$	cNamels(x)	x is the conduit pathname
sub(x,y,z) $x=y-z$	clIdls(x)	x is the conduit id
mul(x,y,z) $x=y*z$	clExists(x)	x is a valid conduit id
div(x,y,z) $x=y/z$	cCurrLenls(x)	x is the conduit length
rem(x,y,z) $x=y\%z$	cNewLenls(x)	x is the new conduit length
concat(x,y) $x \parallel y$	hasPol(c, p)	p is conduit c's policy
vType(x,y) is x of type y?	clsIntrinsic	does this conduit connect two confined processes?
Relational	Session	Declassification rules
eq(x,y) $x=y$	sKeyls(x)	x is the session's authentication key
neq(x,y) $x \neq y$	slpls(x)	x is the session's source IP address
lt(x,y) $x < y$		
gt(x,y) $x > y$	lpPrefix(x,y)	x is IP prefix of y
le(x,y) $x \leq y$	timels(t)	t is the current time
ge(x,y) $x \geq y$		

Table 1: Thoth policy language predicates and connectives

Layer 1: Access policies The first layer of a conduit’s policy contains two rules that specify who can read and update the conduit’s state under what conditions. We write both rules in the syntax of Datalog, which has been used widely in the past for the declarative specification of access policies [18, 20, 30]. Briefly, the read rule has the form (**read** :- cond) and means that the conduit can be read if the condition “cond” is satisfied. The condition “cond” consists of *predicates* connected with conjunction (“and”, written \wedge) and disjunction (“or”, written \vee). All supported predicates are listed in Table 1. Similarly, the update rule has the form (**update** :- cond).

Example (Client policies) Consider a search engine that indexes clients’ private data. A relevant security goal might be that a client Alice’s private emails and profile should be visible only to Alice, and only she should be able to modify this data. This *private data* policy can be expressed by attaching to each conduit holding Alice’s private items **read** and **update** rules that allow these operations only in the context of a session authenticated with Alice’s key. The latter condition can be expressed using a single predicate **sKeyls**(k_{Alice}), which means that the active session is authenticated with Alice’s public key, denoted k_{Alice} . Hence, the read rule would be **read** :- **sKeyls**(k_{Alice}). The update rule would be **update** :- **sKeyls**(k_{Alice}). (Clients, or processes running on behalf of clients, authenticate directly to Thoth, so Thoth does not rely on untrusted applications for session authentication information.)

Alice’s *friends only* blog and OSN profile should be readable by her friends as well, which can be expressed with an additional disjunctive clause in the read rule:

```
read :- sKeyls( $k_{Alice}$ )  $\vee$ 
      (sKeyls(K)  $\wedge$  (“Alice.acl”, Offset) says isFriend(K))
```

The part after the \vee is read as “the key K that authenti-

cated the current session exists in Alice.acl at some offset $Offset$.” Here, Alice.acl is a trusted key-value tuple that contains Alice’s friend list.

Following standard Datalog convention, terms like K and $Offset$ that start with uppercase letters are existentially quantified variables. The predicate **sKeyls**(K) binds K to the key that authenticates the session. During each policy evaluation, application code is expected to provide a binding for the variable $Offset$ that refers to a location in the tuple’s value saying that K belongs to a friend of Alice. Note that policy compliance does not depend on application correctness: if the application does not provide a correct offset, access will be denied.

Extending further, visibility to Alice’s *friends of friends* can be allowed by modifying the read rule to check that Alice and the owner of the current session’s key have a common friend. Then, the application code would be expected to provide an offset in Alice’s acl where the common friend exists and an offset in the common friend’s acl where the current session’s key exists.

Layer 2: Declassification policies The second layer of a conduit’s policy contains a single rule that controls the policies of downstream conduits. This rule is written (**declassify** :- cond), where “cond” is a condition or predicate on all *downstream sequences of conduits*. For instance, “cond” may say that in any downstream sequence of conduits, the access policies must allow read access only to Alice, until the calendar year is at least 2017, after which the policies may allow read access to anyone. This represents the declassification policy “private to Alice until the end of 2016”.

We represent such declassification policies using the notation of *linear temporal logic* (LTL), a well-known syntax to represent predicates that change over time [32]. We allow one new connective in “cond” in the **declassify** rule: c_1 until c_2 , which means that condition c_1 must

hold of all downstream conduits until condition c2 holds. Also, we allow a new predicate `isAsRestrictive(p1, p2)`, which checks that policy `p1` is at least as restrictive as `p2`. The two together can represent expressive declassification policies, as we illustrate next.

Example (Index policy) In the last example, we discussed confidentiality policies that reflect data owners' privacy choices. For the retrieval system to do its job, however, the input data policies must allow some declassification. Without it, the search engine, which consults an index computed over the entire corpus, including the private data of several individuals, would not be allowed to produce any readable output. We rely on the policy language's novel ability to refer to a conduit's (meta-)data to allow the selective, *typed declassification* of search results. The policy can be implemented by adding the following `declassify` rule to all searchable input data:

```
declassify :- isAsRestrictive(read, this.read) until
ONLY_CND_IDS
```

This policy stipulates that data derived from Alice's data can be written into conduits whose read rule is at least as restrictive as Alice's (which is bound to `this.read`), until it is written into a conduit which satisfies the condition `ONLY_CND_IDS`. This macro stipulates that only a list of valid conduit ids has been written. The macro expands to

```
cCurrLenIs(CurrLen) ∧ cNewLenIs(NewLen) ∧
each in(this, CurrLen, NewLen) says(CndId)
{cldExists(CndId)}
```

and permits the declassification of a list of proper conduit ids. A conduit id is a unique identifier for a conduit (conduit ids are defined in Section 3). The predicate “`each in () says () {}`” iterates over the sequence of tuples in the newly written data and checks that each is a valid conduit id. By including this declassification rule in her data item's policy, Alice allows the search engine to index her item and include it in search results. To view the contents, of course, a querier still has to satisfy each conduit's confidentiality policy.²

So far, we have assumed that the conduit ids (i.e., the names of indexed files) are not themselves confidential. If the conduit ids are themselves confidential, then the

²Our declassification policies can be intuitively viewed as state machines whose states are access policies and whose transitions are events in the data flow. For instance, the declassification policy just described is a two state machine, whose initial state has a read policy as restrictive as Alice's, and whose second state allows read access to everyone. The transition from the first to the second state is allowed when data passes through a conduit that satisfies `ONLY_CND_IDS`. This state-machine view of our policies is universal because it is well known that all LTL formulas can be represented as Büchi automata.

above `declassify` rule is insufficient since it stipulates no restriction on policies after `ONLY_CND_IDS` holds. Thus, a more restrictive `declassify` rule is needed. Ideally, we want that the read and declassify rules of the conduit that contains the list of conduit ids be at least as restrictive as the read and declassify rules of all conduits in the list. This can be accomplished by the following replacement for `ONLY_CND_IDS`.

```
cCurrLenIs(CurrLen) ∧ cNewLenIs(NewLen) ∧
each in(this, CurrLen, NewLen) willsay(CndId) ∧
{cldExists(CndId) ∧ hasPol(CndId, P) ∧
isAsRestrictive(read, P.read) ∧
isAsRestrictive(declassify, P.declassify)}
```

The predicate `hasPol(CndId, P)` binds `P` to the policy of the conduit `CndId`, and the predicates `isAsRestrictive(read, P.read)` and `isAsRestrictive(declassify, P.declassify)` enforce that the read and declassify rules of the search results are at least as restrictive as those of `CndId`. We call this modified macro `ONLY_CND_IDS+`.

Other data retrieval policies

We briefly describe several other policies relevant to data retrieval systems that we have represented in our policy language and implemented in our prototype. For the formal encodings of these policies, see Appendix A.

Data analytics Many retrieval systems transform logs of user activity into a user preferences vector, which is used for targeting ads, computing user profiles, and providing recommendations. Raw logs of user clicks and queries are typically private, so a profile vector derived from them cannot be used for any of these purposes without a declassification. A policy that allows typed declassification into a vector of a fixed size can be attached to raw user logs to ensure that the raw logs cannot be leaked from the system, but that the profile vector can be used for the above-mentioned purposes.

Provider policies The provider may need to censor certain documents when a query arrives from a particular country. For this purpose, the system uses a map of IP address prefixes to countries. Separately, the provider maintains a per-country blacklist, containing a list of censored conduit ids. The *censorship policy* takes the form of a common declassification rule on source files. The rule requires that, at a conduit connecting to a client, the client's IP prefix is looked up in the prefix map, and the corresponding blacklist is checked to see if any of the search results are censored. Both the prefix map and the blacklist are maintained in sorted order for efficient lookup. The sort order is enforced by an integrity policy on the conduits.

A second common provider policy allows employees to access client's private data for troubleshooting pur-

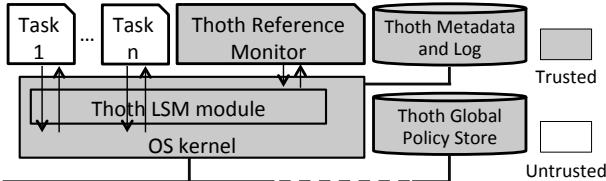

Figure 1: Thoth architecture

poses, as long as such accesses are logged for auditing. A *mandatory access logging (MAL)* policy can be added for this purpose. The policy allows accesses by authorized employees, if and only if an entry exists in a separate log file, which states a signature by the employee, the conduit being accessed, and a timestamp. The log file itself has an integrity policy that allows appends only, thus ensuring that an entry cannot be removed or overwritten. Finally, data sources must consent to provider access by allowing declassification into a conduit readable by authorized employees subject to MAL.

3 Thoth architecture and design

3.1 Overview

Figure 1 depicts the Thoth architecture. At each participating node, Thoth comprises a kernel module that intercepts I/O, a trusted reference monitor process that maintains per-task taint sets³ and evaluates policies, a persistent store for metadata and transaction log, and a persistent policy store. Each node tracks taint and enforces policies independently of other nodes. The policy store is accessible exclusively by the reference monitors and provides a consistent view of all policies. This can be attained by using either central storage for policies or a consensus protocol like Paxos [29].

Figure 2 shows the data flow model of a Thoth-protected system. An application consists of a set of tasks (i.e., processes) that execute on one or more nodes. Data flows among the tasks via *conduits*. A file, named pipe or a tuple in a key-value store is a conduit. A network connection or a named pipe is a pair of conduits, one for each direction of data traffic. Thoth identifies each conduit with a unique numeric identifier, called the conduit id. The conduit id is the hash of the path name in case of a file or named pipe, the hash of the 5-tuple $\langle \text{srcIP}, \text{srcPort}, \text{protocol}, \text{destIP}, \text{destPort} \rangle$ in case of a network connection, or the key in case of a key-value tuple. Any conduit may have an associated policy.⁴

The core of the application system is a set of *CONFINED* tasks within Thoth’s *confinement boundary*. The system interacts with the outside world via conduits (typ-

ically network connections) to external, *UNCONFINED* tasks. *UNCONFINED* tasks represent external users or components. Neither type of task is trusted by Thoth, although an *UNCONFINED* task may represent a user and may possess the user’s authentication credentials.

Policies on inbound and outbound conduits that cross the confinement boundary represent the ingress and egress policies, respectively. The read and declassification rules of an ingress policy control how data can be used and disseminated by the system whereas the update rule of an ingress policy determines who may feed data into the system. The read rule of an egress policy defines who outside the system may read the output data.

3.2 Threat model

The Thoth kernel module and reference monitor, as well as the Linux system and policy store they depend on, are trusted. Active attacks on these components are out of scope. We assume that correct policies are installed on ingress and egress conduits. In our current prototype, storage systems that hold application data are assumed to be trusted. This assumption can be relaxed by encrypting and checksumming application data in the Thoth kernel module.

Thoth makes no assumptions about the nature of bugs and misconfigurations in application components, the type of errors committed by unprivileged operators, or errors in policies on internal conduits. Subject to this threat model, Thoth provably enforces all ingress policies. In information flow control terms, Thoth can control both explicit and implicit flows, but leaks due to covert and side-channels are out of scope.

Justification Trusting the Thoth kernel module, reference monitor, and the Linux system they depend on is reasonable in practice because (i) reputable providers will install security patches on the OS and Thoth components, and correct policies; (ii) OS and Thoth are maintained by a small team of experts and are more stable than applications; thus, an attacker will likely find it more difficult to find a vulnerability in the OS or Thoth than in a rapidly evolving application with a large attack surface.

Typed declassification policies admit limited information flows, which can be exploited by malicious applications covertly. For instance, malware injected into a search engine can encode private information in the set of conduit ids it produces, if the conduits in the set themselves are public. This channel is out of scope. In practice, such attacks require significant sophistication. A successful attack must inject code strategically into the data flow before a declassification point and encode private data on a policy-compliant flow.

On the other hand, Thoth prevents the large class of practical attacks that involve direct flows to unauthorized parties, and accidental policy violations due to applica-

³A task’s taint set is the set of policies of conduits it has read.

⁴If a file has multiple hard links, each of its path names can be associated with a different policy. When a path name is used to access the file, that path name’s policies are checked.

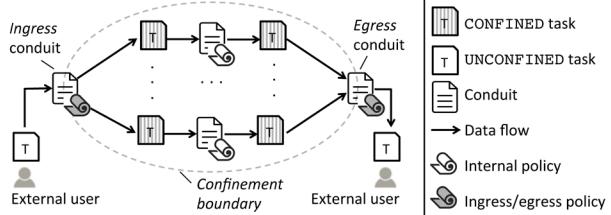

Figure 2: Thoth data flow

tion bugs, misconfigurations, and errors by unprivileged operators. We demonstrate this in Section 6.3 where a Thoth compliant search engine is able to enforce data policies, preventing (real and synthetic) bugs and misconfigurations from leaking information.

3.3 Data flow tracking and enforcement

Tracking data flow Thoth tracks data flows coarsely at the task-level. **CONFINED** and **UNCONFINED** tasks are subject to different policy checks. A **CONFINED** task may read any conduit, irrespective of the conduit’s **read** rule, but Thoth enforces each such conduit’s **declassify** rule when the task writes to other conduits. To do this, Thoth maintains the **declassify** rules of conduits read by each **CONFINED** task in the task’s metadata (these rules constitute the *taint set* of the task).

UNCONFINED tasks form the ingress and egress points for Thoth’s flow tracking; they are subject to access control checks, not tainting. An **UNCONFINED** task may read from (write to) a conduit only if the conduit’s **read** (**update**) rule is satisfied. For example, to read Alice’s private data, an **UNCONFINED** task must authenticate with Alice’s credentials. Conduits without policies can be read and written by all tasks freely.

In summary, Thoth tracks data flows across **CONFINED** tasks coarsely, and enforces declassification policies on these flows. At the ingress and egress tasks (**UNCONFINED** tasks), Thoth imposes access control through the **read** and **update** rules. Every new task starts **UNCONFINED**. The task may transition to the **CONFINED** state through a designated Thoth API call. The reverse transition is disallowed to prevent a task from reading private data in the **CONFINED** state and leaking the data to a conduit without any policy protection after transitioning to the **UNCONFINED** state.

Conduit interceptors The Thoth kernel component includes a conduit interceptor (CI) for each type of conduit. A CI for a given conduit type intercepts system calls that access or manipulate conduits of that type, and associates a conduit with its policy. Thoth has built-in CIs for kernel-defined conduit types, namely files, named pipes, and network connections. CIs for additional conduit types can be plugged in. For instance, our prototype uses a CI for the memcached key-value store (KV).

Question: Should a conduit read or write be allowed?

Inputs: t , the task reading or writing the conduit
 f , the conduit being read or written
 op , the operation being performed (read or write)

Output: Allow or deny the access

Side-effects: May update the taint set of t

```

1 if  $t$  is UNCONFINED:
2   if  $op$  is read:
3     Check  $f$ ’s read rule.
4   if  $op$  is write:
5     Check  $f$ ’s update rule.

6 if  $t$  is CONFINED:
7   if  $op$  is read:
8     Add  $f$ ’s policy to  $t$ ’s taint set.
9   if  $op$  is write:
10    // Enforce declassification policies of  $t$ ’s taint set
11    for each declassification rule  $(c \text{ until } c')$  in  $t$ ’s taint set:
12      Check that EITHER  $c'$  holds OR  $(c \text{ holds AND } f$ ’s declassification policy implies  $(c \text{ until } c'))$ .

```

Figure 3: Thoth policy enforcement algorithm

The CIs for files and named pipes associate a policy with the unique pathname of a file or pipe. The socket CI associates a policy with the network connection’s 5-tuple $\langle \text{srcIP}, \text{srcPort}, \text{protocol}, \text{destIP}, \text{destPort} \rangle$. The 5-tuple may be underspecified. For instance, the policy associated with $\langle ?, ?, ?, ?, \text{destIP}, \text{destPort} \rangle$ applies to any network connection with the specified destination IP address and port. Both ends of a network connection have the same policy. The KV CI associates a policy with a tuple’s key. The KV CI can automatically derive policies from policy templates that cover a subspace of keys (e.g., all keys with prefix `#user_profile`). It can also replace template variables with metadata, e.g., the time at which the key was created.

Policy enforcement algorithm Figure 3 summarizes the abstract checks that Thoth makes when it intercepts a conduit access. If the calling task is **UNCONFINED**, then Thoth evaluates the read or update policy of the conduit (lines 1–5). If the calling task is **CONFINED** and the operation is a read, then Thoth adds the policy of the conduit being read to the taint set of the calling task. No policy check is performed in this case (lines 6–8). To reduce the size of a **CONFINED** task’s taint set, our prototype performs *taint compression* when possible: A policy is not added if the taint set already includes an equally or more restrictive policy.

When a **CONFINED** task t writes a conduit f , there is a potential data flow from every conduit that t has read in the past to f . Hence, all declassification rules in t ’s taint set are enforced (lines 11–12). Suppose $(c \text{ until } c')$ is a **declassification** rule in t ’s taint set. Since this rule means

that condition c must continue to hold downstream *until* the declassification condition c' holds, this rule can be satisfied in one of two ways: Either the declassification condition c' holds now, or c holds now and the next downstream conduit (f here) continues to enforce (c until c'). Line 12 makes exactly this check.

End-to-end correctness of policy enforcement
 Within Thoth’s threat model, the checks described above enforce all policies on conduits and, specifically, all ingress policies. Incorrect policy configuration on internal conduits cannot cause violation of ingress policies but may cause compliant data flows to be denied by the Thoth reference monitor. Informally, this holds because our checks ensure that the conditions in every declassification policy are propagated downstream until they are satisfied.⁵

Policy comparison Thoth compares policies for restrictiveness in three cases: for taint compression, when evaluating the predicate `isAsRestrictive()`, and in line 12 of the enforcement algorithm (Figure 3). The general comparison problem is undecidable for first-order logic, so Thoth uses the following heuristics: 1) *Equality*: Compare the hashes of the two policies. 2) *Inclusion*: Check that all predicates in the less restrictive policy also appear in the more restrictive one, taking into account variable renaming and conjunctions and disjunctions between the predicates. Inclusion has exponential time complexity in the worst case, but is fast in practice. 3) *Partial evaluation*: Evaluate and delete an application-specified subpart of each policy, then try equality and inclusion. These heuristics suffice in all cases we have encountered.

Note that a policy comparison failure can never affect Thoth’s safety. However, a failure can (a) defeat taint compression and therefore increase taint size and policy evaluation overhead; or (b) cause a compliant data flow to be denied. In the latter case, a policy designer may re-state a policy so that the policy comparison succeeds.

3.4 Thoth API

Table 2 lists Thoth API functions provided to user-level tasks by means of a new system call. To check structural properties of written data (e.g., that the data is a list of conduit ids), it is often necessary to evaluate the `update` rule atomically on a *batch* of writes. Hence, Thoth supports write transactions on conduits. By default, a transaction starts with a POSIX `open()` call and ends with the `close()` call on a conduit. This behavior can be overridden by passing additional flags to `open()` and `close()`. Transactions can also be explicitly started and ended using the Thoth API calls `open_tx` and `close_tx`.

⁵A formal proof of this fact is the subject of a forthcoming paper. Our formal model and implementation support nested uses of the `until` operator, which we omitted here.

During a transaction, Thoth buffers writes in a persistent re-do log. When the transaction is closed by the application, Thoth makes the policy checks described in Figure 3. If the policy checks succeed, then the writes are sent to the conduit, else the writes are discarded. The re-do log allows recovery from crashes and avoids expensive filesystem syncs when a transaction commits.

Summary Thoth enforces ingress and egress policies despite application-level bugs, misconfigurations, and compromises, or actions by unprivileged operators. A data source’s policy specifies both access and declassification conditions and describes the source’s allowed uses completely. Thoth uses policies as taint, which differs significantly from the standard information flow control practice of using abstract labels as taint. That practice requires trusted application processes to declassify data and to control access at system edges. In contrast, Thoth relies entirely on its reference monitor for all access and declassification checks, and no application processes have to be trusted.

4 Thoth prototype

Our prototype consists of a Linux kernel module that plugs into the Linux Security Module (LSM) interface, and a reference monitor. We also changed a few (22) lines of the kernel proper to provide additional system call interception hooks not included in the LSM interface, and a new system call that allows applications to interact with Thoth. A small application library consisting of 840 LoC exports the API calls shown in Table 2 based on this system call.

LSM module The Thoth LSM module comprises approximately 3500 LoC and intercepts I/O related system calls including `open`, `close`, `read`, `write`, `socket`, `mknod`, `mmap`, etc. Intercepted system calls are redirected to the reference monitor for taint tracking and validation. The module includes conduit interceptors for files, named pipes and sockets, as well as interceptors for client connections to a memcached key-value store [12].

Thoth reference monitor Thoth’s reference monitor is implemented as a trusted, privileged userspace process. It implements the policy enforcement logic and maintains the process taint, session state and transaction state in DRAM. The monitor accesses the persistent Thoth metadata store, which includes per-conduit metadata (conduit pathname, conduit id, a pointer to the policy in effect in the policy store, and for each persistent file conduit, its current size), the transaction log, and the global policy store. The metadata and transaction log are stored in NVRAM. A write-through DRAM cache holds recently accessed metadata and policies.

The monitor is multi-threaded so it can exploit multicore parallelism. Each worker thread invokes the Thoth

Function	Description
<i>confine ()</i>	Transition calling process from UNCONFINED to CONFINED state.
<i>authenticate (key)</i>	Authenticate process with the private key <i>key</i> to satisfy identity-based policies.
<i>add_policy (p)</i>	Store a policy <i>p</i> in Thoth metadata and return an id <i>p_id</i> for it.
<i>set_tx_flags (c_id, flags)</i>	Set flags <i>flags</i> (type and partial evaluation hints) for a transaction on conduit <i>c_id</i> .
<i>open_tx (c_id)</i>	Open a transaction on conduit <i>c_id</i> and return a file handle.
<i>close_tx (fd)</i>	Close a transaction <i>fd</i> . Return 0 if successful, or error code of a policy check fails.
<i>set_policy (fd, p_id)</i>	Attach policy id <i>p_id</i> to the conduit running transaction <i>fd</i> . Passing (-1) for <i>p_id</i> sets the null policy. The new policy is applied only after <i>fd</i> is successfully closed. The declassification condition of the conduit's existing policy determines whether the policy change or removal is allowed.
<i>get_policy (c_id, buf)</i>	Retrieve the policy attached to conduit <i>c_id</i> into buffer <i>buf</i> .
<i>cache (fd, off, len)</i>	Cache content (for policy evaluation) from file handle <i>fd</i> from offset <i>off</i> with length <i>len</i> .

Table 2: Thoth API calls

system call and normally blocks in the LSM module waiting for work. When an application issues a system call that requires an action by the reference monitor, a worker thread is unblocked and returns to the reference monitor with appropriate parameters; when the work is done, the thread invokes the system call again with the appropriate results causing the original application call to either be resumed or terminated. As an optimization, the LSM seeks to amortize the cost of IPC by buffering and dispatching multiple asynchronous requests to a worker thread whenever possible. The reference monitor was implemented in 19,000 LoC of C, not counting the OpenSSL library used for secure sessions and crypto.

Limitations Memory-mapped files are currently supported read-only. Interception is not yet implemented for all I/O-related system calls. None of these missing features are used by our prototype data retrieval system.

5 Policy-compliant data retrieval

We use Thoth for policy compliance in a data retrieval system built around a distributed Apache Lucene search engine. While Apache Lucene's architecture is not appropriate for large, public search engines like Google or Bing, it is frequently used in smaller, domain-specific data retrieval systems.

5.1 Baseline configuration

Lucene Apache Lucene is an open-source search engine written in Java [2]. It consists of an indexer and a search component. The sequential indexer is a single process that scans a corpus of documents and produces a set of index files. The search component consists of a multi-threaded process that executes search queries in parallel and produces a set of corpus file names relevant to a given search query. The size of the Apache Lucene codebase is about 300,000 LoC.

Lucene can be configured with replicated search processes to scale its throughput. Here, multiple nodes run a copy of the search component, each with the full in-

dex. A search query can be processed by any machine. Lucene can also be sharded to scale with respect to the corpus size. In this case, the corpus is partitioned, each partition is indexed individually, and multiple nodes run a copy of the search component, each with one partition index. A search query is sent to all search components, and the results combined. Replication and sharding can be combined in the obvious way.

Front-end processes A simple front-end process accepts user requests from a remote client and forwards search queries to one or more search process(es) via a pipe. The search process(es) may forward the query to other search processes with disjoint shards. When the front-end receives the search results (a list of document file names), it produces a HTML page with a URL and a content snippet from each of the result documents, and returns the page to the Web client. When the client clicks on one of the URLs, the front-end serves the content.

A second, simple account manager front-end process accepts connections from clients for the purpose of creating accounts, managing personal profiles and policies. Clients choose from a set of policy templates for documents they have contributed to the corpus, and for their personal profile information and activity history.

Search personalization and advertising To include typical features of a data retrieval system, we added personalized search and targeted advertising components. A memcached daemon runs on each search node to provide a distributed key-value store for per-user information, including a suffix of the search and click histories, profile information, and the public key. The front-end process appends a user's search queries and clicks to the histories. It uses the profile information to rewrite search queries, re-order search results, and select ads for inclusion in the results page.

An aggregator process periodically analyses a user's search and click history, and updates the personal profile information accordingly. We are not concerned with the details of user profiling, personalized search, or ad

targeting. It suffices for our purposes to capture the appropriate data flows.

5.2 Controlling data flow with Thoth

With Thoth, the front-end, search, indexing, and aggregation tasks execute as `CONFINED` processes, and the account manager executes as an `UNCONFINED` process. Relative to the baseline system, we made minimal modifications, mostly to set an appropriate policy on output conduits. The modifications to Apache Lucene amounted to less than 20 lines of Java code and 30 lines of C code in a JNI library. These modifications set policies on internal conduits and, like the rest of Lucene, are not trusted. Finding the appropriate points to modify was relatively easy because Lucene’s codebase has separate functions through which all I/O is channelled. For applications without this modularity, a dynamically-linked library can be used that overrides libc’s I/O functions and adds appropriate policies.

Unlike in the baseline, the front-end process must be restarted after each user session, to drop its taint. We implement this by exec-ing the process when a new user session starts.

Ingress/egress policies Recall that the ingress and egress policies determine which data flows are allowed and reflect the policies of users, data sources, and provider. In our system, the network connection between the client and the front-end is both an ingress and an egress conduit. The document files in the corpus and the key-value tuples that contain a user’s personal information are ingress conduits. Policies are associated with all ingress and egress conduits as described below. The primary difficulty here is to determine appropriate policies, a task that is required in any compliant system. Specifying the policies in Thoth’s policy language is straightforward.

Account manager flow When Alice creates an account, credentials are exchanged for subsequent mutual authentication, and stored in the key-value store, along with any personal profile information Alice provides.

Alice can choose policies for her profile and history information, as well as any contributed content, typically from a set of policy templates written by the provider’s compliance team. The declassification rule of each policy implicitly controls who can subsequently change the policy; normally, Alice would choose a policy that allows only her to make such a change. Alice may also edit her friend lists or other access control lists stored in the key-value store, which may be referenced by her policies.

Next, we explain the main data flows through the system. For lack of space, we cannot detail all policies on internal conduits, but we highlight the key steps.

Indexing flow Periodically, the indexer is invoked to regenerate the index partitions. A correct indexer only processes documents with the `ONLY_CND_IDS` (or `ONLY_CND_IDS+`) declassification clause, which is transferred to the index files. Note that the index may contain arbitrary data and can be read by any `CONFINED` process; however, an eventual declassification to an `UNCONFINED` process is only possible for a list of conduit ids.

Profile aggregation flow A profile aggregation task periodically executes in the background, to scan the suffix of a user’s query and click history and update the user’s profile vector. A correct aggregator only analyzes user history data that has the `ONLY_CND_IDS` (or `ONLY_CND_IDS+`) declassification clause, which is transferred to the profile vectors.

Search flow Finally, we describe the sequence of steps when Alice performs a search query. The search front-end authenticates itself to Alice using the credentials stored in the key-value store. A successful authentication assures Alice that (i) she is talking to the front-end, and (ii) the front-end process is tainted with the policy of Alice’s credentials (only Alice can read, else declassify into a list of conduit ids) before Alice sends her search query. Next, Alice authenticates herself to the Thoth reference monitor via the search front-end, which proves to Thoth that the front-end process speaks for Alice.

The front-end now sends Alice’s query to one or more search process(es) and adds it to her search history. The search results are declassified as a list of conduit ids, and therefore do not add new taint to the front-end. While producing the HTML results page, the front-end reads a snippet from each result document using Alice’s credentials. Each document has a censorship policy, which checks that the document’s conduit ID is not blacklisted in the client’s region. These policies differ in the conduit IDs and so, in principle, the taint set on the front-end could become very large. To prevent this, we use partial evaluation (Section 3): *Before* a document’s policy is added to the front-end’s taint, we check that the document is not blacklisted. This way, the front-end’s taint increases by a *single predicate* (which verifies Alice’s IP address) when it reads the first document and does not increase when it reads subsequent documents.

Finally, the front-end sends the results page to the client. For this, it must satisfy the egress conduit policy, which verifies Alice’s identity and her IP address.

Result caching High-performance retrieval systems cache search results and content snippets for reuse in similar queries. Although we have not implemented such caching, it can be supported by Thoth. Intermediate results can be cached at various points in the data flow, usually before their policies have been specialized (through

partial evaluation) for a particular client or jurisdiction.

Summary Assuming that the account manager correctly installs ingress and egress policies, Thoth ensures that Alice’s documents, history and profile are used according to her wishes and that the provider’s censorship and MAL policies are enforced, despite any bugs in the indexer, the front-end or the profile aggregator. Thoth’s use in a data retrieval system highlights two different ways of preventing process overtainting. The front-end process is *user-specific*—it acts on behalf of one client. Consequently, the front-end must be re-executed at the end of a user session session to discard its taint. In contrast, the indexer is an *aggregator* process that is designed to combine documents with conflicting policies into a single index. To make its output (the index) usable downstream, the provider installs a typed declassification clause (ONLY_CND_IDS or ONLY_CND_IDS+) on all documents. Due to the declassification clause, there is no need to re-exec the search process.

6 Evaluation

In this section, we present results of an experimental evaluation of our Thoth prototype.

All experiments were performed on Dell R410 servers, each with 2x Intel Xeon X5650 2.66 GHz 6 hyper-threaded core CPUs, 48GB main memory, running OpenSuse Linux 12.1 (kernel version 3.13.1, x86-64). The servers are connected to Cisco Nexus 7018 switches with 1Gbit Ethernet links. Each server has a 1TB Seagate ST31000424SS disk formatted under ext4, which contains the OS installation and a 258GB static snapshot of English language Wikipedia articles from 2008 [43].

We allocate a 2GB memory segment on /dev/shm to simulate NVRAM used by Thoth to store its metadata and transaction log. NVRAM is readily available and commonly used to store frequently updated, fixed-sized persistent data structures like transaction logs.

In the following experiments, we compare a system where each OS kernel is configured with the Thoth LSM kernel module and reference monitor against an otherwise identical baseline system with unmodified Linux 3.13.1 kernels.

6.1 Thoth-based data retrieval system

We study the total Thoth overheads in the prototype retrieval system described in Section 4.

Indexing First, we measure the overhead of the search engine’s index computation. We run the Lucene indexer over a) the entire 258GB snapshot of the English Wikipedia, and b) a 5GB part of the snapshot. The sizes of the resulting indices are 54GB and 959MB, respectively. Table 3 shows the average indexing time and standard deviation across 3 runs. In both cases, Thoth’s runtime overhead is below 1%.

	Dataset 258GB		Dataset 5GB	
	Avg. (mins)	σ	Avg. (mins)	σ
Linux	1956.1	30	27.8	0.06
Thoth	1968.6	24	28.0	0.11
Overhead	0.65%		0.7%	

Table 3: Indexing runtime overhead

Even in a sharded configuration, Lucene relies on a sequential indexer, which can become a bottleneck when a corpus is large and dynamic. Larger search engines may rely on parallel map/reduce jobs to produce their index. As a proof of concept, we built a Hadoop-based indexer using Thoth, although we don’t use it in the following evaluation because it does not support all the features of the Lucene indexer. All mappers and reducers run as confined tasks, and receive the same taint as the original, sequential indexer.

Search throughput Next, we measure the overhead of Thoth on the query latency and throughput. To ensure load balance, we partitioned the index into two shards of 22GB and 33GB, chosen to achieve approximately equal query throughput. We use two configurations:

2Servers: 2 server machines execute a Lucene instance with different index shards. **4Servers**: Here, we use two replicated Lucene instances in each shard to scale the throughput. The front-end forwards each search request to one of the two Lucene instances in each shard and merges the results.

We drive the experiment with the following workload. We simulate a population of 40,000 users, where each user is assigned a friend list consisting of 12 randomly chosen other users, subject to the constraint that the friendship relationship is symmetric. Each item in the corpus is assigned either a private, public, or friends-only policy in the proportion 30/50/20%, respectively. A total of 1.0% of the dataset is censored in some region. All simulated clients are in a region that blacklists 2250 random items.

We use query strings based on the popularity of Wikipedia page accesses during one hour on April 1, 2012 [42]. Specifically, we search for the titles of the top 20K visited articles and assign each of the queries randomly to one of the users. 24 simulated active users connect to each server machine, maintain their sessions throughout the experiment, and issue 48 (**2Servers**) and 96 (**4Servers**) queries concurrently to saturate the system. In addition, a simulated “employee” sporadically issues a read access to protected user files for a total of 200 MAL accesses.

During each query, the front-end looks up the user profile and updates the user’s search history in the key-value store. To maximize the performance of the baseline and fully expose Thoth’s overheads, the index shard and

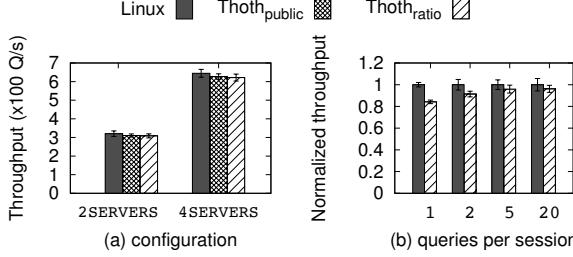

Figure 4: Search throughput

parts of the corpus relevant to our query stream are pre-loaded into the servers’ main memory caches, resulting in a CPU-bound workload.

Figure 4 (a) shows the average throughput over 10 runs of 20K queries each, for the baseline (Linux) and Thoth under **2SERVERS** and **4SERVERS**. The error bars indicate the standard deviation over the 10 runs. We used two Thoth configurations, **Thoth_{public}** and **Thoth_{ratio}**. In **Thoth_{public}**, the policies permit all accesses. This configuration helps to isolate the overhead of Thoth’s I/O interposition and reference monitor invocation. In **Thoth_{ratio}**, input files are private to a user, public, or accessible to friends-only in the ratio 30:50:20. All files allow employee access under MAL, enforce region-based censorship, and have the declassification condition with **ONLY_CONDUIT_IDS+**.

The query throughput scales approximately linearly from **2SERVERS** (320 Q/s) to **4SERVERS** (644 Q/s), as expected. Thoth with all policies enforced (**Thoth_{ratio}**) has an overhead of 3.63% (308 Q/s) in **2SERVERS** and 3.55% in **4SERVERS** (621 Q/s). We note that the throughput achieved with **Thoth_{public}** (310 Q/s and 627 Q/s, respectively) is only slightly higher than **Thoth_{ratio}**’s. This suggests that Thoth’s overhead is dominated by costs like I/O interception, Thoth API calls, and metadata operations, which are unrelated to policy complexity.

To test whether overheads can be reduced further, we also implemented a rudimentary reference monitor in the kernel, which does not support session management and policy interpretation (which require libraries that are unavailable in the Linux kernel). This reduced in-kernel monitor suffices to execute **Thoth_{public}**. Moving the reference monitor to the kernel reduced the overhead of **Thoth_{public}** from 3% to under 1%, which suggests that overheads can be further reduced by moving the reference monitor to the kernel and, hence, eliminating the cost of IPC between the LSM and the reference monitor.

With Thoth, the front-end is re-exec’ed at the end of every user session to shed the front-end’s taint. The relative overhead of doing so reduces with session length. Figure 4 (b) shows the average throughput normalized to the Linux baseline for session lengths of 1, 2, 5 and

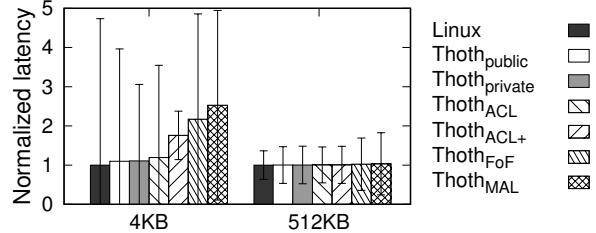

Figure 5: Read latency, normalized to Linux’s

20 queries in **2SERVERS**. Due to the per-session front-end exec, Thoth’s overhead is higher for small sessions (15.8% for a single query); however, the overhead diminishes quickly to 8.6% for 2 queries per session, and the throughput is within a standard deviation of the maximum for 5 or more queries per session in all configurations, including **4SERVERS**.

Search latency Next, we measure the overhead on query latency. Table 4 shows the average query latency across 5 runs of 10K queries in **2SERVERS**. The results in **4SERVERS** are similar. In all cases, Thoth adds less than 6.7ms to the baseline latency.

	Avg. (ms)	σ	Overhead
Linux	47.09	0.43	-
Thoth _{public}	51.60	0.29	9.6%
Thoth _{ratio}	53.78	0.20	14.2%

Table 4: Query search latency (ms)

6.2 Microbenchmarks

Next, we perform a set of microbenchmarks to isolate Thoth’s overheads on different policies. We measure the latency of opening, reading sequentially, and closing 10K files in the baseline and with Thoth under different policies associated with the files. The files were previously written to disk sequentially to ensure fast sequential read performance for the baseline and therefore fully expose the overheads.

In the Thoth experiments, accesses are performed by an UNCONFINED task to force an immediate policy evaluation. The following policies are used. **Thoth_{public}**: files can be read by anyone. **Thoth_{private}**: access is restricted to a specific user. **Thoth_{ACL}**: access to friends only (all users have the same friend list). **Thoth_{ACL+}**: access to friends only (each user has a different friend list). **Thoth_{FoF}**: access to friends of friends (each user has a different friend list). All friend lists used in the microbenchmark have 100 entries. **Thoth_{MAL}**: each file has a MAL policy, where each read requires an entry in a log with an append-only integrity policy.

Figure 5 shows the average time for reading a file of sizes 4K and 512K, normalized to the baseline Linux latency (0.145ms and 3.6ms, respectively); the error bars indicate the standard deviation among the 10K file reads. We see that Thoth’s overheads increase with the complexity of the policy, in the order listed above. For the 4KB files, the overheads range from 10.6% for **Thoth_{public}** and **Thoth_{private}** to 152.7% for **Thoth_{MAL}**. The same trend holds for larger files, but the overhead range diminishes to 0.6%–23% for 96KB files (not shown in the figure) and 0.34%–3.3% for 512KB files.

We also experimented with friend list sizes of 12 and 50 entries for **Thoth_{ACL}**, **Thoth_{ACL+}** and **Thoth_{FoF}**; the resulting latency was within 2.4% of the corresponding 100-entry friend list latency. This is consistent with the known complexity of the friend lookup, which is logarithmic in the list size.

We also looked at the breakdown of Thoth latency overheads. With **Thoth_{ACL}** and 4KB files, Thoth’s overhead for file read is on average 28 μ s, which are spent intercepting the system call and maintaining the session state. Interpreting the policy and checking the friend lists takes 6 μ s, but this time is completely overlapped with the disk read.

Write transaction latency We performed similar microbenchmarks for write transactions. In general, Thoth’s write transactions have low overhead since its transaction log is stored in (simulated) NVRAM. As in the case of read latency, the overhead depends on the granularity of writes and the complexity of the policy being enforced. Under the index policy, the overhead ranges from 0.25% for creating large files to 2.53x in the case of small files. The baseline Linux is very fast at creating small files that are written to disk asynchronously, while Thoth has to synchronously update its policy store when a new file is created. The overhead is 5.8x and 8.6x in the case of a write of 10 conduit ids to a file under the **ONLY_CND_IDS** and **ONLY_CND_IDS+** policies, respectively. This high overhead is due to checking that each conduit id being written exists (and is written into a file with a stricter policy in the case of **ONLY_CND_IDS+**). However, this overhead amounts to only a small percentage of the overall search query processing, as is evident from Table 4.

6.3 Fault-injection tests

To double-check Thoth’s ability to stop unwanted data leaks, we injected several types of faults in different stages of the search pipeline.

Faulty Lucene indexer We reproduced a known Lucene bug [5] that associates documents with wrong attributes during index creation. This bug is security-relevant because, in the absence of another mechanism, attributes can be used for labeling data with their owners.

In our experiment Thoth successfully stopped the flow in all cases where the search results contained a conduit whose policy disallowed access to the client.

We also intentionally misconfigured the indexer to index the users’ query and click histories, which should not show up in search results. Thoth prevented the indexer from writing the index after it had read either the query or the click history.

Faulty Lucene search We reproduced a number of known Lucene bugs that produce incorrect search results. Such bugs may produce Alice’s private documents in Bob’s search. The bugs include incorrect parsing of special characters [7], incorrect tokenization [9], confusing uppercase and lowercase letters [10], using an incorrect logic for query expansion [4, 3], applying incorrect keyword filters [8], and premature search termination [6]. We confirmed that all policy violations resulting from these bugs faults were blocked by Thoth.

To check the declassification condition **ONLY_CND_IDS+**, we modified the search process to (incorrectly) output text from the index in place of conduit ids. Thoth prevented the search process from producing such output.

Faulty front-end We issued accesses to a private file protected by the **MAL** policy without adding appropriate log entries. Thoth prevented the front-end process from extricating data to the caller. We performed similar tests for the region-based censorship policy with similar results.

7 Related work

Search engine policy compliance Grok [36] is a privacy compliance tool for the Bing search engine. Grok and Thoth differ in techniques, expressiveness and target policies. Grok uses heuristics and selective manual verification by developers to assign *attributes* — abstract labels that represent intended confidentiality — to processes and data stores. Grok policies, written in a language called Legalese, specify allowed data flows on attributes. Attributes and policies apply at the granularity of fields (types), not individual users or data items, so Legalese cannot express the private, friends only and friends of friends policies from Section 2. (This restriction applies broadly to most static analysis-based policy enforcement techniques.) Legalese also does not support content-dependent policies and cannot express the mandatory access logging, censorship and typed declassification policies from Section 2. Grok enforces policies with a fast static analysis on computations written in languages like Hive, Dremel, and Scope. Grok imposes no runtime overhead. Thoth uses kernel-level interception and is language-independent, but has a small runtime overhead. Grok-assigned attributes may be incorrect, so Grok may have false negatives. In contrast,

Thoth enforces all conduit policies without false negatives.

Cloud policy compliance Maniatis et al. [31] outline a vision, architecture and challenges for data protection in the Cloud using secure data capsules. Thoth can be viewed as a realization of that vision in the context of a data retrieval system, and contributes the design of a policy language, enforcement mechanism, and experimental evaluation. Secure Data Preservers (SDaPs) [27] are software components that mediate access to data according to a user-provided policy. Unlike Thoth, SDaPs are suitable only for web services that interact with user data through simple, narrow interfaces, and do not require direct access to users' raw data. LoNet [26] enforces data-use policies at the VM-level. Unlike Thoth, declassification requires trusted application code and interception is limited to file I/O using FUSE, which results in very high overhead.

Information flow control (IFC) Numerous systems restrict a program's data flow to enforce security policies, either in the programming language (Jif [34]), in the language runtime (Resin [46], Nemesis [19]), in language libraries (Hails [25]), using software fault isolation (duPro [35]), in the OS kernel (e.g., Asbestos [22], HiStar [47], Flume [28], Silverline [33]), or in a hypervisor (Neon [48]). Thoth differs from these systems in a number of ways. Unlike language-based IFC, Thoth applications can be written in any language.

Architecturally, Thoth is close to Flume. Both isolate processes using a Linux security extension and a user-space reference monitor, both enforce policies on conduits and both distinguish between `CONFINED` and `UNCONFINED` processes in similar ways. However, like all other kernel-level solutions for IFC (Asbestos, HiStar, Silverline), Flume uses abstract labels as taints. In contrast, Thoth uses declarative policies as taints. This results in two fundamental differences. First, Flume relies on trusted application components to map system access policies to abstract labels and for all declassification. In contrast, in Thoth, the reference monitor enforces all access conditions (specified in the `read` and `update` rules) and all declassification conditions (specified in the `declassify` clauses). Application components are trusted only to install correct policies on ingress and egress nodes. Second, Thoth policies describe the policy configuration completely. In Flume, the policy configuration is implicit in the `code` of the trusted components that declassify and endorse data, and map access policies to labels (although mapping can be automated to some extent [21]).

Resin [46] enforces programmer-provided policies on PHP and Python web applications. Unlike Thoth's declarative policies, Resin's policies are specified as

PHP/Python functions. Resin tracks flows at object granularity. Thoth tracks flows at process granularity, which matches the pipelined structure of data retrieval systems and reduces overhead significantly. Hails [25] is a Haskell-based web development framework with statically-enforced IFC. Thoth offers IFC in the kernel, and is independent of any language, runtime, or framework used for developing applications. COWL [39] confines JavaScript browser contexts using labels and IFC. Thoth addresses the complementary problem of controlling data flows on the server side. Both Hails and COWL use DC-labels [38] as policies. DC-labels cannot express content-dependent policies like our censorship, mandatory access logging and ONLY_CND_IDS policies.

Declarative policies Thoth's policy language is based on Datalog and linear temporal logic (LTL). Datalog and LTL are well-studied foundations for policy languages (see [30, 18, 20] and [15, 16, 23], respectively), known for their clarity, conciseness, and high-level of abstraction. The primary innovation in Thoth's policy language is its two-layered structure, where the first layer specifies access policies and the second layer specifies declassification policies. Some operating systems (Nexus and Taos [37, 45]), file systems (PFS and PCFS [41, 24]), and at least one cyber-physical system (Grey [17]) and one storage system (Guardat [40]) enforce access policies expressed in Datalog-like languages. Thoth can enforce similar policies but, additionally, Thoth tracks flows and can enforce declassification policies that these systems cannot enforce. Like Guardat, but unlike the other systems listed above, Thoth's policy language supports data-dependent policies. The design of Thoth's reference monitor is inspired by Guardat's monitor. However, Thoth's monitor tracks data flows, supports declassification policies, and intercepts memcached I/O and network communication, all of which Guardat's monitor does not do.

8 Ongoing work

In this section, we briefly describe ongoing work related to Thoth.

Lightweight isolation Information flow control requires the isolation of computations that handle different users' private data. In general-purpose operating systems, this means that separate processes must be used to handle user sessions. Thoth, for instance, requires that front-end processes be exec'ed for each new session. We are working on an operating system primitive that provides isolation among different user sessions within the same process with low cost.

Database-backed retrieval systems Thoth includes conduit interceptors for files, named pipes, network connections and a key-value store (memcached). In current

work, we are building a system to ensure compliance of SQL database queries with declarative policies associated with the database schema. The system can be used as a conduit interceptor, thus extending Thoth’s protection to database-backed data retrieval systems.

Policy testing Assigning policies to internal conduits in Thoth, and making sure that they permit all data flows compliant with the ingress and egress policies, can be a tedious task in a large system. In current work, we are developing a tool that generates internal conduit policies semi-automatically using a system’s dataflow graph and the ingress/egress policies as inputs. Moreover, the tool performs systematic testing to ensure all compliant dataflows are allowed, and helps the policy developer generate appropriate declassification policies as needed.

9 Conclusion

Efficient policy compliance in data retrieval systems is a challenging problem. Thoth is a kernel-level policy compliance layer to address this problem. The provider has the option to associate a declarative policy with each data source and sink. The policy specifies confidentiality and integrity requirements and may reflect the data owner’s privacy preferences, the provider’s own data-use policy, and legal requirements. Thoth enforces these policies by tracking and controlling data flows across tasks through kernel I/O interception. It prevents data leaks and corruption due to bugs and misconfigurations in application components (including misconfigurations in policies on internal conduits), as well as actions by unprivileged operators.

Our technical contributions include a declarative policy language that specifies both access (read/write) policies and how those access policies may change. The latter can be used to represent declassification policies. Additionally, the language supports content-dependent policies. Thoth uses policy sets as taint, which eliminates the need to trust application processes with access checks at the system boundary and with declassification. Our Linux-based prototype shows that Thoth can be deployed with low overhead in data retrieval systems. Among other things, this demonstrates the usefulness and viability of coarse-grained taint tracking as a basis for policy enforcement.

A Thoth policies for data flows in a search engine

In this Appendix we provide details of the policies used in our Thoth-compliant search engine. All policies are represented in the **read**, **update** and **declassify** rules on source conduits (documents that the search engine indexes, the user profile, etc.). We describe these rules incrementally: We start from a set of base rules, which we refine to include more policies.

Base rules Our base rules allow anyone to read, update or destroy the source conduit they are attached to.

```
read :- TRUE
update :- TRUE
destroy :- TRUE
declassify :- isAsRestrictive(read, this.read)
until FALSE
```

The **read**, **update** and **destroy** rules have condition *TRUE*, which always holds, so these rules do not re-

strict access at all. The **declassify** rule insists that the **read** rule on any conduit containing data derived from the source conduit be at least as restrictive as the **read** rule above, which will always be the case (because the **read** rule above is the most permissive read rule possible). This base policy is pointless in itself, but it serves as the starting point for the remaining policies.

A.1 Client policies

First, we describe policies to represent client privacy preferences.

Private data policy A user Alice may wish that her private files (e.g., her e-mails) be accessible only to her. This can be enforced by requiring that accesses to Alice’s private files happen in the context of a session authenticated with Alice’s key. Technically, this is accomplished by replacing the conditions in the base **read**, **update** and **destroy** rules as shown below and attaching the resulting rules to Alice’s private files. The predicate *sKeyls(k)* means that the current session is authenticated using the public key *k*.

```
read :- sKeyls(kAlice)
update :- sKeyls(kAlice)
destroy :- sKeyls(kAlice)
```

The **declassify** rule remains unchanged. It ensures that any conduit containing data derived from Alice’s private files is subject to a **read** rule that is at least as restrictive as the revised **read** rule above. Hence, no such conduit can be read by anyone other than Alice.

Friends only policy Alice might want that her blog and online social network profile be readable by her friends. To do this, she could add a disjunctive (“or”-separated) clause in the **read** rule requiring that **read** accesses happen in the context of a session authenticated with a key *k_X* of one of Alice’s friends. Alice’s friends are assumed to be listed in the file *Alice.acl*, which contains an entry of the form *isFriend(k_X, X_{ACL})* for each public key *k_X* that belongs to a friend of Alice. The *isFriend* entry also states the file *X_{ACL}* which lists the friends of the key *k_X*’s owner. Note that the *isFriend* entry format presented in the paper was slightly simplified for readability.

```
read :- sKeyls(kAlice) ∨
[sKeyls(kX) ∧ (“Alice.acl”, off) says isFriend(kX, XACL)]
```

The *says* predicate ((“Alice.acl”, *off*) *says* *isFriend(k_X, X_{ACL})*) checks that *k_X* exists in the list of Alice’s friends (file “Alice.acl”) at some offset *off*.

Friends of friends policy To additionally allow read access to friends of friends, the policy would require read accesses to happen in the context of an authenticated session whose key is present in the friend list of any of Alice’s friends.

```

read :- sKeyls( $k_{Alice}$ ) ∨
[sKeyls( $k_X$ ) ∧ (“Alice.acl”,  $off$ ) says isFriend( $k_X, X_{ACL}$ )] ∨
[sKeyls( $k_Y$ ) ∧ (“Alice.acl”,  $off_1$ ) says isFriend( $k_X, X_{ACL}$ )
 ∧ ( $X_{ACL}, off_2$ ) says isFriend( $k_Y, Y_{ACL}$ )]

```

The predicate $((‘Alice.acl’, off_1) \text{ says } \text{isFriend}(k_X, X_{ACL}))$ checks that k_X exists in the list of Alice’s friends (file “Alice.acl”) at some offset off_1 . It also binds the variable X_{ACL} to the friend list of the key k_X ’s owner. Next, the predicate $((X_{ACL}, off_2) \text{ says } \text{isFriend}(k_Y, Y_{ACL}))$ checks that the public key that authenticated the session k_Y exists in the list of friends for the k_X ’s owner at some offset off_2 .

A.2 Provider policies

Next, we describe two policies that a provider may wish to impose, possibly to comply with legal requirements.

Mandatory Access Logging (MAL) The MAL policy allows an authorized employee of the provider read access to a source conduit F if the access is logged. The log entry must have been previously written to the file $k.log$, where k is the public key of the employee. The log entry must mention the employee’s key, the ID of the accessed conduit and the time at which the conduit is accessed with a tolerance of 60 seconds. To enforce these requirements, a new disjunctive condition is added to the last **read** rule above. The \dots in the rule below abbreviate the conditions of the last **read** rule above.

```

read :- ... ∨
sKeyls( $k$ ) ∧ cldls( $F$ ) ∧
(“auth_employees”,  $off$ ) says isEmployee( $k$ ) ∧
( $LOG_k = \text{concat}(k, “.log”)$ ) ∧
( $LOG_k, off_1$ ) says readLog( $k, F, T$ ) ∧ timels( $curT$ ) ∧
gt( $curT, T$ ) ∧ sub( $diff, curT, T$ ) ∧ lt( $diff, 60$ )

```

The predicate $sKeyls(k)$ binds the public key that authenticated the session (i.e., the public key of the employee) to the variable k , and $cldls(F)$ binds the name of source conduit to F . Next, the predicate $((“auth_employees”, off) \text{ says } \text{isEmployee}(k))$ checks that k exists in the list of authorized employees (file “auth_employees”) at some offset off , to verify that the source conduit’s reader is really an employee. Next, LOG_k is bound to the name of the employee’s log file, $k.log$. The predicate $((LOG_k, off_1) \text{ says } \text{readLog}(k, F, T))$ checks that the log file contains an appropriate entry with some time stamp T and the remaining predicates check that the current time, $curT$, satisfies $T \leq curT \leq T + 60s$.

Every log file has a **read** rule that allows only authorized auditors to read the file (the public keys of all authorized auditors are assumed to be listed in the file “auditors”). It also has an **update** rule that allows appends

only, thus ensuring that a log entry cannot be removed or overwritten.

```

read :- sKeyls( $k$ ) ∧ (“auditors”,  $off$ ) says isAuditor( $k$ )
update :- sKeyls( $k$ ) ∧
(“auth_employees”,  $off$ ) says isEmployee( $k$ ) ∧
cCurrLenls( $cLen$ ) ∧ cNewLenls( $nLen$ ) ∧
gt( $nLen, cLen$ ) ∧ (this, 0,  $cLen$ ) hasHash ( $h$ ) ∧
(this, 0,  $cLen$ ) willHaveHash ( $h$ )

```

In the append-only policy (rule **update** above), the predicate $cCurrLenls(cLen)$ binds the current length of the log file to $cLen$ and the predicate $cNewLenls(nLen)$ binds the new length of the log file to $nLen$. Next, the predicate $gt(nLen, cLen)$ ensures that the update only increases the log file’s length. (c, off, len) hasHash (or willHaveHash) is a special mode of using says (or willsay) which allows the policy interpreter to refer to the hash of the conduit c ’s content (or updated content in a write transaction) from offset off with length len . In the **update** rule, hasHash and willHaveHash are used to verify that the existing file content is not modified during an update by checking that the hashes of the file from offset 0 to $cLen$, originally and after the prospective update, are equal.

A more efficient implementation of the append-only policy could rely on a specialized predicate $\text{unmodified}(off, len)$, which checks that the conduit contents from offset off with length len were not modified. The **update** rule could then be simplified to:

```

update :- sKeyls( $k$ ) ∧
(“auth_employees”,  $off$ ) says isEmployee( $k$ ) ∧
cCurrLenls( $cLen$ ) ∧ cNewLenls( $nLen$ ) ∧
gt( $nLen, cLen$ ) ∧ unmodified(0,  $cLen$ )

```

Region-based censorship Legal requirements may force the provider to blacklist certain source files in certain regions. Accordingly, the goal of the censorship policy is to ensure that content from a document F can only reach users in regions whose blacklists do not contain F . The policy relies on a mapping from IP addresses to regions and a per-region blacklist file. The blacklist file is maintained in a sorted order to efficiently lookup whether it contains a given document or not.

The censorship policy is expressed by modifying the **declassify** rule of every source conduit $cndID$ as follows:

```

declassify :- isAsRestrictive(read, this.read) until
(CENSOR( $cndID$ ) ∧ isAsRestrictive(read, this.read))

```

The rule says that the **read** rule on any conduit to which $cndID$ flows must be as restrictive as $cndID$ ’s **read** rule *until* a conduit at which the condition $CENSOR(cndID)$ holds is reached. $CENSOR(cndID)$ is a macro defined below. The predicate $slpls(IP)$ checks

that the IP address of the connecting (remote) party is IP and the predicate $\text{IpPrefix}(IP, R)$ means that IP belongs to region R . The blacklist file for region R is $R.\text{BlackList}$. In words, $\text{CENSOR}(\text{cndID})$ means that the remote party's IP belongs to a region R and cndID lies strictly between two consecutive entries in R 's blacklist file (and, hence, cndID does not exist in R 's blacklist file).

```
slpls(IP) ∧ IpPrefix(IP, R) ∧
(FBL = concat(R, ".BlackList")) ∧
(FBL, off1) says isCensored(cnd1) ∧
add(off2, off1, CENSOR_ENTRY_LEN) ∧
(FBL, off2) says isCensored(cnd2) ∧
lt(cnd1, cndID) ∧ lt(cndID, cnd2)
```

A.3 Search engine flows

Indexing flow The indexer reads documents with possibly contradictory policies and, in the absence of a dedicated provision for declassification, the index (and any documents derived from it) cannot be served to any client. To prevent this problem, searchable documents allow typed declassification. The **declassify** rule for each searchable document is modified with a new clause that allows complete declassification into an (internal) conduit whose **update** rule allows the conduit to contain only a list of object ids. The modified **declassify** rule of each source document has the form:

```
declassify :- ... until (... ∨ (clsIntrinsic ∧
isAsRestrictive(update, ONLY_CND_IDS)))
```

The macro `ONLY_CND_IDS` stipulates that only a list of valid conduit ids can be written and it expands to:

```
cCurrLenls(cLen) ∧ cNewLenls(nLen) ∧
each in(this, cLen, nLen) says(cndId)
{cldExists(cndId)}
```

In the macro above, the predicate $\text{cNewLenls}(nLen)$ binds the new length of the output file to $nLen$. The predicate willsay checks that the content update from offset 0 and length $nLen$ is a list of conduit IDs, and the predicate $\text{cldExists}(cndId)$ checks that $cndId$ corresponds to an existing conduit.

So far we have assumed that the conduit ids are not themselves confidential. If the presence or absence of a particular conduit id in the search results may leak sensitive information, then the source declassification policy can be augmented to require that the list of conduit ids is accessible only to a principal who satisfies the confidentiality policies of all listed conduits. Then, the macro `ONLY_CND_IDS` can be re-written to:

```
cCurrLenls(cLen) ∧ cNewLenls(nLen) ∧
each in(this, cLen, nLen) willsay(cndId)
{cldExists(cndId) ∧ hasPol(cndId, P) ∧
isAsRestrictive(read, P.read) ∧
isAsRestrictive(declassify, P.declassify)}
```

Additionally in the macro above, the predicate $\text{hasPol}(cndId, P)$ binds P to the policy of the conduit $cndId$, and the predicate $\text{isAsRestrictive}(\text{read}, P.\text{read})$ requires that the confidentiality of the list of conduit ids is as restrictive as the confidentiality requirements of the source conduit ids themselves.

Profile aggregation flow Since raw user activity logs are typically private, a declassification is required that enables a profile generator to produce a user preferences vector (a vector of fixed length) from the activity logs. However, this preferences vector must further be restricted so that it can be used to produce only a list of conduit ids (the search results). Further, the user might also want to ensure that only activity logs generated in the past 48 hours be used for personalization. This can be achieved by allowing the declassification into the fixed-size vector to happen only within 172800 seconds of the log's creation. Suppose an activity log is created at time t and that the preferences vector has length n . Then, the relevant policy rules on the activity log are the following (note that t and n are constants, not variables).

```
read :- sKeyls(kAlice)
declassify :- [isAsRestrictive(read, this.read) until
isAsRestrictive(update, ONLY_FLOATS(n)) ∧
clsIntrinsic ∧ timels(curT) ∧ gt(curT, t) ∧
sub(diff, curT, t) ∧ lt(diff, 172800)] ∧
[isAsRestrictive(read, this.read) until clsIntrinsic ∧
isAsRestrictive(update, ONLY_CND_IDS)]
```

This policy ensures that the raw user logs can only be transformed into the user preferences vector, which in turn can only be declassified into the search results of the search engine.

The macro `ONLY_FLOATS(n)` stipulates that only a vector of n floats can be written. It expands to:

```
cNewLenls(nLen) ∧
each in(this, 0, nLen) willsay(value)
{vType(value, FLOAT) ∧ (Cnt ++)} ∧
eq(Cnt, n)
```

In the macro above, the predicate $\text{cNewLenls}(nLen)$ binds the new length of the output file to $nLen$. The predicate willsay checks that the content update from offset 0 and length $nLen$ is a list of $values$, and the predicate $\text{vType}(value, FLOAT)$ checks that each $value$ in the list is of type `FLOAT`. The predicate $\text{eq}(cnt, n)$ checks that the update contains n floats.

Dancing on the Lip of the Volcano: Chosen Ciphertext Attacks on Apple iMessage

Abstract

Apple’s iMessage is one of the most widely-deployed end-to-end encrypted messaging protocols. Despite its broad deployment, the encryption protocols used by iMessage have never been subjected to rigorous cryptanalysis. In this paper, we conduct a thorough analysis of iMessage to determine the security of the protocol against a variety of attacks. Our analysis shows that iMessage has significant vulnerabilities that can be exploited by a sophisticated attacker. In particular, we outline a novel chosen ciphertext attack on Huffman compressed data, which allows *retrospective* decryption of some iMessage payloads in less than 2^{18} queries. The practical implication of these attacks is that any party who gains access to iMessage ciphertexts may potentially decrypt them remotely and after the fact. We additionally describe mitigations that will prevent these attacks on the protocol, without breaking backwards compatibility. Apple has deployed our mitigations in the latest iOS and OS X releases.

1 Introduction

The past several years have seen widespread adoption of end-to-end encrypted text messaging protocols. In this work we focus on one of the most popular such protocols: Apple’s iMessage. Introduced in 2011, iMessage is an end-to-end encrypted text messaging system that supports both iOS and OS X devices. While Apple does not provide up-to-date statistics on iMessage usage, in February 2016 an Apple executive noted that the system had a peak transmission rate of more than 200,000 messages per second, across 1 billion deployed devices [12].

The broad adoption of iMessage has been controversial, particularly within the law enforcement and national security communities. In 2013, the U.S. Drug Enforcement Agency deemed iMessage “a challenge for DEA intercept” [22], while in 2015 the U.S. Department of

Justice accused Apple of thwarting an investigation by refusing to turn over iMessage plaintext [11]. iMessage has been at the center of a months-long debate initiated by U.S. and overseas officials over the implementation of “exceptional access” mechanisms in end-to-end encrypted communication systems [7, 26, 33], and some national ISPs have temporarily blocked the protocol [32]. Throughout this controversy, Apple has consistently maintained that iMessage encryption is end-to-end and that even Apple cannot recover the plaintext for messages transmitted through its servers [10].

Given iMessage’s large installed base and the high stakes riding on its confidentiality, one might expect iMessage to have received critical attention from the research community. Surprisingly, there has been very little analysis of the system, in large part due to the fact that Apple has declined to publish the details of iMessage’s encryption protocol. In this paper we aim to remedy this situation. Specifically, we attempt to answer the following question: how secure is Apple iMessage?

Our contributions. In this work we analyze the iMessage protocol and identify several weaknesses that an attacker may use to decrypt iMessages and attachments. While these flaws do not render iMessage completely insecure, some flaws reduce the level of security to that of the TLS encryption used to secure communications between end-user devices and Apple’s servers. This finding is surprising given the protection claims advertised by Apple [10]. Moreover, we determine that the flaws we detect in iMessage may have implications for other aspects of Apple’s ecosystem, as we discuss below.

To perform our analysis, we derived a specification for iMessage by conducting a partial black-box reverse engineering of the protocol as implemented on multiple iOS and OS X devices. Our efforts extend a high-level protocol overview published by Apple [9] and two existing partial reverse-engineering efforts [1, 34]. Armed with a protocol specification, we conducted manual cryptanal-

ysis of the system. Specifically, we tried to determine the system’s resilience to both back-end infrastructure attacks and more restricted attacks that subvert only client-local networks.

Our analysis uncovered several previously unreported vulnerabilities in the iMessage protocol. Most significantly, we identified a *practical* adaptive chosen ciphertext attack on the iMessage encryption mechanism that allows us to retrospectively decrypt certain iMessage payloads and attachments, provided that a single Sender or Recipient device is online. To validate this finding, we implemented a proof of concept exploit against our own test devices and show that the attack can be conducted remotely (and silently) against any party with an online device. This exploit is non-trivial and required us to develop novel exploit techniques, including a new chosen ciphertext attack that operates against ciphertexts containing gzip compressed data. We refer to this technique as a *gzip format oracle* attack, and we believe it may have applications to other encryption protocols. We discuss the details of this attack in §5.

We also demonstrate weaknesses in the device registration and key distribution mechanisms of iMessage. One weakness we exploit has been identified by the reverse engineering efforts in [34], while another is novel. As they are not the main result of this work, we include them in Appendix A for completeness.

Overall, our determination is that while iMessage’s end-to-end encryption protocol is an improvement over systems that use encryption on network traffic only (e.g., Google Hangouts), messages sent through iMessage may not be secure against sophisticated adversaries. Our results show that an attacker who obtains iMessage ciphertexts can, at least for some types of messages, *retrospectively* decrypt traffic. Because Apple stores encrypted, undelivered messages on its servers and retains them for up to 30 days, such messages are vulnerable to any party who can obtain access to this infrastructure, e.g., via court order [11] or by compromising Apple’s globally-distributed server infrastructure [36]. Similarly, an attacker who can intercept TLS using a stolen certificate may be able to intercept iMessages on certain versions of iOS and Mac OS X that do not employ certificate pinning on Apple Push Network Services (APNs) connections.

Given the wide deployment of iMessage, and the attention paid to iMessage by national governments, these threats do not seem unrealistic. Fortunately, the vulnerabilities we discovered in iMessage are relatively straightforward to repair. In the final section of this paper, we offer a set of mitigations that will restore strong cryptographic security to the iMessage protocol. Some of these are included in iOS 9.3 and Mac OS X 10.11.4, which shipped in March 2016.

Other uses of the iMessage encryption protocol. While

our work primarily considers the iMessage instant messaging system, we note that the vulnerabilities identified here go beyond iMessage. Apple documentation notes that Apple’s “Handoff” service, which transmits personal data between Apple devices over Bluetooth Low Energy, encrypts messages “in a similar fashion to iMessage” [9]. This raises the possibility that our attacks on iMessage encryption may also affect inter-device communication channels used between Apple devices. Attacks on this channel are particularly concerning because these functions are turned on by default in many new Apple devices. We did not investigate these attack vectors in this work but subsequent discussions with Apple have confirmed that Apple uses the same encryption implementation to secure both iMessage and inter-device communications. Thus, securing these channels is one side effect of the mitigations we propose in §7.

1.1 Responsible disclosure

In November 2015 we delivered a summary of the results in this paper to Apple. Apple acknowledged the vulnerability in §5 and has initiated substantial repairs to the iMessage system. These repairs include: enforcing certificate pinning across all channels used by iMessage,¹ removing compression from the iMessage composition (for attachment messages), and developing a fix based on our proposed “duplicate ciphertext detection” mitigation (see §7). Apple has also made changes to the use of iMessage in inter-device communications such as Hand-off, although the company has declined to share the details with us. The repairs are included in iOS 9.3 and OS X 10.11.4, which shipped in March 2016.

1.2 Attack Model

Our attacks in §5 require the ability to obtain iMessage ciphertexts sent to or received by a client. Because Apple Push Network Services (APNs) uses TLS to transmit encrypted messages to Apple’s back-end servers, exploiting iMessage requires either access to data from Apple’s servers or a forged TLS certificate. We stress that while this is a strong assumption, it is the appropriate threat model for considering end-to-end encrypted protocols.

A more interesting objection to this threat model is the perception that iMessage might be too weak to satisfy it. For example, in 2013 Raynal *et al.* pointed out a simple attack on Apple’s key distribution that enables a TLS MITM attacker to replace the public key of a recipient with an attacker-chosen key [34]. One finding of this work is that as of December 2015 such attacks have been entirely mitigated by Apple through the addition of

¹This feature was added to OS X 10.11 in December, as a result of our notification.

certificate pinning on key server connections (see Appendix A). More fundamentally, however, such attacks are *prospective* – in the sense that they require the attacker to target a particular individual before the individual begins communicating. By contrast, the attacks we describe in this paper are *retrospective*. They can be run against any stored message content, at any point subsequent to communication, provided that one target device remains online. Moreover, unlike previous attacks which require access to the target’s local network, our attacks may be run remotely through Apple’s infrastructure.

2 The iMessage Protocol

To obtain the full iMessage specification, we began with the security overview provided by Apple, as well as detailed previous software reverse-engineering efforts conducted by Raynal [34] and others [1]. While these previous results provide some details of the protocol, they omit key details of the encryption mechanism, as well as the complete key registration and notification mechanisms. We conducted additional black-box reverse engineering efforts to recover these elements. Specifically, we analyzed and modified protocol exchanges to and from several jailbroken and non-jailbroken Apple devices.² In conformity to Apple’s terms of service, we did not perform any software decompilation.

2.1 System overview

iMessage clients. iMessage clients comprise several pieces of software running on end-user devices. On iOS and OS X devices, the primary user-facing component is the Messages application. On OS X computers, this application interacts with at least three daemons: apsd, the daemon responsible for pushing and pulling application traffic over the Apple Push Notification Service (APNs) channel; imagent, a daemon that pulls notifications even if Messages is closed; and identitieservicesd, a daemon which maintains a cache of other users’ keys. iOS devices also contain an apsd daemon, while other daemons handle the task of managing identities.

Apple services. iMessage clients interact with multiple back-end services operated by Apple and its partners. We focus on the two most relevant to our attack. The Apple directory service (IDS, also known as ESS) maintains a mapping between user identities and public keys and is responsible for distributing user public keys on request. iMessage content is transmitted via the Apple Push Notification Service (APNs). Long iMessages and attachments are transmitted by uploading them to the iCloud

²In this analysis we considered iOS 6, 8, and 9 devices, as well as Mac clients running OS X 10.10.3, 10.10.5, and 10.11.1.

service, which is operated by Apple using both their own servers and virtual servers provisioned on Amazon AWS, Microsoft Azure, and Google’s Cloud Platform.

Identity and registration The basic unit of identity in iMessage is the iCloud account name, which typically consists of an email address or phone number controlled by the user. End-user devices are registered to the iCloud service by associating them with an account. The mapping between client devices and accounts is not one-to-one: a single account may be used across multiple devices, and similarly, multiple accounts can be associated with a single device. We give further information about the registration process in Appendix A.

Message encryption and decryption To transmit a message to some list of Recipient IDs, the Sender’s iMessage client first contacts the IDS to obtain the public key(s) PK_1, \dots, PK_D and a list of APNs push tokens associated with the Sender and Recipient identities.³ It then encodes the Sender and Recipient addresses and plaintext message into a binary plist key-value data structure and compresses this structure using the gzip compression format. The client next generates a 128-bit AES session key K and encrypts the resulting compressed message using AES-CTR with $IV = 1$. This produces a ciphertext c , which is next partitioned as $c = (c_1 \| c_2)$ where c_1 represents the first 101 bytes of c . The Sender parses each PK_i to obtain the public encryption key $pk_{E,i}$ and for $i = 1$ to D , calculates $C_i = \text{RSA-OAEP}(pk_{E,i}, K \| c_1)$ and a signature $\sigma_i = \text{ECDSASign}(sk_S, C_i \| c_2)$. For each distinct push token received from IDS, the Sender transmits (C_i, c_2, σ_i) to the APNs server. This process is illustrated in Figure 1.

For each ciphertext, the APNs service delivers the tuple $(ID_{\text{sender}}, ID_{\text{recipient}}, C_i, c_2, \sigma_i)$ to the intended destination. The receiving device contacts IDS to obtain the Sender’s public key PK , parses for the signature verification key vk_S , then verifies the signature σ . If verification succeeds, it decrypts C_i to obtain $K \| c_1$, reconstructs $c = (c_1 \| c_2)$ and decrypts the resulting AES-CTR ciphertext using K . It decompresses the resulting gzip ciphertext, parses the resulting plist to obtain the list of Recipient IDs, and verifies that each of ID_{sender} and $ID_{\text{recipient}}$ are present in this list. If any of the preceding checks fail, or if the Recipient is unable to parse or decompress the resulting message, the receiving device silently aborts processing.

³This list includes one entry for each device registered to each Sender and Recipient ID. The Messages client encrypts the message with each Sender public key to ensure that message transcripts can be read across all of the Sender’s devices.

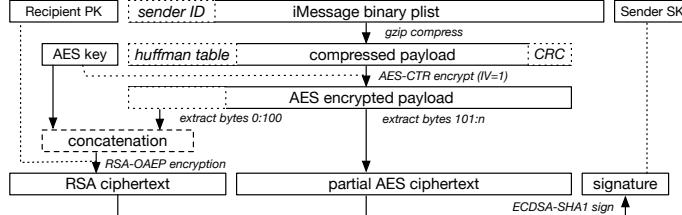

Figure 1: The iMessage encryption mechanism. From the top, each iMessage is encoded in a binary plist key/value structure. The structure encodes a list of Sender and Recipient account identifiers, as well as the message contents. This payload is subsequently gzip compressed, and encrypted under a freshly-generated 128-bit message key using AES in CTR-mode. The AES key and the first 101 bytes of the AES ciphertext are concatenated and are encrypted to each Recipient’s public key using RSA-OAEP. The remaining bytes of the AES ciphertext are concatenated to the RSA ciphertext and the result is signed using ECDSA under the Sender’s registered signing key.

Attachments and long messages For long messages and messages containing file attachments (e.g., images or video), iMessage delivers the encrypted data using a separate mechanism. First, the client generates a 256-bit AES key K' and encrypts the attached data using AES in CTR mode. It next uploads the resulting encrypted document to Apple’s iCloud service and obtains a unique `icloud.com` URL and an access token for the attachment. In the course of this process, the iCloud service may redirect the client to upload the encrypted file to a third-party storage server operated by an outside provider such as Amazon, Microsoft or Google. Having uploaded the attachment, the client now constructs a standard iMessage plist containing the URL and access token, the key K' , and a SHA1 hash of the encrypted document. This plist, which may also include normal message text, is encrypted and transmitted to the Recipient using the standard message encryption mechanism. Upon receiving and decrypting the message, the Recipient downloads the attachment using the provided URL and access token, verifies that the provided hash matches the received attachment, and decrypts the attachment using K' .

3 Security goals & Threat model

Apple has stated that iMessage is an end-to-end encryption protocol that should be secure against all attackers that do not have control of Apple’s network. We base our threat model on a recent survey on secure messaging by Unger *et al.* [38]. This threat model includes the following attackers:

Local Adversary. This includes an attacker with control over local networks, either on the Sender or Recipient side of the connection.

Global Adversary. An attacker controlling large segments of the Internet, such as powerful nation states

or large Internet service providers.

Network operator. Apple operates centralized infrastructure for both public key distribution and message transmission/storage. Potential adversaries include Apple, a government, or a malicious party with access to Apple’s servers.

Each of these attackers may be active or passive. A passive attacker simply observes traffic and does not seek to alter or inject its own messages. An active attacker may issue arbitrary messages to any party. In many cases, these adversary classes may interact. As in [38] we assume that adversaries also have access to the messaging system and can use the system to register accounts and transmit messages as normal participants. We also assume that the endpoints in the conversation are secure.

4 High-level Protocol Analysis

An initial analysis of the iMessage specification shows that the protocol suffers from a number of defects. In this section we briefly detail several of these limitations. In the following sections we focus on specific, exploitable flaws in the encryption mechanism.

Key server and registration iMessage key management uses a centralized directory server (IDS) which is operated by Apple. This server represents a single point of compromise for the iMessage system. Apple, and any attacker capable of compromising the server, can use this server to perform a man-in-the-middle attack and obtain complete decryption of iMessages. The current generation of iMessage clients do not provide any means for users to compare or verify the authenticity of keys received from the server.

Of more concern, Apple’s “new device registration” mechanism does not include a robust mechanism for notifying users when new devices are registered on their

Figure 2: Example of a simple ciphertext replay.

account. This mechanism is triggered by an Apple push message, which in turn triggers a query to an Apple-operated server. Our analysis shows that these protections are fragile; in Appendix A we implement attacks against both the key server and the new device registration process.

Lack of forward secrecy iMessage does not provide any forward secrecy mechanism for transmitted messages. This is due to the fact that iMessage encryption keys are long-lived and are not replaced automatically through any form of automated process. This exposes users to the risk that a stolen device may be used to decrypt captured past traffic.

Moreover, the use of long term keys for encryption can increase the impact of other vulnerabilities in the system. For example, in §5, we demonstrate an active attack on iMessage encryption that exposes current iMessage users to decryption of past traffic. The risk of such attacks would be greatly mitigated if iMessage clients periodically generated fresh encryption keys. See §7 for proposed mitigations.

Replay and reflection attacks The iMessage encryption protocol does not incorporate any mechanism to prevent replay or reflection of captured ciphertexts, leading to the possibility that an attacker can falsify conversation transcripts as illustrated in Figure 2. A more serious concern is the possibility that an attacker, upon physically capturing a device, may replay previously captured traffic to the device and thus obtain the plaintext.

Lack of certificate pinning on older iOS versions iMessage clients interact with many Apple servers. As of December 2015, Apple has activated certificate pinning on both APNs and ESS/IDS connections in iOS 9 and OS X 10.11. This eliminates a serious attack noted by Raynal *et al.* [34] in which an MITM attacker who controls the Sender’s local network connection and possesses an Apple certificate can intercept calls to the ESS/IDS key server and substitute chosen encryption keys for any Recipient (see Appendix A for further details). We note that

devices running iOS 8 (and earlier) or versions of OS X released prior to December 2015 may still be vulnerable to such attacks. For example, at the time of our initial disclosure in November 2015 to Apple, pinning was not present in OS X 10.11.

Non-standard encryption iMessage encryption does not conform to best cryptographic practices and generally seems *ad hoc*. The protocol (see Figure 1) insecurely composes a collection of secure primitives, including RSA, AES and ECDSA. Most critically, iMessage does not use a proper authenticated symmetric encryption algorithm and instead relies on a digital signature to prevent tampering. Unfortunately it is well known that in the multi-user setting this approach may not be sound [21]. In the following sections, we show that an on-path attacker can replace the signature on a given message with that of another party. This vulnerability gives rise to a *practical* chosen ciphertext attack that recovers the full contents of some messages.

5 Attacks on the Encryption Mechanism

In this section we describe a practical attack on the iMessage encryption mechanism (Figure 1) that allows an attacker to completely decrypt certain messages.

5.1 Attack setting

Our attack assumes that an adversary can recover encrypted iMessage payloads and subsequently access the iMessage infrastructure in the manner of a normal user. The first requirement implies one of two conditions: in condition (1) the attacker is on-path and capable of intercepting encrypted iMessage payloads sent from a client to Apple’s Push Notification Service (APNs) servers. Since the APNs protocol employs TLS to secure connections between the client and APNs server, this attacker must possess some means to bypass the TLS encryption layer; we discuss TLS interception in more detail in Appendix B. In condition (2) the attacker can recover iMessage ciphertexts from within Apple’s network. This requires either a compromise of Apple’s infrastructure, a rogue employee, or legal compulsion. Figure 3 describes the network flow of a single iMessage, along with potential attacker locations.

5.2 Attack overview

There are two stages of the attack. The first exploits a weakness in the design of the iMessage encryption composition: namely, that iMessage does not properly authenticate the symmetrically encrypted portion of the message payload. In a properly-designed composition,

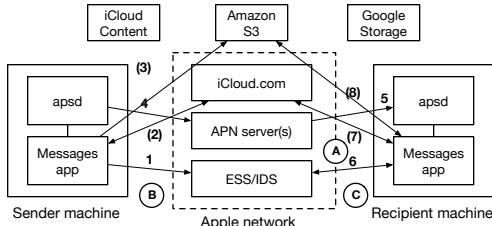

Figure 3: The process of sending an iMessage through the APNS network. The steps are as follows: (1) The Sender contacts ESS/IDS to obtain the public keys for each Recipient; (2) (*optional*) the Sender contacts iCloud to upload an attachment; (3) (*optional*) the Sender uploads the encrypted attachment to an outside storage provider as directed by iCloud; (4) the Sender’s apsd instance transmits the encrypted iMessage payload to Apple’s APNs server; (5) Apple delivers the payload to a Recipient; (6) the Recipient contacts ESS/IDS to obtain the Sender’s public key; (7) (*optional*) the Recipient contacts iCloud if an attachment is present; (8) (*optional*) the Recipient downloads the encrypted attachment from an outside storage provider. Potential attacker locations are labeled A, B and C.

this section of the ciphertext would be authenticated using a MAC in generic composition [14] or via an AEAD mode of operation. Apple, instead, relies on an ECDSA signature to guarantee the authenticity of this ciphertext. In practice, a signature is insufficient to prevent an attacker from mauling the ciphertext since an on-path attacker can simply replace the existing signature with a new signature using a signing key from an account controlled by the attacker. In practice, the actual attack is slightly more complex; the first phase includes additional operations to defeat a countermeasure in the decryption mechanism, which we discuss below.

The second stage of the attack leverages the ability to modify the AES ciphertext (specifically, the section not contained within the RSA ciphertext). This phase consists of an adaptive chosen ciphertext attack exploiting the structure of the underlying plaintexts. The attack repeatedly modifies the ciphertext and sends it to either the Sender or a Recipient for decryption. If the attacker can determine if decryption and parsing were successful on the target device, she can gradually recover the underlying iMessage payload.

The attack specifics are reminiscent of Vaudenay’s padding oracle attack [40], but relies on the usage of *compression* within the iMessage protocol. Specifically, our attack takes advantage of the 32-bit CRC checksum, computed over the pre-compressed message, incorporated into gzip compressed ciphertexts. Since CRCs are

linear under XOR but the compression function is not, we can verify guesses about message content by editing the compressed, encrypted message and testing if the corresponding correction to the CRC results in a valid message.⁴

5.3 A format oracle attack for gzip compression

The gzip format [23] uses DEFLATE compression which itself combines LZ77 [41] and Huffman coding to efficiently compress common data types. The format supports both static and dynamically-generated Huffman tables, though most encoders use dynamic tables for all but the shortest messages. To compress a message, a CRC32 C is calculated over the uncompressed input. Next, the encoder identifies repeated strings and replaces each repeated instance with a tuple of the form $\langle length, backwards\ distance \rangle$, where distance indicates the relative position of the previous instance of the string. The input is encoded using an alphabet of 286 symbols, comprising the 256 byte literals, an end-of-block (EOB) symbol, and 29 string replacement length values.⁵ If dynamic generation is selected, a Huffman table T is calculated using the resulting text as a basis (for static tables, $T = \epsilon$), and the text is Huffman coded into a string of variable-length symbols $S = (s_1, \dots, s_N)$ where string replacement symbols are internally partitioned into a pair $\langle length, distance \rangle$. The resulting compressed message consists of (T, S, C) . On decompression the process is reversed and the CRC of the resulting string is compared to C . If any step fails, the decompressor outputs \perp .

Attack intuition. Our attack assumes that the attacker has intercepted a gzip compressed message encrypted using an unauthenticated stream cipher and that we have access to a decryption oracle that returns 1 if and only if the message decrypts and successfully decompresses. Our goal is to recover a substantial fraction of the plaintext message.

For clarity, we assume the attacker knows the Huffman table T and the length in bits L of the uncompressed input. We further assume the attacker knows the exact location in the ciphertext corresponding to some (unknown) ℓ -bit Huffman symbol s that she wishes to recover, as well as the position of the corresponding decoded literal in the uncompressed text. These are simplifying assumptions and we will remove them as we proceed.

Given a ciphertext c , our attack works by first selecting a mask $M \in \{0, 1\}^\ell, M \neq 0^\ell$ and perturbing the ci-

⁴Were the compression function and CRC both linear, the edit to the CRC and compressed text would always cancel.

⁵A separate Huffman table is used to encode backwards distances.

phertext such that the underlying symbol s will decrypt to $s' = s \oplus M$. This is done by *xoring* M into the ciphertext at the appropriate location. Let $\text{decode}(T, s)$ and $\text{decode}(T, s')$ represent the Huffman decoding of s and s' respectively, and let repeats be a boolean variable that is true if and only if s (resp. s') is repeated subsequently via a DEFLATE string replacement reference. The potential values of these three variables can be categorized into the following seven cases:

Case	$\text{decode}(T, s)$	$\text{decode}(T, s \oplus M)$	repeats
1	[0, 255]	[0, 255]	False
2	[0, 255]	[0, 255]	True
3	[0, 255]	[256, 285]	(either)
4	[0, 255]	\perp	(either)
5	[256, 285]	[0, 255]	(either)
6	[256, 285]	[256, 285]	(either)
7	[256, 285]	\perp	(either)

In the following paragraphs, we consider the outcome of our experiment for each of the cases above.

CASE 1: In this case, when the attacker submits the mangled ciphertext to the decryption oracle, the oracle will internally decode a result that differs from the original input string in exactly one byte position: the position corresponding to symbol s' . However, with overwhelming probability, the CRC C' of the decompressed string will not match C and cause the oracle to output 0.

Because CRC is linear under XOR, the attacker may correct the encrypted value C by further mauling the ciphertext. Let d indicate the bit position of the symbol associated with s (resp. s') in the decoded message. For each $i \in \{0, 1\}^8$ the attacker *xors* the string $\bar{C} = \text{CRC}(0^d || i || 0^{L-d}) \oplus \text{CRC}(0^L)$ with the ciphertext at the known location of C and submits each of the resulting ciphertexts for decryption. Since we have that $\text{decode}(T, s') \in [0, 255]$, one of these tests will always result in a successful CRC comparison.

Upon receiving a successful result from the decryption oracle, the attacker now examines the Huffman table T to identify candidate symbols s for which relation $\text{decode}(T, s \oplus M) = \text{decode}(T, s) \oplus i$ holds. If the attacker cannot identify a unique solution for s , she may select a new $M' \neq M \neq 0^\ell$ and repeat the procedure described above until she has uniquely identified s . The attacker can now increment her position in the ciphertext by ℓ bits and repeat this process to obtain the next plaintext symbol.

If this experiment is unsuccessful, it indicates that the ciphertext is not in Case 1 from the above table. To determine which case applies, the attacker must conduct additional experiments as described below. Sometimes recovery of the symbol s will not be feasible at all; when this occurs, the attacker must simply continue to the next symbol in S . Occasionally, the adversary may still be able to recover s at some additional cost.

CASE 2: In this case, the symbol represented by s (resp. s') is referenced by one or more subsequent instances of DEFLATE string repetition. The practical impact is that modifying s will produce an identical alteration at two or more positions in the decoded string and with high probability none of the experiments indicated for Case 1 will succeed.

In some circumstances, it may be cost effective for the attacker to skip s and simply move on to the next symbol in S . Alternatively, the attacker can experimentally modify the CRC to indicate the same alteration at *all* positions that could be affected by modifying s . Since the attacker does not know the locations at which s is repeated or the number of such locations, this requires the attacker to submit many candidate ciphertexts to the oracle, one for each possible set of locations where s may repeat. In the event that s (resp. s') is repeated only once, this requires the attacker to issue $2^8 \cdot (L - d)/8$ queries to the oracle (one for each value of i and for each possible location for the repeated value of s'). This may be feasible for reasonably short strings.

CASES 3-4: In these cases, the original decoding of s was a byte literal, but the decoding of s' is either an invalid symbol or a special symbol (EOB or string replacement symbol). The former case always results in decompressor failure, while the latter will typically cause the decoded string to differ from the original input at multiple locations, resulting (with high probability) in a CRC comparison failure that will not be corrected by the procedure described above.

To address these cases, the attacker may select a new mask $M' \neq M \neq 0^\ell$ and repeat the complete experiment described above. Depending on the structure of the Huffman table T , and provided that $s \in [0, 255]$, the new result $s \oplus M'$ may produce an outcome that satisfies the conditions of cases (1) or (2).⁶

CASES 5-7: These cases occur when the original symbol represented by $\text{decode}(T, s)$ is a string replacement or EOB symbol. In most instances, replacing s with $(s \oplus M)$ produces a decoded string that differs from the original in many positions, making it challenging for the attacker to repair the CRC. If s decodes to a string replacement token, and the replacement reference points to a location that the attacker has already recovered, it may be possible for the attacker to detect the alteration using the technique described under Case 2. Otherwise the attacker must skip s and move on to the next symbol in S .

Recovering the unknowns. The procedure described so far requires the attacker to know the Huffman table T , the

⁶In principle, this approach might require as many as $2^8 \cdot 2^{|M|} = 2^{8+\ell}$ decryption queries to obtain a successful result, or rule out these cases. In practice, however, the number of candidate mask values M' is likely to be much more limited.

length of the uncompressed message L , the location and length of the symbol s , and the byte index of the corresponding decompressed literal. In practice many of these quantities may be determined experimentally by iterating through candidate values for L, ℓ, k and the symbol position. This requires the attacker to issue many candidate decryption requests until one succeeds. In the case of iMessage attachment messages, the length L is fixed and an attacker can generate a representative corpus of messages offline and easily estimate the other parameters *without* oracle queries.

Recovering the Huffman table is more challenging. If the message is encoded using a static table, then the table is known to the attacker. However, if T is dynamically generated, then the attacker learns only the relation $\text{decode}(T, s \oplus M) = \text{decode}(T, s) \oplus i$, but has no clear way of learning s or $\text{decode}(T, s)$. Nonetheless, it might still be possible to recover enough information from these relations to recover the value of the underlying literals.

However, in iMessage this proves unnecessary as we take advantage of iMessage’s structure to recover a large fraction of the dynamic table T . iMessage payloads containing attachments embed a URL within the encrypted message, requests to which can be monitored (described below). In this way, we learn the file path and/or hostname indicated by the plaintext URL within each ciphertext. Given this information, and by mauling individual symbols s contained within the URL string, the attacker can recover the value $\text{decode}(T, s \oplus M)$ for many different values of M . This allows the attacker to identify a relative-distance map of a portion of the Huffman tree. This proves sufficient to recover much of the Huffman table T .

Detecting successful decryption. Our attack assumes that the attacker can detect successful decryption of a modified ciphertext. To simplify this assumption, we focused on messages containing attachments, such as images and videos. These messages include a URL for downloading the attachment payload, as well as a 256-bit AES key to be used in decrypting the attachment. When an iMessage client correctly decrypts such a message, it automatically initiates an HTTPS POST request to the provided URL. A local network attacker can view (and intercept) this request to determine whether decryption has occurred. Moreover, if the attacker blocks the connection, the device will retry several times and then silently abort. Since the client provides no indication to the user that a message has been received, this admits silent decryption of ciphertexts.

This technique can also be extended to situations where the attacker is not on the target device’s local network. By mauling the URL field to change the requested hostname (e.g., from `icloud.com` to a domain that the

attacker controls), the attacker can simply direct the target device to issues HTTPS to a machine that the attacker controls. This allows the attacker to conduct the attack remotely by transmitting ciphertexts through Apple’s APNs network, at which point she obtains the full HTTPS POST request from the target device. Since the attacker controls the request domain, there is no need to MITM the TLS connection.⁷

5.4 An Attack on Attachment Messages

Having provided an overview of the attack components, we will describe each individual step of the complete attack. This attack scenario assumes that a target Sender has transmitted an attachment-bearing message to one or more online receivers, and the attacker has the ability to monitor the local network connection (and intercept TLS connections) on one of the Sender or Recipient devices.

Step 1. Removing and replacing the iMessage signature.

Each iMessage is authenticated using an ECDSA signature, formulated using the private key of the iMessage Sender. This signature prevents the attacker from directly tampering with the message. However, a limitation of using signatures for authenticity is that they do not prevent ciphertext mauling when an attacker controls another account in the system. An attacker who intercepts a signed iMessage may simply remove the existing signature from the message and re-sign the message using a different key, corresponding to a separate account that the attacker controls.⁸ The attacker now transmits the resulting encrypted payload, signed and delivered as though from a different Sender address. The signature replacement process is illustrated in Figure 4.

In practice, simply replacing the signature on a message proves insufficient. In iMessage, a full list of Sender and Recipient addresses is specified both in the unencrypted metadata for the message *and* in the encrypted message payload. Upon decrypting each message, iMessage clients verify that the message was received from one of the accounts listed in the Sender/Recipient list, and silently abort processing if this condition does not hold.⁹ While it is trivial to replace the unencrypted Sender field, replacing encrypted envelope information is more challenging. Fortunately, in most cases this field of the iMessage plist is contained within the malleable

⁷The current versions of Apple’s Messages client do not enforce that this URL contains `icloud.com` and will connect to any hostname provided in the URL. Similarly, the Messages client does not pin certificates for the HTTPS connection.

⁸On Mac OS X, iMessage signing keys are readily accessible from the Apple Keychain.

⁹Based on our experiments, the participant list does not appear to be ordered, or to distinguish between Sender and Recipients. It is sufficient that the Sender identity appears somewhere in this list.

AES-CTR ciphertext, and we are able to alter the contents of the Sender/Recipient list so that it contains the identity of the replacement Sender account.

Step 2. Altering the Sender identity.

To alter the Sender identity, the attacker must selectively maul the AES-CTR ciphertext to change specific bytes of the Sender/Recipient plist field to incorporate the new Sender identity she is using to transmit the mauled ciphertext. This is challenging for several reasons.

First, the initial 101 bytes of the AES ciphertext are stored within the RSA-OAEP ciphertext, which is strongly non-malleable. Thus we are restricted to altering the subsequent bytes of the ciphertext. Fortunately, the binary plist key-value data structure is *top heavy*, in that it stores a list of all key values in the data structure prior to listing the values associated with each key. In practice, this ensures that the relevant Sender identity appears some distance into the data structure. Moreover, the application of gzip compression produces additional header information, including (in many cases) a dynamic Huffman table. In all of the cases we observed, the symbols encoding the Sender identity are located subsequent to the first 101 bytes, and are therefore not included within the OAEP ciphertext.

The use of gzip compression somewhat complicates the attack. Rather than mauling uncompressed ASCII bytes, the attacker must alter a set of compressed Huffman symbols which have been encoded using a (dynamically-generated) table T that the attacker does not know. Fortunately, the attacker knows the original identity of the Sender, as this value is transmitted in the unencrypted apsd metadata. Moreover, in all iMessage clients that we examined, the Sender identity is transmitted as the first string in the Sender/Recipient list, which – due to iMessage’s predictable format – appears in a relatively restricted range of positions within the ciphertext. Even with this knowledge, altering the Sender ID involves a large component of guessing. The attacker first estimates the location of the start of the Sender/Recipient list, then selectively mauls the appropriate portions of the AES ciphertext, while simultaneously updating the CRC to contain a guess for the modified (decoded) symbol. This is a time consuming process, since the attacker must simultaneously identify (1) the appropriate location in the ciphertext for the symbol she wishes to modify and (2) a modification that causes the symbol to change to the required symbol. The target device will silently ignore any incorrect guesses and will proceed with attachment download only when the mauled Sender ID in the plist is equal to the Sender ID from which the attacker is transmitting.

To simplify the attack, the attacker may restrict her at-

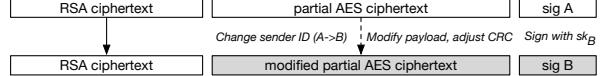

Figure 4: Modifying the partial AES ciphertext, including the Sender ID and CRC, and replacing the signature with a new signature corresponding to an account (and signing key) we control.

tention to addresses that differ from the original Sender ID in at most one symbol position. This is accomplished by registering new iCloud addresses that are “one off” from the target Sender identity. To increase the likelihood that we will succeed in altering the Sender account to match one that we have selected, we register multiple new Sender identities that are near matches to the original identity. For each attempt at mauling the ciphertext, we must also “repair” the CRC by guessing the effect of our changes on the decompressed message.

In our experiments, we found that an email address of the form `abcdef@icloud.com` could be efficiently modified to a new account of the form `abcdef@i8loud.com` in approximately 2^{10} decryption queries to a target device.¹⁰ Since Huffman tables vary between messages, we cannot mutate every message to the same domain, and thus we need to control several variants of `icloud.com` for this strategy to be successful in all cases. Fortunately, the edits are predictable and our simulations indicate that we require only one domain to recover most messages.

A side effect of this modification is that, due to string replacement in gzip, the attachment URL is simultaneously altered to point to `i8loud.com`, which means that attachment HTTPS POST requests are sent to a computer under our control. This makes it possible to conduct the attack remotely.

Step 3. Recovering the Huffman table. Given the ability to intercept the attachment request POST URL to `icloud.com`, we now recover information about the dynamic Huffman tree T used in the message. The attachment path consists of a string of alphanumeric digits, which in most instances are encoded as Huffman symbols of length $\ell \in [4, 8]$.

By intercepting the HTTPS connection to `icloud.com`, the attacker can view the decoded URL path and systematically maul each Huffman symbol in turn, repairing the CRC using the technique described in the previous subsection. This allows the attacker to gradually recover a portion of the Huffman tree (Figure 5). In practice, the attacker is able to recover only a subset of the tree, however, because the iMessage client will silently fail on any URL that

¹⁰These email addresses are examples and not the real email addresses we used in our experiments.

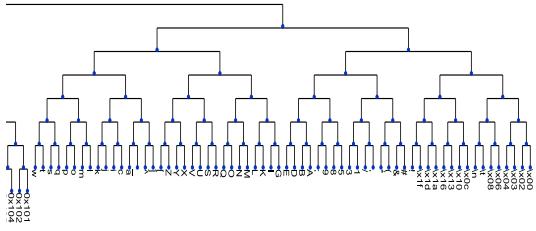

Figure 5: Fragment of a Huffman tree from an attachment iMessage.

contains characters outside the allowed URL character set.¹¹ Fortunately this set includes most printable alphanumeric characters.

Our implementation recovers a portion of the Huffman tree that is sufficient to identify the characters in the set $0 - 9, A - F$. Our experiments indicate that this phase of the process requires an average 2^{17} decryption requests and a maximum of 2^{19} .

Step 4. Recovering the attachment encryption key. When an iMessage contains an attachment, the message embeds a 256-bit AES key that can be used to decrypt the attachment contents. This key is encoded as 64 ASCII hexadecimal characters and is contained within a field named `decryption-key`. An attacker with oracle access to a target device, and information on the Huffman table T , can now systematically recover bytes from this key. Upon recovering the key, they can use the intercepted HTTPS request information to download the encrypted attachment and decrypt it using the recovered key.

The approach used in recovering the attachment key is an extension of the general format oracle attack described above. The attacker first searches the ciphertext to identify the first position of the decryption key field. The attacker identifies a mask M (typically a single or double-bit change to the ciphertext) that produces a change in the decoded message at the first position of the encryption key, which is known due to the predictable structure of attachment messages. To identify this change, the attacker “fixes” the CRC to test for each possible result from the decryption key, then learns whether the decryption/decompression process succeeds. To obtain the full key, the attacker repeats this process for each of the 64 hexadecimal symbols of the encryption key.

This process does not reliably produce every bit of the key, due to some complications described in the general attack description above. Principal among these is the fact that some Huffman symbols represent string replacement tokens rather than byte literals. While it seems

counterintuitive to expect repeated strings within a random key, this occurrence is surprisingly common due to the fact gzip will substitute even short (3 digit) strings. Indeed, on average we encounter 1.9 three-digit repetitions within each key. In this case, we attempt to identify subsequent appearances of the symbol by guessing later replacement locations. If this approach fails, our approach is to simply ignore the symbol and experimentally move forward until we reach the next symbol.

While it is possible to recover a larger fraction of the symbols in the message by issuing more decryption queries (see §6 for a discussion of the tradeoffs), in many cases it is sufficient to simply guess the missing bits of the key offline after recovering an encrypted attachment. In practice, the entropy of the missing sections is usually much lower than would be indicated by the number of missing bits, since in most cases the replacement string is drawn from either the URL field or earlier sections of the key, both of which are known to the attacker.

Step 5. Recovering the message contents. Each attachment message may also contain message text. This text can be read in a manner similar to the way the key is recovered in the previous step, by mauling the message portion of the text and editing the CRC appropriately. This approach takes slightly more effort than the hexadecimal key recovery step, due to the higher number of potential values for each Huffman symbol in the message text.

6 Implementation and Evaluation

6.1 Estimating attack duration

To validate the feasibility of the attack described in §5.4, we implemented a prototype of the gzip format oracle attack in Python and executed it against the Messages client on OS X 10.10.3. Our attack successfully recovered 232 out of 256 key bits after 2^{18} decryption queries to the target device. The main challenge in running the attack was to determine the correct timeout period after which we can be confident that a message has not been successfully decrypted. This timeout period has a substantial impact on the duration of the attack, as we describe below.

Experimental Setup To deliver iMessage payloads to the device, we customized an open-source Python project called `pushproxy` (hereinafter called the proxy) and used it to intercept connections from the device to Apple’s APNs server [3]. This approach models an attacker who can either impersonate or control Apple’s APNs servers. While our attack assumed local network interception and did not send messages through Apple’s

¹¹iMessage does not perform URL coding on disallowed characters.

servers, we note that if an attacker is able to capture messages in transit (by bypassing TLS or by compromising Apple’s servers), the remainder of the attack can in principle be conducted remotely (see the end of §5.3 for details). For ethical and legal reasons, we explicitly chose not to test attacks that relayed messages via Apple’s production servers. Thus all of our attacks were conducted via a local network.

To address the use of TLS on apsd connections, we configured our modified proxy with a forged Apple certificate based on a CA root certificate we created and change `/etc/hosts` to redirect APNs connections intended for Apple towards our local proxy. We generate the forged certificate by installing our root CA on the target system.¹²

To monitor and intercept attachment download requests, we configured an instance of a TLS MITM proxy (`mitmproxy`) using our self-signed root certificate to intercept all outbound requests from the device made via HTTP/HTTPS. When the target device receives an attachment message, it makes two HTTPS POST requests to `{0, ..., 255}-content.icloud.com`. Based on the result of these requests, the device issues a second HTTP GET request to download the actual attachment. In our experiments we block both of the POST requests, ensuring that no indication of the message processing is displayed by the Messages client. For each oracle query, the attack code waits for `mitmproxy` to report an attachment POST request as defined above or, after a set time out, assumes the oracle query resulted in a failed message.

Finally, we created an iMessage account for the attacker that is a single-character edit of the sender’s address (e.g. if the sender is `alice@example.com`, the attacker might be `clice@example.com`). We only generate one such account for the edit we expect to be successful, although a real attacker might register a large corpus of iMessage accounts and thus increase the success probability of this phase of the attack.

Verifying the existence of the oracle To ensure that iMessage behavior is as expected, we conducted a series of tests using hand-generated messages to determine if we were able to detect decryption success or failure on these messages. Our results were sufficient to confirm the vulnerability of §5 and verify iMessage’s behavior sufficiently well that we could construct a simulated oracle for our experiments of §6.2.

Estimating the timeout for failed queries The main goal of our experiment was to determine the maximum

¹²Since OS X 10.10.3 does not include certificate pinning for APNs connections, this allowed us to intercept and inject iMessage ciphertexts.

timeout period after which we can determine that the device has been unable to successfully decrypt and process a message. To determine this, our attack queries the gzip format oracle by sending a candidate message and waiting until it either sees a resulting attachment download (in which case the message decrypted) or some timeout passes. Too long of a timeout results in unreasonable runtimes and too short of a timeout produces false negatives, which lead to incorrect key recovery.

Small scale experiments proved unable to reliably estimate the maximum timeout: the observed wait time distribution seemingly has a long tail and may be dependent on load not encountered in small experiments (e.g. due to failed decryptions). Using the full attack code to find the max timeout, on the other hand, is impractical, since we must run 2^{18} queries, each lasting as long as the timeout. This would take between 18 hours and 3 days depending on the timeout duration we wish to test.

In order to estimate the correct timeout, we ran our attack on the device in tandem with a local instance of the format oracle which, using the recipient’s private key, also decrypts the message and emulates iMessage’s behavior. If the candidate message fails to decrypt against the local oracle, we use a short (400ms) timeout period. If the candidate message decrypts successfully on this local oracle, then we wait an unbounded amount of time for the oracle query and record the necessary delay. We stress that this local-oracle approach was used only to speed up the process of finding the maximum delay; the full attack can be conducted *without* knowledge of the private key.

Results We ran our main experiment on a real message intercepted using the proxy. It recovers 232 out of 256 key bits in 2^{18} queries and took 35 hours to run. The maximum observed delay between a query and the resulting download request was 903ms, while the average was 390ms with a standard deviation of 100ms. Based on this data, and without considering further optimizations, we estimate that the full attack would require approximately 73 hours to run if we naively used 1 second as the timeout.

Optimizing runtime The obvious approach to optimizing our attack is to reduce the timeout period to the minimum period that iMessage requires to successfully process and queue a message. Through experiments, we determined this to be approximately 400ms. Thus one avenue to optimizing the experiment is to reduce the timeout period for all messages to 400ms, using the assumption that a successful experiment may result in a “late” download. Since we would not be able to neatly determine the specific message query that occasioned the

download, we would need to temporarily increase the delay period and “backtrack” by repeating the most recent, e.g., 10 queries to determine which one caused the download. Because the issue is patched and further exploration difficult, we have elected not to implement these optimizations.

Because successful queries are quite sparse,¹³ this does not meaningfully affect the number of queries needed for the attack. In our estimation, these techniques will reduce the cost of the full attack down to 35 hours and requires only straightforward modifications to our proof of concept code.

A second optimization is to run the attack against multiple devices with attack queries split and conducted in parallel against them. For n devices, the attack time is reduced by approximately a factor of n . As many users may have 2 or 3 devices, this can offer substantial reductions.

Finally, we can reduce the raw number of queries needed to mount the attack by refining the gzip-oracle attack techniques. In particular, we can reduce the number of queries needed to recover the Huffman table by inferring the structure of the tree from the partial information we have and from the observation that the Huffman trees fall within a fairly limited range of distributions. In particular we note that for the Huffman trees used in gzip, recovering the symbol lengths alone is sufficient to recover the tree. An approach drawing from techniques in machine learning to recover the Huffman table given only a few queries, the distribution of such tables, and known partial information could offer substantial improvements. We leave a full exploration of these optimizations to future work.

6.2 Simulation results

Although we have conducted our attack on iMessage, we have not explored its effectiveness with a large range of messages. Given the time it takes to run an experiment, doing so is prohibitive. We opt instead to simulate our results.

Simulation To evaluate the overall effectiveness of our format oracle attack, we constructed a simulated message generator and decryption oracle. Messages produced by our generator are distributed identically to real attachment-bearing messages, but contain randomly-generated strings in place of the filename, URL path, Sender and Recipient addresses, decryption key, and “signature” (hash) fields. The decryption oracle emulates the iMessage client’s parsing of the inner binary plist.

¹³Out of the 2^{18} , only 418 were successful.

For performance, it skips encryption and decryption.¹⁴ Decompression is done using Python’s `gzip` module, which is a wrapper around `zlib`. We experimentally validate the oracle’s correctness against the transcript of a real attack and against separate messages.

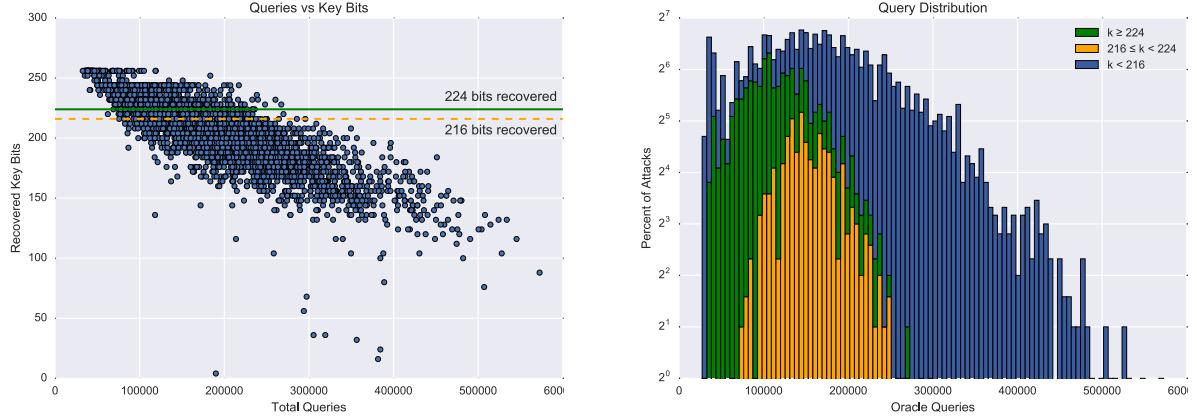

Results We ran our simulated attack on a corpus of 10,000 generated messages and show the results in Figure 6. In all cases, our experiments completed in at most 2^{19} queries, with an average of approximately 2^{17} queries. For 34% of the experiments we ran, our attack was able to recover ≥ 216 bits of the attachment AES key. For 23% of the messages we experimented with, we recovered ≥ 224 bits of the key, enabling rapid brute-force of the remaining bits on commodity hardware.¹⁵

Optimizing success rate Many of the failures we experience in key recovery are caused by issues with string repetition. Recall that repeated substrings in a message are compressed in gzip by replacing all subsequent repetitions of the substrings with a backwards-pointing reference. As a result, editing the canonical location of a substring in the compressed message may cause similar changes to future instances of the same substring in the decompressed message. Our CRC correction for a given location fails to compensate for these later changes because we simply do not know where in the uncompressed message the second instance of the substring appears. As a result, our current attack simply skips these bits.

However, we can address this weakness with only a modest increase in the number of oracle queries. By scanning through the remaining bytes and applying the same CRC correction at each subsequent location in the uncompressed message, we can identify the location of the subsequent instances of the substring. This is efficient mainly for strings that are repeated twice, but our experiments indicate this is the most common case. Note that we do not need to scan through the entire message. As a result of the particular format of the messages, there are only a few points where we can get duplicates: most of the message is in lowercase letters or non-printable characters, whereas the `decryption-key` and `mmcs-url` field (i.e. the locations where repeats cause the most serious issues) are upper case alpha-numeric and hence will not contain repeats from the majority of the other fields. For the experiments described above,

¹⁴Our implementation prevents the attacker from modifying the first 101 bytes of the message, as those are normally contained within the RSA ciphertext. Additionally, the oracle enforces that the alleged Sender identity is included within the `plist`, which is a condition enforced by iMessage.

¹⁵Experiments on an inexpensive Intel Core i7 show that we can recover 32 missing key bits in approximately 7 minutes using an AES-NI implementation. Therefore recovering 40 missing key bits should take approximately 28 hours on a single commodity desktop.

(a) Number of queries vs number of recovered key bits. The orange dashed line represents 216 bits recovered, the solid green line 224.

(b) Distribution of attack length, measured in queries. The high concentration of attacks near zero is due to a rapid failure when it fails to edit the sender email.

Figure 6: Simulation results for the attachment recovery attack.

this would result in a 14% increase in the number of messages for which we can recover 224 bits.

7 Mitigations

Our main recommendation is that Apple should replace the entirety of iMessage with a messaging system that has been properly designed and formally verified. However, we recognize this may not be immediately feasible given the large number of deployed iMessage clients. Thus we divide our recommendations into short-term “patches” that preserve compatibility with existing iMessage clients and long-term recommendations that require breaking changes to the iMessage protocol.

7.1 Immediate mitigations

Duplicate RSA ciphertext detection. The attacks we described in §5 are possible because the unauthenticated AES encryption used by iMessage is malleable and does not provide security under adaptive chosen ciphertext attack, unlike RSA-OAEP encryption [15]. Maintaining a list of all previously-received RSA ciphertexts should prevent these replay and CCA attacks without the need for breaking changes in the protocol. Upon receiving a stale RSA ciphertext, the Recipient would immediately abort decryption. This fix does not prevent all possible replays, given that iMessage accounts may be shared across multiple distinct devices. However, it would substantially reduce the impact of our attacks until a more permanent fix can be implemented. *Note: This modification has been incorporated into iOS 9.3 and Mac OS X*

10.11.4.

Force re-generation of all iMessage keys and destroy message logs. iMessage uses long-term decryption keys and offers no mechanism to provide forward secrecy. If possible, Apple should force all devices to re-generate their iMessage key pairs and destroy previously-held secret keys. In addition, Apple should destroy any archives of encrypted iMessage traffic currently held by the company.

Pin APSD/ESS certificates or sign ESS responses. The current iMessage protocol relies heavily on the security of TLS, both for communications with the key server and as an additional layer of protection for iMessage push traffic. Apple should enhance this security by employing certificate (or public key) pinning within the Messages application and apsd to prevent compromise of these connections. Alternatively, Apple could extend their proprietary signing mechanisms to authenticate key server responses as well as requests.

Reorganize message layout. The current layout of encrypted messages includes approximately 101 bytes of the CTR message within the RSA-OAEP ciphertext, which is resilient to ciphertext malleability attacks. Modifying sender-side code to re-organize the layout of the underlying plist data structure to incorporate the sender and receiver fields within this section of the message would immediately block our attack. Implementing this change requires two significant modifications: (1) Apple would need to disable dynamic construction of Huffman tables within the gzip compression, and (2) restructure the binary plist serialization code to place the sender address first. We stress that this is a fragile patch:

if any portion of the sender ID is left outside of the RSA ciphertext, the ciphertext again becomes vulnerable to mauling. Moreover, this fix will not protect group messages where the list of Recipients is longer than 100 bytes.

7.2 Long term recommendations

Replace the iMessage encryption mechanism. Apple should deprecate the existing iMessage protocol and replace it with a well-studied construction incorporating modern cryptographic primitives, forward secrecy and message authentication (e.g., OTR [17] or the TextSecure/Axolotl protocol [4]). At minimum, Apple should use a modern authenticated cipher mode such as AES-GCM for symmetric encryption. This change alone would eliminate our active attack on iMessage encryption, though it would still not address any weaknesses in the key distribution mechanism. In addition, iMessage should place the protocol versioning information within the public key block and the authenticated portions of the ciphertext, in order to prevent downgrade attacks.

Implement key transparency. While many of the protocol-level attacks described in this paper can be mitigated with protocol changes, iMessage’s dependence on a centralized key server represents an architectural weakness. Apple should take steps to harden iMessage against compromise of the ESS/IDS service, either through the use of key transparency [31] or by exposing key fingerprints to the user for manual verification.

8 Related Work

There are three lines of research related to our work: secure message protocols, attacks on symmetric encryption, and decryption attacks using compression schemes.

Instant messaging has received a great deal of attention from the research community. Borisov et al. introduced OTR [17] and proposed strong properties for messaging, such as per-message forward secrecy and deniability. Frosh et al. analyze descendant protocols such as TextSecure [24]. More recent work has focused on multi-party messaging [25] and improved key exchange deniability [39]. In a related area, Chen *et al.* analyzed push messaging integrations, including Apple push networking [20]. For a survey of secure messaging technologies, see [38].

A number of works have developed attacks on unauthenticated, or poorly authenticated, encryption protocols. In addition to the padding oracle of Vaudenay [40] and later applications [13], padding oracle attacks have been extended to use alternative side channels such as

timing [8, 19]. Some more recent works have proposed attacks on more complex data formats such as XML [27, 30].

Various works have addressed the combination of compression and encryption. Some attacks use knowledge of a relatively small number of bytes in the plaintext to learn information about the compression algorithm and eventually recover an encryption key [16, 37]. Kelsey [28] and others [29, 35] used compression in the (partially) chosen plaintext setting to recover information about plaintexts.

9 Conclusion

In this work we analyzed the security of a popular end-to-end encrypted messaging protocol. Our results help to shed light on the security of deployed messaging systems, and more generally, provide insight into the state of the art in security mechanisms currently deployed by industry. This insight raises questions about the way research results are disseminated and applied in industry and how our community should ensure that widely-used protocols employ best cryptographic practices.

This work leaves several open questions. First, the gzip format oracle attack we describe against iMessage may apply to other protocols as well. For example, OpenPGP encryption (as implemented by GnuPG) [18] also employs gzip and may be vulnerable to similar attacks when it is used for online applications such as instant messaging [2]. Moreover, our attack requires that the adversary have some access to a portion of the decrypted information. We leave to future work the development of a pure “blind” attack on gzip encryption, one that does not require this additional information.

A Attacks on Key Registration

While this work focuses on the retrospective decryption of iMessage payloads, in the course of our reverse engineering we were able to implement attacks on Apple’s key registration infrastructure. The first attack is an implementation of attacks previously noted by Raynal *et al.* [34]. In these attacks, which work only against versions of iOS prior to iOS 9 and Mac devices prior to OS X 10.11.4 (i.e., devices without key pinning), an attacker with a forged Apple TLS certificate can intercept the connection to the Apple key server in order to substitute chosen public keys. Additionally, we find a novel attack against the device registration process that allows an attack with stolen credentials to circumvent existing protection mechanisms.

The protocol for registering a device is shown in Figure 8. The user first establishes a TLS connection to Apple’s IDS server and authenticates using their iCloud credentials. The client generates two separate key pairs: a 1280-bit RSA public key pair (pk_E, sk_E) for use in encrypting and decrypting messages and an ECDSA keypair (vk_S, sk_S) for authenticating messages. The client transmits the public portion of these keys $PK = (pk_E, vk_E)$ to the IDS, which registers it to the

Figure 9: Excerpts from an ESS/IDS directory lookup request (top) and response (bottom). The request address and a portion of the response Push token have been redacted.

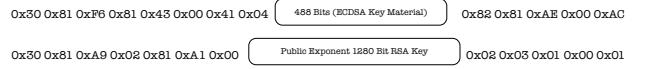

Figure 10: Format of public key payload in ESS server response

user’s iCloud account name. We diagram the full login and registration protocols in Figures 7 and 8. To support multiple devices on a single account, the IDS will store and return all public keys associated with a given account.

A.1 Key Substitution Attack

The Apple key distribution systems are accessed each time a legitimate user wants to send an iMessage to a new Recipient. The Messages client first contacts `query.ess.apple.com` to look up the keys for a given username. In response, the server returns the user’s public key(s), status, and push tokens for addressing APNs communications to the user. A fragment of the request and response is shown in Figure 9.

The `query.ess.apple.com` response message contains public keys, along with push tokens, for each of the devices registered to an account. Each of the key entries is a 332 character long base64 encoded binary payload. When decoded, they take the form shown in Figure 10.

Upon receiving the RSA public key in the above diagram, the Messages client uses this key to encrypt the outgoing iMessage payload. The ECDSA key is not used when sending a message, but is used to verify the integrity of a message when it is received from that user. iMessage clients appear to accept the most recent key delivered by ESS/IDS even if it disagrees with previous entries cached by the device.

Notably, the only security measures embedded in this conversation are authentication fields in the header of the *request*; the server does not sign the response. Thus the authenticity of the response depends entirely on the security of the TLS connection. This seems like an oversight, given that many other fields in the Apple protocols are explicitly authenticated. Worse, in iOS 8 and versions of OS X 10.11 released prior to December 2015, the Messages client does not use certificate pinning to ensure that the connection terminated at an Apple server. Thus an attacker with a stolen TLS root certificate can intercept key requests and substitute their own key as a response. This degrades the security of iMessage to that of TLS.

We implemented this attack by installing a self-signed X.509 root certificate into the local root certificate store of a Mac device. This allowed us to verify that there were no warning mechanisms that might alert a user to the key substitution. By further intercepting messages transmitted via the APNs network, we were able to respond to all key lookup requests with our own attacker key, and subsequently decrypt any iMessages transmitted via the device.

Our experiments demonstrate that iOS 9 is no longer subject to simple key substitution attacks, due to the addition of certificate pinning on TLS connections. This increases the relative impact of our novel decryption attacks. Surprisingly, our experiments demonstrated that OS X 10.11.1 remained vulnerable as of November 2015. We notified Apple of this oversight, and they have added key pinning as of OS X 10.11.13.

A.2 Credential theft

The first message in the registration process, shown in Figure 7, passes the user’s credentials to the `profile.ess.apple.com` server to be verified. As noted in previous sections, OS X 10.10.5 and iOS 8 devices do not employ certificate pinning on this server, and the credentials are sent in plaintext within the TLS connection.¹⁶ By conducting a TLS MITM attack on this connection, we are able to intercept iCloud login credentials. Using this information we can register new iMessage devices to an account, ensuring that we will be able

¹⁶OS X 10.11 devices do not employ certificate pinning on this connection either, but they do not appear to send the credentials in plaintext.

to receive future messages.

Apple’s primary defense against registration of new devices is a notification message that is sent to all previously-registered devices. In order to register a new device to a target account without alerting the victim, we also developed a method to overcome these notification mechanisms. We observed two such mechanisms:

1. Upon registration of a new device, all devices logged into the account receive a push notification over the APNs network. In response, each device initiates the `GetDependantRegistrations` call shown in Figure 8.
2. When an iMessage account is registered to a device that has not previously been registered to that account, a notification email is generated and sent to the account’s registered email.

In the first instance, once the APNs push notification signaling that a `GetDependantRegistrations` call should be executed has arrived at a client, the client will continuously send the request until it receives a response. An active attacker on the victim’s network can simply block all these requests, but this is not sustainable over long periods of time. We discovered that the client is satisfied when it receives any response — even a poorly formatted unreadable one. Thus, an attacker can edit the server response causing it to decode incorrectly. The client will accept this response and terminate the repeated `GetDependantRegistrations` calls. This blocks notifications that would alert the victim to the fact that a new device has been registered to their account. All subsequent iMessage traffic, both incoming and outgoing, will be forwarded to the attack device. Until a user logs out of their iMessage client, logs into a new iMessage client, or manually checks the list of devices associated with their account, they will never notice that their traffic is being forwarded to the attack device.

A.3 Updates in OS X 10.11

The ESS messaging protocol changed in a number of ways with the 10.11 update to OS X. The exchange of credentials for an authorization token has moved to point to `gsa.apple.com` and that connection has certificate pinning implemented. Due to this fact, we are unable to MITM this connection, but attempting to login to an account with bad credentials will result only in a message to that server and an error message displayed on the client. Additionally, there is a message sent to `setup.icloud.com` with a username and password pair in which the password is no longer transmitted in plaintext.

The key substitution attack still worked against OS X 10.11 versions as of November 2015, but the additional certificate pinning of apsd made it more difficult to intercept the message. In order to make sure the attack still functioned properly, we recovered the encrypted payload of the message from the apsd logs and were able to successfully decrypt the message using our own keys. Although we are not able to easily intercept the messages as we could with 10.10.5, this attack still effectively reduces the security of iMessage to that of TLS.

B Bypassing TLS

To execute the attacks described in this paper, the attacker must obtain encrypted iMessages from the APNs link. Since iMessage secures the APNs connection using TLS, this requires the attacker to penetrate to the TLS encryption on the link between Apple and the end-device.

We identified three approaches to bypassing TLS on the APNs connections: (1) Apple, or an attacker with access to Apple’s infrastructure, can intercept the contents of push messages as they transit the APNs servers; (2) on certain iOS and OS X versions that do not include certificate pinning for APNs, an attacker with access to a stolen CA root certificate may be able to conduct an MITM attack on the TLS connection; or (3) on the same versions, an attacker can “sideload” a root certificate on the target device, by briefly taking physical control of it, or convincing a victim to install a root certificate via a malicious email or web page. The latter technique is particularly concerning due to the similarity between Apple’s interface for installing root CAs and other non-critical certificate installation requests that may be presented to the user (see Figure 11). Since some Apple operating systems do not use certificate pinning, installation of a root certificate allows arbitrary interception of both APNs and HTTPS connections.

We identified attacks (2) and (3) as infeasible on all iOS 9 versions due to the inclusion of certificate pinning on APNs connections in that operating system. As of November 2015 when we first notified Apple of the results in this paper, we discovered that the then-current version of OS X 10.11 did not include certificate pinning. In response to our disclosure, Apple added certificate pinning to OS X as of December 2015.

We stress that given the interest in iMessage expressed by nation-states [26], a compromise of CA infrastructure cannot be ruled out. Even without such attacks, there have been several recent examples of CA-signed root or intermediate certificates being issued for use within corporate middle-boxes, primarily for the purposes of enterprise TLS interception [5]. TLS interception may occur even within Apple OS distributions: a recent incident involving iOS 9 allowed ad-blocking software to install a

TLS root certificate [6].

Predicting, Decrypting, and Abusing WPA2/802.11 Group Keys

Abstract

We analyze the generation and management of 802.11 group keys. These keys protect broadcast and multicast Wi-Fi traffic. We discovered several issues and illustrate their importance by decrypting all group (and unicast) traffic of a typical Wi-Fi network.

First we argue that the 802.11 random number generator is flawed by design, and provides an insufficient amount of entropy. This is confirmed by predicting randomly generated group keys on several platforms. We then examine whether group keys are securely transmitted to clients. Here we discover a downgrade attack that forces usage of RC4 to encrypt the group key when transmitted in the 4-way handshake. The per-message RC4 key is the concatenation of a public 16-byte initialization vector with a secret 16-byte key, and the first 256 keystream bytes are dropped. We study this peculiar usage of RC4, and find that capturing 2^{31} handshakes can be sufficient to recover (i.e., decrypt) a 128-bit group key. We also examine whether group traffic is properly isolated from unicast traffic. We find that this is not the case, and show that the group key can be used to inject and decrypt unicast traffic. Finally, we propose and study a new random number generator tailored for 802.11 platforms.

1 Introduction

In the last decennia, Wi-Fi became a de facto standard for medium-range wireless communications. Not only is it widely supported, several new enhancements also make it increasingly more performant. One downside is that (encrypted) traffic can easily be intercepted. As a result, securing Wi-Fi traffic has received considerable attention from the research community. For example, they showed that WEP is utterly broken [11, 42, 4], demonstrated attacks against WPA-TKIP [43, 45, 47, 41], performed security analysis of AES-CCMP [24, 39, 13], studied the security of the 4-way handshake [17, 18, 34], and so on.

However, most research only focuses on the security of pairwise keys and unicast traffic. Group keys and group traffic have been given less attention, if mentioned at all.

In this paper we show that generating and managing group keys is a critical, but underappreciated part, of a modern Wi-Fi network. In particular we investigate the generation of group keys, their transmission to clients, and the isolation between group and unicast traffic. We discovered issues during all these phases of a group key's lifetime. To address some of our findings, we propose and implement a novel random number generator that extracts randomness from the physical Wi-Fi channel.

First we study the random number generator proposed by the 802.11 standard. Among other things, the Access Point (AP) uses it to generate group keys. Surprisingly, we find that it is flawed by design. We argue that implementing the algorithm as specified, results in an unacceptably slow algorithm. This argument is supported empirically: all implementations we examined, modified the generator to increase its speed. We demonstrate that these modified implementations can be broken by predicting the generated group key within mere minutes.

The generated group keys are transferred to clients during the 4-way WPA2 handshake. We found that it is possible to perform a (type of) downgrade attack against the 4-way handshake, causing RC4 to be used to encrypt the transmission of the group key. We analyze the construction of the per-message RC4 key and its effect on biases in the keystream. This reveals that an attacker can abuse biases to recover an 128-bit group key by capturing 2^{30} to 2^{32} encryptions of the group key, where the precise number depends on the configuration of the network.

Group keys should only be used to protect broadcast or multicast frames. In other words, pairwise and group keys should be properly isolated, and unicast packets should never be encrypted with a group key. An AP can enforce this by only sending, but never receiving, group addressed frames. However, all APs we tested did not provide this isolation. We demonstrate that this allows

FC	addr1	addr2	addr3	KeyID / PN	Data
----	-------	-------	-------	------------	------

Figure 1: Simplified 802.11 frame with a WPA2 header.

an attacker to use the group key to inject, and in turn decrypt, any traffic sent in a Wi-Fi network.

Finally, we propose and study a novel random number generation tailored for 802.11 platforms. It extracts randomness from the wireless channel by collecting fine-grained Received Signal Strength Indicator (RSSI) measurements. These measurements can be made using commodity devices even if there is no background traffic. We show our algorithm can generate more than 3000 bits per second, and even when an adversary can predict individual RSSI measurements with high probability, the output of the generator still remains close to uniformly random.

To summarize, our main contributions are:

- We show that the 802.11 random number generator is flawed, and break several implementations by predicting its output, and hence also the group key.
- We present a downgrade-style attack against the 4-way handshake, allowing one to recover the group key by exploiting weaknesses in the RC4 cipher.
- We show that the group key can be used to inject and decrypt any (internet) traffic in a Wi-Fi network.
- We propose and study a random number generator that extracts randomness from the wireless channel.

The rest of this paper is organized as follows. Section 2 introduces relevant parts of the 802.11 standard. We break the random number generator of 802.11 in Section 3. Section 4 presents a downgrade attack against the 4-way handshake, and attacks on its usage of RC4. In Section 5 we use the group key to inject and decrypt any frames, including unicast ones. In Section 6 we propose a new random number generator. Finally, we explore related work in Section 7, and conclude in Section 8.

2 Background

This section provides a background on the 802.11 protocol, the 4-way handshake, and the RC4 stream cipher.

2.1 The 802.11 Protocol

When a station wishes to transmit data, it needs to add a valid 802.11 header (see Figure 1). This header contains the necessary MAC addresses to route the frame:

```
addr1 = Receiver MAC address
addr2 = Sender MAC address
addr3 = Destination MAC address
```

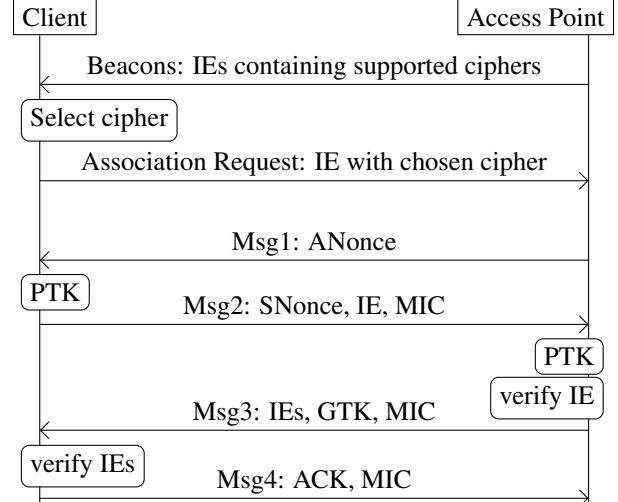

Figure 2: Discovering APs by listening to beacons, followed by the association and 4-way WPA2 handshake.

The Access Point (AP) forwards received frames to their destination, which is either a node on the wired network, or a Wi-Fi client. In frames received by a client, `addr1` should equal `addr3`, hence no further routing is required. For example, when a client sends an outbound IP packet, `addr1` equals the address of the AP, `addr2` contains his own address, and `addr3` equals the address of the router.

If a client wishes to transmit a broadcast or multicast frame, i.e., a group addressed frame, he first sends it as a unicast frame to the AP. This means `addr1` equals the address of the AP, and `addr3` equals the broadcast or multicast destination address. The AP then encrypts the frame using the group key if needed, and broadcasts it to all associated clients. This assures all clients within the range of the AP will receive the frame, even if certain stations are not within range of each other.

The Frame Control (FC) field contains, among other things, the ToDS and FromDS flags. The ToDS flag is set if the frame is sent from a client to an AP, and the FromDS flag is set if the frame is sent in the reverse direction. The fifth field in Figure 1 is only included when encryption is used, and contains the Key ID and Packet Number (PN). The PN prevents replay attacks. The 2-bit Key ID field is only used in group addressed frames, where it identifies which group key is used to protect and encrypt the frame.

2.2 Discovering APs and Negotiating Keys

Clients can discover APs by listening for beacons, which are periodically broadcasted by the AP (see Figure 2). These beacons contain the supported cipher suites of the AP in Information Elements (IEs). When a client wants to connect to an AP, and has selected a cipher to use, it starts by sending an association request to the AP. This

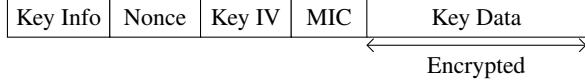

Figure 3: Simplified layout of EAPOL-Key frames.

request includes the selected cipher in an information element (IE). To prevent downgrade attacks, the client and AP will verify the received and selected IEs in the 4-way handshake. In this handshake, the client and AP also authenticate each other, and negotiate a Pairwise Temporal Key (PTK). The PTK is essentially the set of negotiated session keys. The first part of the PTK is called the Key Confirmation Key (KCK), and is used to authenticate handshake messages. The second part is called the Key Encryption Key (KEK), and is used to encrypt any sensitive data in the handshake messages. Finally, the third part is called the Temporal Key (TK), and is used to protect data frames that are transmitted after the handshake. To assure a new PTK is generated, both the client and AP first generate unpredictable, random nonces called SNonce and ANonce, respectively. The PTK is then derived from a shared secret or passphrase, the ANonce and SNonce, and the MAC addresses of the client and AP.

In the first message of the 4-way handshake, the AP sends the ANonce to the client (see Figure 2). On receipt of this message, the client calculates the PTK. In the second message, the client sends the SNonce, the IE representing the previously selected cipher, and includes a Message Integrity Code (MIC) calculated over the complete message. Note that the MIC is calculated using the KCK key contained in the PTK. After receiving Msg2 and the SNonce, the AP also derives the PTK. At this point both parties know the PTK, and all messages are authenticated using a MIC. Using the KCK and received MIC, the AP verifies the integrity of Msg2. The AP then checks whether the included IE matches the IE that was received in the initial association request. If these IEs differ, the handshake is aborted. Otherwise the AP replies with the Group Temporal Key (GTK), and its supported ciphers as a list of IEs. The client verifies the integrity of Msg3, and compares the included IEs with the ones previously received in the beacons. If the IEs differ, the handshake is aborted. Otherwise the client finishes the handshake by sending Msg4 to the AP.

Messages in the 4-way handshake are defined using EAPOL-Key frames, whose most important fields are shown in Figure 3. The Key Info field contains flags identifying which message this frame represents in the handshake. It also states which algorithm is used to calculate the MIC, and which cipher is used to encrypt the Key Data field (see Section 4). Note that the KCK key is used to calculate the MIC, and that the KEK key is used to encrypt the Key Data field. Finally, the Key IV

Key Scheduling (KSA)	Keystream Output (PRGA)
<pre>L = len(key) j, S = 0, range(256) for i in range(256): j += S[i] + key[i % L] swap(S[i], S[j]) return S</pre>	<pre>S, i, j = KSA(key), 0, 0 while True: i += 1 j += S[i] swap(S[i], S[j]) yield S[S[i] + S[j]]</pre>

Figure 4: Implementation of RC4 in Python-like pseudo-code. All additions are carried out modulo 256.

field may contain an initialization vector (IV) to assure the Key Data field is always encrypted using a unique key. The most common usage of the Key Data field is to transport the group key (GTK), and to transfer any IEs.

2.3 The RC4 Stream Cipher

RC4 is a fast and well-known stream cipher consisting of two algorithms: a Key Scheduling Algorithm (KSA) and a Pseudo-Random Generation Algorithm (PRGA). Both are shown in Figure 4. The KSA takes as input a variable-length key, and generates a permutation S of the set $\{0, \dots, 255\}$. This gradually changing permutation, combined with a public counter i and a private index j , form the internal state of the PRGA. In each algorithm, a swap operation is performed near the end of every round. We use the notations i_t , j_t , and S_t , for the indices i and j and the permutation S after round t . Rounds are indexed based on the value of i after the swap operation. Hence the KSA has rounds $t = 0, \dots, 255$ and the PRGA has rounds $t = 1, 2, \dots$. We let Z_r denote the keystream byte outputted at round r . Whenever it might not be clear whether we are referring to the KSA or PRGA, we use the notations S_t^{KSA} and S_t^{PRGA} , respectively.

Multiple biases have been found in the first few keystream bytes of RC4. These are called short-term biases. Arguably the most well known was found by Mantin and Shamir [30]. They showed that the value zero occurs twice as often at position 2 compared to uniform. In contrast, there are also biases that keep occurring throughout the whole keystream. We call these long-term biases. For example, Fluhrer and McGrew (FM) found that the probability of certain consecutive bytes deviate from uniform throughout the whole keystream [12]. Similarly, Mantin discovered a long-term bias towards the pattern $ABSAB$, where A and B represent byte values, and S a short sequence of bytes called the gap [29]. Letting g denote the length of the gap, the bias can be written as follows:

$$\Pr[Z_r, Z_{r+1} = Z_{r+g+2}, Z_{r+g+3}] = 2^{-16} \left(1 + \frac{e^{(-4-8g)/256}}{256} \right)$$

Hence the longer the gap, the weaker the bias.

Listing 1: Random number generator as proposed by the 802.11 standard in Python-like pseudocode [21, §M.5].

```

1 def PRF-256(key, label, data):
2     R = HMAC-SHA1(key, label + "\x00" + data + "\x00")
3     R += HMAC-SHA1(key, label + "\x00" + data + "\x01")
4     return R[:32]
5
6 def Hash(data):
7     return PRF-256(0, "Init Counter", data)
8

11        return LSB(receive time of ethernet packet)
12    else:
13        Start 4-way handshake, stop after receiving Msg2
14        return LSB(Msg1.sent_time) + LSB(Msg2.rssi)
15        + LSB(Msg2.receive_time) + Msg2.snonce
16
17 def GenRandom():
18    local = "\x00" * 32
19    # Wait for Ethernet traffic or association, and
20    # loop until result is "random enough" or 32 times
21    for i in range(32):
22        buf = Hash(macaddr + currttime + local + i)
23        for j in range(32):
24            local += NetworkJitter()
25    return Hash(macaddr + currttime + local + "\x20")

```

3 Breaking the 802.11 RNG

In this section we argue that the Random Number Generator (RNG) of 802.11 is flawed, and break several implementations by predicting the generated group key.

3.1 The Proposed RNG in 802.11

The security enhancements amendment to 802.11, called 802.11i, includes a software-based RNG [22, §H.5.2]. It extracts randomness from clock jitter and frame arrival times. While the standard states the proposed algorithm is only expository, and real implementations should extend it with other sources of entropy, we found that several platforms directly implement it and even simplify it.

Listing 1 contains the proposed RNG as the function `GenRandom`. The outer for-loop first calculates a hash over the MAC address of the station, the current time, the `local` variable, and the loop counter. Then it makes multiple calls to `NetworkJitter` in order to collect randomness from the arrival times of Ethernet or Wi-Fi frames. Here `LSB` returns the least significant byte of a timestamp. Note the comment on line 20, which is copied almost verbatim from the standard. It instructs to either run the outer loop 32 times, or until the `lcoal` variable is “random enough”. No clarification is made on what this exactly means. The standard also mentions that the variable `currttime` can be set to zero if the current time is not available. However, there is no discussion on how

this impacts the RNG, e.g., whether additional iterations of the outer for-loop should be executed. Additionally, the standard does not mandate a minimum resolution for the timestamps that are used. It only states that the send and receive timestamps of frames should use the highest resolution possible, *preferably* 1 ms or better. Finally, the RNG is executed on demand, i.e., there is no state saved between two invocations of `GenRandom`.

3.2 Analysis

A careful inspection of the RNG shows it is ill-defined and likely insecure. One problem lies with the `NetworkJitter` function, which is called 256 times by `GenRandom`. First, the if test on line 10 is ambiguous. If it checks whether there was Ethernet traffic in the last x seconds, repeated calls will probably operate on the same Ethernet packet, and the function will return the same data. On the other hand, if this test implies monitoring the Ethernet interface for x seconds, this might cause a total delay of $256 \cdot x$ seconds. Furthermore, the value of x is not given. In any case, either calling `NetworkJitter` implies waiting a significant amount of time until there is new traffic, or repeated calls return the same value.

When the second clause of the if statement on line 10 is taken, the arrival times of frames transmitted during the 4-way handshake are used. Specifically, it mentions to initiate the 4-way handshake. This is something only an AP can do when a client is trying to connect to this AP (see Figure 2). Therefore the proposed algorithm is only usable by APs. We also remark that if the AP were to constantly abort the handshake after receiving message 2 (see line 13), most clients will blacklist the AP for a certain period. During this period, the client will no longer attempt to connect to the network. Hence it becomes infeasible to initiate and abort 256 4-way handshakes, which is something the random number generator is supposed to do. We conclude that the function `NetworkJitter` is unusable in practice. Based on this we conjecture, and empirically confirm in Section 3.4, that vendors will not implement this function.

Another design flaw is that no state is kept between subsequent calls to `GenRandom`. Hence its output depends only on a small amount of network traffic and timestamp samples. A better design is to collect randomness in a pool, and regularly reseed this pool with new randomness. When done properly, this protects against permanent compromise of the RNG, iterative guessing attacks, backtracking attacks, and so on [25, 3, 9].

We conclude that the proposed RNG is questionable at best. Either it returns bytes having a low amount of entropy, or calling it will incur significant slowdowns. In Section 3.4 we will show that in practice this construction results in defective and predictable RNGs.

3.3 Generation of the Group Key

The 802.11 standard defines, but does not mandate, a key hierarchy for the generation of group keys [21, §11.6.1]. This hierarchy is described in Listing 2, where `macaddr` denotes the MAC address of the AP, and `currtime` is either the current time or zero. The `on_startup` function is executed at boot time, and generates a random auxiliary key called the Group Master Key (GMK). Additionally, it initializes the `key_counter` variable to a pseudo-random value [21, §11.6.5]. Actual group keys, called Group Temporal Keys (GTKs), are derived from the GMK and `key_counter` using a Pseudo-Random Function (PRF) in `new_gtk`. The length of the generated GTK depends on the cipher being used to protect group traffic. If TKIP is used, the GTK is 32 bytes long. If CCMP is used, the GTK is 16 bytes long. This implies the PRF has to generate either 128 or 256 bits of keying material, depending on the configuration of the network. Hence we use the function name `PRF-X`, where the value of X depends on the amount of requested keying material. Note that the implementation of `PRF-256` is shown in Listing 1, and that `PRF-128` closely resembles this function. The latest standard also states [21, §11.6.1.4]:

“The GMK is an auxiliary key that may be used to derive a GTK at a time interval configured into the AP to reduce the exposure of data if the GMK is compromised.”

However, this makes no sense: there is no point in introducing a new key to reduce the impact if that key itself leaks. Curiously, we found that older versions of the standard did not contain this description of the GMK. Instead, older versions stated that the GMK may be reinitialized to reduce the exposure of data in case the current value of the GMK is ever leaked.

Most implementations renew the GTK every hour by calling a function similar to `new_gtk`. More importantly, the `key_counter` variable is also used to initialize the Key IV field of certain EAPOL-Key frames (see Figure 3). After using the value of `key_counter` for this purpose, it is incremented by one. Since these IVs are public values, the value of `key_counter` is known by adversaries. We found that some implementations even use `key_counter` to generate nonce values during the 4-way handshake, though this is not recommended as it may enable precomputation attacks [21, §8.5.3.7].

One major disadvantage of the proposed key hierarchy, is that fresh entropy is never introduced when generating a new group key in `new_gtk`. Hence, once the value of GMK has been leaked, or recovered by an attacker, all subsequent groups keys can be trivially predicted.

Since the standard assumes that `GenRandom` provides cryptographic-quality random numbers, there appears

Listing 2: Python-like pseudocode describing the group key hierarchy (and generation) according to the 802.11 standard.

```
1 def on_startup():
2     GMK, key = GenRandom(), GenRandom()
3     buf = macaddr + currtime
4     key_counter = PRF-256(key, "Init Counter", buf)
5
6 def new_gtk():
7     gnonce = key_counter++
8     buf = macaddr + gnonce
9     GTK = PRF-X(GMK, "Group key expansion", buf)
```

to be no advantage in using this key hierarchy. Instead, the AP can directly call `GenRandom` to generate new group keys. Some consider this key hierarchy a relic from older 802.11 standards, which did not yet require that devices must implement a strong RNG [20]. Perhaps the only (unintended) advantage this construction has, is that the *first* group key is now determined by two calls to `GenRandom`, instead of only one call. Hence, if an adversary is trying to attack a weak implementation of `GenRandom`, he has to predict its output twice (see Section 3.4). Nowadays implementations are allowed to directly generate a random value for the GTK [21, §11.6.1.4], though many platforms still implement the proposed group key hierarchy (see Section 3.4).

3.4 Practical Consequences

We now study the RNG of real 802.11 platforms. First we focus on popular consumer devices. To estimate the popularity of a specific brand, we surveyed wireless networks in two Belgian municipalities. We were able to recognize specific brands based on vendor-specific information elements in beacons. We detected 6803 networks, and found that MediaTek- and Broadcom-based APs alone covered at least 22% of all Wi-Fi networks. We will focus on both because of their popularity. Additionally we examine Hostapd for Linux. Finally, we study embedded systems by analysing the Open Firmware project. We found that, apart from Hostapd, all these platforms produce predictable random numbers.

3.4.1 MediaTek-based Routers

Access points with a MediaTek radio use out-of-tree Linux drivers to control the radio¹. These drivers directly manage the 4-way handshake and key generation. They implement the 802.11 RNG as shown in Listing 1, but do not call `NetworkJitter`. This strengthens our hypothesis that this function is infeasible to implement in

¹Available from www MEDIATEK.com/en/downloads

practice. It also means the only source of randomness is the current time, for which it uses the *jiffies* counter of the Linux kernel. This counter is initialized to a fixed value at boot, and incremented at every timer interrupt. The number of timer interrupts per second is configured at compile time and commonly lies between 100 and 1000. Hence it is a coarse grained timestamp, meaning the `currtime` variable likely has the same value each time it is sampled in `GenRandom`. That is, the current time is the only random source being used, and provides little entropy.

The group key hierarchy is implemented according to the 802.11 standard, with one exception. Instead of initializing `gnonce` to `key_counter` in line 7 of Listing 2, it generates a new value using `GenRandom`, and assigns the result to `gnonce`.

We show that this RNG is flawed by predicting the group key generated by an Asus RT-AC51U. A similar approach can be followed for other routes that also use a MediaTek radio. The first step is to predict the GMK generated at boot. By recompiling the firmware, and printing out the jiffies values that were used at the start and end of an invocation of `GenRandom`, we observe that it uses at most two different values. Note that we printed these values out only after calling `GenRandom`, to assure we did not noticeably influence the used jiffies values. Hence the jiffies values is incremented at most by one while executing `GenRandom`. Since this increment may happen in any of the 32 loops, `GenRandom` can result in total 32 possible values if the initial jiffies value is known. If AES-CCMP is used to protect group traffic, the initial jiffies value when generating the GMK lies in the range $[2^{32} - 72\,889, 2^{32} - 72\,884]$. If WPA-TKIP is used, it lies in $[2^{32} - 73\,067, 2^{32} - 73\,061]$. The number of attached USB or Ethernet devices, amount of Ethernet traffic, or other Wi-Fi options, did not impact these estimates. Since it is trivial to determine whether AES or TKIP is used, and less than 10 possible initial values are used in both cases, we end up with at most $32 \cdot 10$ possible values for the GMK.

The second step is to estimate the jiffies count when the GTK, i.e., group key, was generated. By default, a new group key is generated every hour. Hence, if we know the uptime of the router, we can determine when the current group key was generated. Conveniently, beacons leak the uptime of a device in their timestamp field. This field is used to synchronize timers between all stations [21, §10.1], and is generally initialized to zero at boot. Hence its value corresponds to the uptime of the router. From this we can estimate the jiffies counter's value at the time the group key was generated. However, as the device keeps running, clock skew will affect our prediction. By logging jiffies values, we observed that the clock skew over one month made our prediction off

by at most 4500 jiffies. Therefore, even after an uptime of year, our prediction of the jiffies value will only be off by roughly 50000. In other words, we conjecture that the prediction after a year will be off by at most 200 seconds.

We created an OpenCL program to search for the group key on a GPU. It tests candidate keys by decrypting the first 8 bytes of a packet, and checking if they match the predictable LLC/SNAP header. If the targeted router has been running for one year, it has to test $320 \cdot 50\,000 \cdot 32 \approx 2^{29}$ candidates to recover the group key. However, testing each key is rather costly, as it involves calculating $33 \cdot 4$ SHA-1 hashes to derive the group key, and we must then decrypt the first 8 bytes of the packet to verify the key. Nevertheless, on our NVIDIA GeForce GTX 950M, it takes roughly two minutes to test all 2^{29} candidates and recover the GTK. We confirmed this by successfully predicting several group keys generated by our Asus RT-AC51U, when it had an uptime of more than a month. We conclude the group key generated by a MediaTek driver can be brute-forced using commodity hardware in negligible time.

3.4.2 Broadcom Network Authentication

The network access server of Broadcom implements the 4-way handshake, including the necessary key generation. It implements the group key hierarchy according to the 802.11 standard (see Listing 7). Additionally, it uses the `key_counter` variable to initialize the Key IV field of EAPOL-Key frames. However, it does not implement the RNG as proposed in the 802.11 standard. Instead, the RNG it uses depends on the kernel used by the device.

When running on a VxWorks or eCos kernel, random numbers are generated by taking the MD5 checksum of the current time in microsecond accuracy. Hence random numbers are straightforward to predict. And since the output of MD5 is used, only 16 bytes of supposedly random data is generated in every call. One widely used device that uses a VxWorks kernel, is version 5 or higher of the popular WRT54G router. Furthermore, the Apple AirPort Extreme also uses a VxWorks kernel. To predict the group key generated by these devices, we only have to predict the value of GMK. Recall that the value of `key_counter` is leaked in the Key IV field of certain EAPOL-Key fields, and can simply be passively sniffed. Since GMK is a 32-byte value, it is initialized by calling the random number generator twice. In order to predict the output of these two calls, we must first determine the time at which the group key was generated based on the uptime of the router. Similar to the MediaTek case, the uptime can be derived from the timestamp field in beacons. Assuming we can estimate time at which the group key was generated with an accuracy of one second, and that the timestamp in the next call to the RNG differs by

Listing 3: Generation of random nonces by the Open Firmware project in Python-like pseudocode.

```
1 def on_system_boot():
2     rn = lcg_next(milliseconds since boot)
3     data = macaddr + rn
4     rn = lcg_next(rn)
5     nonce = PRF-256(rn, "Init Counter", data)
6
7 def lcg_next(rn):
8     return rn * 0x107465 + 0x234567
9
10 def compute_next_snonce():
11     nonce += 1
12     return nonce
```

at most 10 ms, we have to test $1000000 \cdot 10000 \approx 2^{33}$ keys. We implemented an OpenCL program to simulate this search, and on our GeForce GTX 950M, it takes around 4 minutes to test all candidate keys. Hence the generated group keys by this RNG can be predicted using commodity hardware.

When running on a Linux kernel, random bytes are read from `/dev/urandom`. This is problematic since, on routers and embedded devices, `/dev/urandom` is commonly predictable at boot [19]. And since entropy for the group keys is only collected at boot (see Section 3.3), this again means all groups keys may be predictable.

3.4.3 The Linux Hostapd Daemon

Hostapd implements the 802.11 group key hierarchy as shown in Listing 2. However, when generating a new group key using a function similar to `new_gtk`, it also samples and incorporates new entropy. Additionally, Hostapd does not implement the 802.11 RNG. Instead, it generates keys by reading from `/dev/random`. In case insufficient entropy is available, it will re-sample from `/dev/random` when the first client is attempting to connect. In case there still is not enough entropy available, the client is not allowed to connect. All combined, this means the keys used by Hostapd should be secure.

3.4.4 Open Firmware (OpenBoot)

The Open Firmware project, previously called Open-Boot, is a free and open source boot loader programmed in Forth². Most notably it is used in the One Laptop Per Child project. Interestingly, it provides basic but secure Wi-Fi functionality during the early stages of the boot process. Since at this stage no operating system is loaded, we consider it an ideal candidate to investigate how vendors implement RNGs in a constrained (embedded) environment.

²Available from [svn://openbios.org/openfirmware](http://openbios.org/openfirmware)

Currently, the Wi-Fi module of Open Firmware only provides client functionality. Therefore we focus on the generation of random nonces during the 4-way handshake. Listing 3 illustrates how Open Firmware generates these nonces. Summarized, when loading the Wi-Fi module, a random initial nonce is generated, and this nonce is incremented whenever it is used. In this regard, the algorithm follows the 802.11 standard [21, §11.6.5]. However, the generation of the initial random nonce is very weak. It takes the uptime of the device in number of milliseconds, runs this twice through a linear congruential generator, combines it with its own MAC address, and finally expands this data using a Pseudo-Random Function (PRF). All this information can be predicted or brute-forced by an adversary.

We attribute this weak construction to a careless implementation, and treat it as an indication that a better design is to let the Wi-Fi chip generate random numbers itself. Users can then query the Wi-Fi chip when new randomness is needed. In Section 3 we demonstrate how a strong random number generator can be implemented using commodity Wi-Fi devices.

4 RC4 in the 4-Way Handshake

In this section we present a (type of) downgrade attack against the 4-way handshake. As a result, RC4 is used to encrypt sensitive information in the handshake. We present two attacks against the usage of RC4 in the handshake, and show how it allows an attacker to recover the group key. We also determine the performance of our attacks, and propose countermeasures.

4.1 Downgrading to RC4

When inspecting the 4-way handshake in Figure 2, we can see that the AP sends the group key (GTK) to the client before the client verifies the IEs of the AP. Recall that these IEs contain the supported cipher suites of the AP, which are advertised in plaintext beacons. In other words, the client can only detect that a downgrade attack has occurred *after* the AP has transmitted the group key in Msg3. This is problematic because, if multiple ciphers can be used to protect the handshake, an adversary can try to perform a downgrade attack to induce the AP into encrypting and transmitting the group key using a weak cipher.

Interestingly, the 4-way handshake can indeed be protected by several cipher suites [21, §11.6.2], meaning a downgrade attack is possible. More specifically, the cipher suite that is used to protect the handshake is determined by two settings that may, or may not, be requested by the client in its association request (see Figure 2). In

Table 1: Cipher suites used in the 4-way handshake.

Selected Options	Ciphers Used
Fast Transition (FT)	AES-CMAC, AES key wrap
CCMP without FT	HMAC-SHA1, AES key wrap
TKIP without FT	HMAC-MD5, RC4

particular, when support for fast network transitions is requested, AES-CMAC and NIST AES key wrap are used to protect messages in the 4-way handshake. Otherwise, the cipher used to protect the handshake depends on the pairwise cipher that will be used to protect normal data frames transmitted after the handshake. In case CCMP will be used, the 4-way handshake uses HMAC-SHA1 and NIST EAS key wrap. More troublesome, if TKIP will be used, then HMAC-MD5 and RC4 are used to authenticate and encrypt data, respectively. An overview of this selection process is shown in Table 1.

Our idea is now to create a rogue AP that only advertises support for TKIP. Hence victims wanting to connect to the AP will use TKIP, and in turn the group key transmitted in the 4-way handshake will be encrypted using RC4. This works because the client will only detect the downgrade attack after receiving message 3. However, to make the AP send message 3, it must first receive and successfully verify the integrity of message 2. If its integrity cannot be verified, which is done using the negotiated session keys, the AP will not continue the handshake. Since the session keys depend on the MAC addresses of the client and AP, it means we must create a rogue AP with the same MAC address as the real one. Fortunately this is possible by performing a channel-based man-in-the-middle attack [46]. Essentially, the attacker clones the AP on a different channel, and forwards packets to, and from, the real AP. The MAC addresses in forwarded frames are not modified. This assures the station and AP will generate the same session keys, meaning the AP will successfully verify the authenticity of message 2. This man-in-the-middle position allows the attacker to reliably manipulate messages. In particular, it will use this position to modify the beacons and probe responses so it seems the AP only supports (WPA-)TKIP. Hence the client will be forced to select TKIP, causing the AP use to RC4 for encrypting the group key.

We tested this downgrade-style attack against a network that advertised both support for TKIP and CCMP. Since the rogue AP only advertised support for TKIP, the victim indeed selected TKIP. We then confirmed that the AP encrypts the group key using RC4, and that the client detected our attack only after receiving message 3.

Interestingly, the 4-way handshake uses RC4 in a rather peculiar manner [22, §8.5.2j]. The per-message RC4 key is the concatenation of the 16-byte Initial-

ization Vector (IV) and the 16-byte Key Encryption Key (KEK). Additionally, the initial 256 keystream bytes are dropped. This construction is similar to the one used by WEP, except that the IV is longer, and that some initial keystream bytes are dropped. Interestingly, using a longer IV likely weakens this per-message key construction [28, 36], while dropping the initial keystream bytes should strengthen it [33, 28]. In the next two sections, we analyze the impact of this peculiar combination.

4.2 Recovering the Key Encryption Key

We first examine whether it is possible to perform a key recovery attack similar to those that broke WEP [11, 42]. In general, these attacks are applicable if a public IV is prepended (or appended) to a fixed secret key. This matches the construction of the per-message key K in the 4-way handshake, where the public 16-byte IV is prepended to the secret but static 16-byte KEK key. More formally, the per-message key is constructed as follows:

$$K = IV \parallel KEK$$

Although the first 256 keystream bytes of RC4 are dropped, Mantin showed this does not prevent key recovery attacks [28]. We will adapt Mantin’s attack to the 4-way handshake, and study whether it is feasible to perform this attack in practice.

Similar to the original FMS attack [11], Mantin’s extension of the FMS attack uses an iterative process to recover the key K [28]. That is, each iteration assumes the first x bytes of K are known, and attempts to recover the next key byte $K[x]$. In the first step of each iteration of Mantin’s new attack, keystreams are collected that were generated with an IV for which the condition $S_{x-1}^{KSA}[1] = x$ holds. We call these *applicable* IVs. Mantin proved that applicable IVs leak information about the key byte $K[x]$ through the following relation [28]:

$$\Pr[K[x] = S_{x-1}^{-1}[i_{257} - z_{257}] - j_{x-1} - S_{x-1}[x]] \approx 1.1 \cdot 2^{-8} \quad (1)$$

This relation can be used to recover $K[x]$ with a simple voting mechanism as follows. Each applicable IV casts a vote for a certain value through equation (1). After all IVs are processed, the value with the most votes is assumed to be the value of $K[x]$. Unfortunately, this has the downside that a single incorrect guess for any byte means the complete key K is also wrong. To mitigate this, we pick the C most likely values for each byte, and construct C^{16} candidate values for K . Each candidate can be tested based on the captured IVs and corresponding keystreams. We simulated this attack against the 4-way handshake, with as goal to determine how many applicable IVs have to be captured to recover the KEK key. The result of this simulation is shown in Figure 5. To obtain

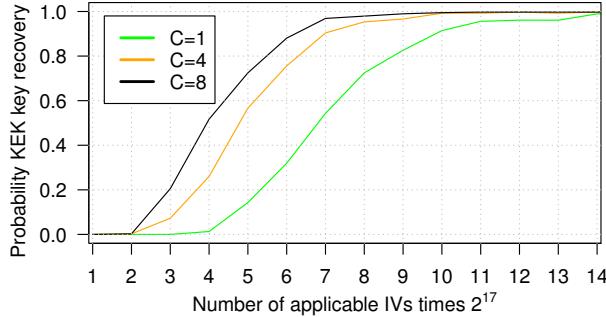

Figure 5: Probability of finding the 16-byte KEK key given the number of applicable IVs and the branch factor C .

a 80% success ratio of recovering the *KEK*, roughly 2^{21} applicable IVs have to be collected. Note that to execute the attack, we must be able to determine the value of z_{257} . Fortunately, this is possible by relying on the predictable IEs that are located at the start of the EAPOL Key Data field, meaning we can derive the keystream at these initial positions.

We now determine how much effort it takes to collect the required number of applicable IVs. First notice that the most likely way the condition $S_{x-1}^{KSA}[1] = x$ is satisfied, is when the value x is swapped into position 1 at round 1 of the KSA (recall Listing 4). Or more formally, that $j_1 = x$, since $K[x]$ is likely not modified in the first round. Indeed, the 15 other rounds only affect position 1 if j ever equals 1. Assuming a random initial IV is used, this will not happen with a probability of $(\frac{255}{256})^{15} = 0.94$. At round one, $j_1 = K[0] + 1 + K[1]$ (we assume $K[0] \neq 1$ which holds with high probability). Hence, with high probability, an IV is applicable when $K[0] + K[1] = x - 1$.

The 802.11 standard states that a station must generate an initial random IV at startup, and increment this IV after it is used in a message [21, §11.6.5]. In other words, the IV is used as a counter. However, it does not specify whether little or big endian counters must be used. Our experiments indicate that most devices we use the IV as a big endian counter. Fortunately, from a defenders perspective, this means that generating the required number of applicable IVs takes an enormous amount of time. Assuming that the condition $K[0] + K[1] = x - 1$ does not hold, we must wait until $K[1]$ has been incremented sufficiently many times. However, only every $256^{14} = 2^{112}$ IVs does the value of $K[1]$ change. Clearly, this means that collecting the required number of IVs is infeasible when the AP uses a big endian counter. If the IV is generated by a little endian counter, the condition $K[0] + K[1] = x - 1$ is generally satisfied every 256th message. This means around $256 \cdot n$ messages must be

collected in order to have roughly n applicable IVs for all iterations.

While it is possible to generate many handshakes by forcibly disconnecting clients, new handshakes will use a different KEK key. Since our attack assumes that the KEK is constant, this is not an option. The only method we identified to make the AP send several handshake messages protected by the same KEK, is by not acknowledges them, and letting the AP retransmit them. Note that each retransmission uses a new IV. Unfortunately, only a few messages will be retransmitted before the AP gives up and aborts the handshake process. In the next Section we present an attack that does tolerate frequent changes of the KEK key. We conclude that the 4-way handshake, as defined in the 802.11i standard, is vulnerable to key recovery attacks. However, these attacks seem difficult to pull off against popular implementations.

4.3 Plaintext Recovery Attacks

We now turn our attention to plaintext recovery attacks, where an adversary targets information that is repeatedly encrypted under different RC4 keys. Previous work on RC4 has shown that these types of attacks can be very successful, with attacks against TLS and TKIP being on the verge of practicality [2, 47]. In particular, the attack against WPA-TKIP by Paterson et al. [37] is fairly similar to our scenario. They showed that for WPA-TKIP, the public 3-byte prefix of the per-message RC4 key induces large, prefix-dependent, biases into the RC4 keystream [37, 15]. An adversary can precompute these prefix-dependent biases, and mount a powerful plaintext recovery attack against the first few bytes encrypted by RC4. This inspired us to investigate whether the public 16-byte IV used in the 4-way handshake also induces IV-dependent biases, even though the first 256 keystream bytes are dropped. Hence we examine the biases induced by the public IV contained in EAPOL frames, and then demonstrate through simulations that these can be used to recover the group key.

It is impossible to empirically investigate every possible IV, since this would mean inspecting 2^{128} values. Instead, we initially generated detailed keystream statistics for four randomly selected IVs. This indicated that large, IV-dependent biases indeed persist in the keystream, even after the first 256 bytes (which are dropped). Motivated by this result, we took the all-zero initialization vector IV_0 , and investigated how changing the values at each specific position in the IV influences the keystream distribution. Changing a byte at position x to value y is denoted by $IV_0[x] = y$. The generation of all datasets took more than 13 CPU years.

Figure 6a and 6b show the keystream distribution for the initialization vectors IV_a and IV_b , respectively. The

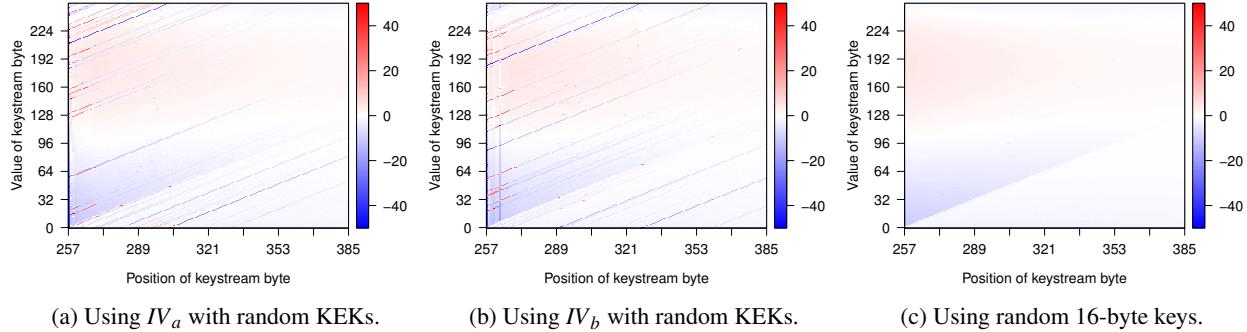

Figure 6: Biases in the RC4 keystream when concatenating a fixed 16-byte IV with a random 16-byte key (here called KEK key), and when using random 16-byte keys. Each points encodes a bias as the number $(pr - 2^{-8}) \cdot 2^{24}$, capped to values in $[-50, 50]$, with pr the empirical probability of the keystream byte value (y-axis) at a given location (x-axis).

distributions of IV_c and IV_d behave similarly. Their values were randomly generated in Python and are:

$$\begin{aligned} IV_a &= 0x2fe931f824ef842bf262dbca357bb31c \\ IV_b &= 0x48d9859f9fa08bb1599744a20491dd49 \\ IV_c &= 0x6c1924761b03faf8decc0dfc09dd3078 \\ IV_d &= 0xe31257489cbe7d91e5365286c26f5023 \end{aligned}$$

These keystream distributions were generated using 2^{45} RC4 keys for each IV. For comparison, Figure 6c and Figure 9c shows the keystream distribution for fully random 16-byte keys, generated using roughly 2^{47} RC4 keystreams [47]. We observe that the initialization vector induces strong biases that are visible as straight lines, even after position 256. By comparing these biases with the keystream distribution of 16-byte random RC4 keys in Figure 6c, we can conclude that the biases represented by the light and red background, are not caused by the specific IV values. Instead, they appear inherent to RC4.

We also generated 16 datasets, where in each dataset the value at one specific position in the all-zeros IV is changed. That is, for $0 \leq x \leq 15$, we generated datasets for the vectors $IV_0[x] = y$, where y ranges between 0 and 255. Each dataset was generated using 2^{43} keys, resulting in rather noisy distributions. Nevertheless, an inspection of these datasets confirmed that each IV induces specific biases, visible as straight lines in our graphs. A more detailed discussion of these biases is out of scope, and is left as future work.

We now use the IV-dependent biases to recover repeated plaintext, in order to get an indication of how well a plaintext recovery attack works against the 4-way handshake. This is done by combining the precomputed keystream distributions with captured ciphertexts, in order to calculate likelihood estimates for each plaintext value. The actual plaintext value is then assumed to be the one with the highest likelihood. Since our goal is mainly to evaluate the performance of the resulting at-

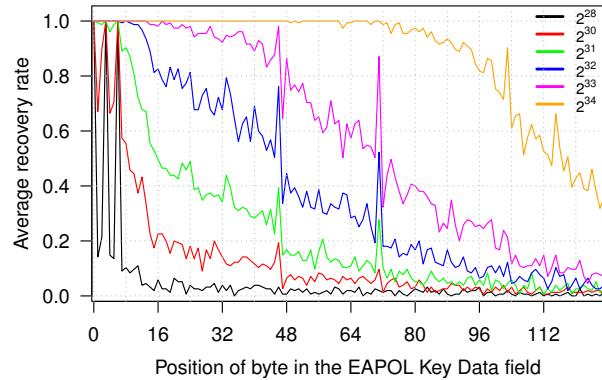

Figure 7: Success rate of decrypting a byte in the EAPOL Key Data field, in function of the byte position and number of collected ciphertexts. The legend shows the total number of ciphertexts used, where half of the ciphertexts were generated using IV_a , and the other half using IV_b .

tacks, we refer to previous work for the technicalities behind these calculations [2, 37, 47]. In particular, we implemented the binning algorithm proposed by Patterson et al. [37], and the single-byte candidate generation algorithm proposed by Vanhoef and Piessens [47]. To keep the computations feasible, we assumed that half of the captured ciphertext were generated by IV_a , and the other half by IV_b . For the binning algorithm of Patterson et al., Figure 7 shows the probability of correctly decrypting a byte. For the candidate generation algorithm, which returns a list of plaintext candidates for a sequence of bytes, we first need to determine at which position the group key is stored in the EAPOL Key Data field.

The location of the group key depends on which cipher suites are supported. If only TKIP is supported in a RSN network, it starts at position 30. In contrast, if both TKIP and AES are supported, and if the older WPA informa-

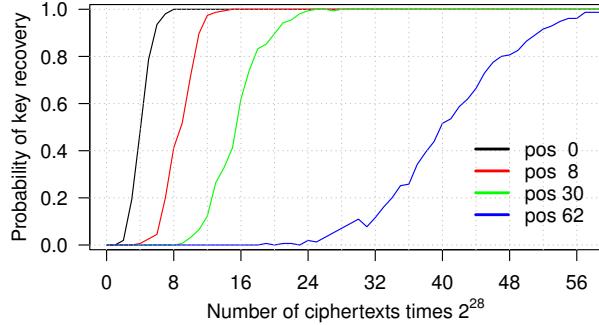

Figure 8: Probability of recovering a 16-byte key using short-term biases and 2^{26} candidates. The legend shows its starting position in the EAPOL key data field.

tion elements are included in addition to the RSN IEs³, the group key starts at position 62. For other configurations, the group key is located somewhere between position 30 and 62. The probability of recovering a 16-byte key at these positions, in function of the number of captured ciphertexts (handshakes), is shown in Figure 8. We remark that if the group key starts at position 62, attacks that exploit Mantin’s ABSAB bias become more efficient [29, 6]. This is because the 62 bytes that precede the group key are predictable, and hence an attack similar to the one that broke RC4 in TLS can be launched [47].

Finally, in principle it is also possible to attack group key update messages, since the 802.11 standard does not mandate that these messages should be encrypted using the pairwise cipher [21, §11.6.7]. Group key updates use EAPOL frames, and are sent when the AP generates a new group key. Interestingly, in these messages the group key is either located at position 8, or at position 0. The success rate of recovering a 16-byte key at these positions is shown in Figure 8. For example, if the key starts at position 8, roughly 2^{31} encryptions of the GTK have to be captured in order to decrypt it. Since in this case there is little surrounding known plaintext, it is the best attack an adversary can launch [2, 47, 6].

4.4 Countermeasures

To prevent the downgrade attack, APs should disable support of WPA-TKIP. Even when an adversary creates a rogue AP advertising TKIP, the real AP will reject any request for TKIP, and hence will never use RC4 in the 4-way handshake. Similarly, clients should not connect to a network using WPA-TKIP.

³Early implementations based on the draft 802.11i standard use WPA IEs, instead of RSN IEs as used in modern networks.

5 Abusing the Group Key

In this section we show that the group key can be used to decrypt and inject any traffic, including unicast traffic.

5.1 Injecting Unicast Frames

First we explain how to inject unicast traffic using the group key. This is not possible by simply encrypting a unicast frame with the group key, and setting the KeyID field to the id used by the group key. The receiver always uses pairwise keys to decrypt unicast frames, and ignores the KeyID value (recall Section 2.1). Furthermore, it is not possible to encapsulate unicast IP packets in group addressed frames. Indeed, RFC 1122 states that stations should discard unicast IP packets that were received on a broadcast or multicast link-layer address [5, §3.3.6]. However, this check is only performed when the packet is passed on to the IP layer. Since an AP does not operate at the IP layer, but on the MAC layer, it does not perform this check. Inspired by this observation, we encrypt the unicast IP packet using the group key, and send it to the AP. For the three address fields in the frame we use the following values:

```
addr1 = FF:FF:FF:FF:FF:FF
addr2 = Spoofed sender MAC address
addr3 = Spoofed destination MAC address
```

Although in a normal network the AP never processes group addressed frames, we found that APs can be forced to process our injected broadcast packet by setting the ToDS bit in the Frame Control (FC) field. To assure the correct value of the KeyID field is used, an adversary can monitor other broadcast frames, or brute-force this value. The AP will then decrypt this packet using the group key. It will notice that the destination address (addr3) does not equal its own MAC address, and hence will forward the frame to the actual destination. If the destination MAC address is another wireless station, the AP will encrypt the frame using the appropriate pairwise key, and transmit it. As a result, the receiver will decrypt and process the forwarded, now unicast, frame. If the destination address is not a wireless station, it will be forwarded over the appropriate Ethernet connection. This technique can be used to inject IP packets, ARP packets, and so on, using the group key.

5.2 Decrypting All Traffic

Since unicast frames are encrypted with pairwise keys, we cannot directly use the group key to decrypt them. Nevertheless, it is possible to trick stations into sending all IP traffic to the broadcast MAC address, meaning the

group key will now be used to encrypt this traffic. This is done by performing an ARP poisoning attack. The malicious ARP packets are injected using the technique presented in Section 5.1. In our attack, we poison the ARP cache of the client so the IP address of the gateway is associated with the broadcast MAC address. Similarly, on the router, the IP address of the client will also be associated with a broadcast address. Since IP addresses in local networks are generally predictable, an attacker can brute-force the IP address of the client and router. After the ARP poisoning attack, all IP packets sent by the client and router are encrypted using the group key. An attacker can now capture and decrypt these packets. Furthermore, he can forward them to their real destination using the (unicast) packet injection technique of Section 5.1, so the victim will not notice he is under attack.

5.3 Experimental Verification

We tested this attack against an Asus RT-AC51U and a laptop running Windows 7. The group key was obtained by exploiting the weak random number generator as discussed in Section 3.4.1. In order to successfully perform the ARP poisoning attack against Windows, we injected malicious ARP requests. First, we were able to successfully inject the ARP packets using the group key. This confirms that the group key can be used to inject unicast packets. Once we poisoned the ARP cache of both the victim and router, they transmitted all their packets towards the broadcast MAC address. At this point we were able to successfully decrypt these broadcast packets using the group key, and read out the unicast IP packets sent by both the victim and router.

5.4 Countermeasures

If the network is operating in infrastructure mode, the AP should ignore all frames with a broadcast or multicast receiver address. This prevents an attacker from abusing the AP to forward unicast frames to stations. Another option is to disable all group traffic. While this may seem drastic, it is useful for protected but public hotspots. In these environments, connected stations do not trust each other, meaning group keys should not be used at all. Interestingly, the upcoming Hotspot 2.0 standard already supports this feature under the Downstream Group Addressed Forwarding (DGAF) option [49]. If DGAF is disabled, no group keys are configured, meaning the stations and AP ignore all group addressed Wi-Fi frames.

6 A New RNG for 802.11 Platforms

In this section we propose a random number generator that extracts randomness from fine-grained Received

Signal Strength Indicator (RSSI) values. Specifically, we rely on the spectral scan feature of commodity 802.11 radios. This gives us roughly three million RSSI measurements per second, even if there is no background traffic.

6.1 Spectral Scan Feature

Most Atheros Wi-Fi radios, such as the AR9280, can perform RSSI measurements over the 56 sub-carriers used in high throughput (HT) OFDM⁴. Atheros calls this feature a spectral scan. It matches the requirement to decode HT OFDM modulated frames, where the channel is divided into 64 subcarriers [21, §18]. Eight of these subcarriers are used as guards to avoid channel cross talk, and are thus not sampled, resulting in 56 usable subcarriers. Therefore the spectral scan feature matches the normal OFDM demodulation requirements, and should be straightforward to implement by other vendors as well. The sweep time of one sample, i.e., spectral scan, is 4μs, and these scans can be made even when there is no background traffic. Each RSSI measurement is reported as an 8-bit value. After some optimizations, we could make our AR2980 chip generate around 50k samples per second. Since each sample contains 56 RSSI values, this totals to roughly three million measurements per second.

6.2 Random Number Generation

In our random number generator, we want to extract randomness out of every single RSSI measurement. Since our commodity devices can generate a large number of measurements per second, even when there is no background traffic, we need a fast method to process all these measurements. Hence our main goal is to design a technique to rapidly process all measurements. The resulting output can then be given as input to a system that properly extracts and manages randomness (see for example Yarrow-160 [25], or the model by Barak and Halevi [3] and its improvements [9]). In other words, our goal is only to design a method to rapidly process RSSI measurements which can be implemented in Wi-Fi radios, and to assess the quality of the resulting output.

We start by deriving one (possibly biased) bit out of each RSSI measurement. Any biases will be suppressed in a later step. Due to random variations in the background noise, the transmissions of other stations, and internal imperfections of the hardware, antenna, and radio, we expect that each RSSI measurement contains some amount of randomness. More concretely, we expect that the least significant bit of each RSSI measurement displays the most amount of randomness. To also take into account the other bits, we perform an exclusive or over all bits in the 8-bit RSSI measurement. Even if the other

⁴See <http://wikidevi.com/wiki/Atheros> for a list.

Table 2: Average number statistical test results for various configurations of the random number generator.

Configuration	Pass	Poor	Weak	Fail
1 bit per subcarrier	97.2%	0%	2.8%	0%
1 bit per spectral scan	98.1%	0%	1.9%	0%
normal mode	98.1%	0%	1.9%	0%

bits are not random, this can only increase the overall randomness. Since we are extracting 1 bit per subcarrier, we call this initial generator the “1 bit per subcarrier” configuration. When running the Dieharder statistical test suite [7] on this configuration, we noticed promising results (see Table 2). The Dieharder suite is a reimplementation of the Diehard tests [31], and in addition contains several tests from the NIST test suite [40]. While none of the tests fail, on average 2.8% of the tests return a weak result. However, this only means that the generated bits do not contain any obvious deficiencies. Subtle or small biases may still be present, and have to be filtered out. We do this by relying on the large number of measurements that our commodity devices can generate.

To suppress possible biases in the 1-bit per subcarrier construction, we combine several bits using an exclusive-or chain. More formally, if we have a sequence of bits b_1, b_2, \dots, b_n , the exclusive-or chain of these bits is $bit = b_1 \oplus b_2 \oplus \dots \oplus b_n$. Assuming that each bit b_i is equal to one with probability p , combining n bits in this manner has the following characteristics [10]:

$$\Pr[bit = 1] = 0.5 - 2^{n-1} \cdot (p - 0.5)^n \quad (2)$$

$$\Pr[bit = 0] = 0.5 + 2^{n-1} \cdot (p - 0.5)^n \quad (3)$$

We can now see that as n goes to infinity, both probabilities approach 0.5, meaning any possible biases will be suppressed. Moreover, an exclusive-or chain should also be straightforward to implement in a Wi-Fi radio.

In the second version of our generator, we use the exclusive-or chain to generate one random bit for each spectral scan sample. That is, all 56 random bits extracted from the subcarriers are XOR’ed together. We call this the “1-bit per spectral scan” mode. The reasoning behind this construction is that one bit is now influenced by all subcarriers, i.e., all available frequencies. An attacker that wants to influence the generation of any bit, now has to predict or influence all 56 subcarriers. The new results of the Dieharder tests show this improves the quality of the random numbers (see Table 2).

In a last step we combine 16 bits generated using the 1-bit per spectral scan construction. Again this is done using an exclusive-or chain. We call this the “normal mode”. Interestingly, the results of the Dieharder test suite no longer improve. We conjecture that the 1.9% of

tests that are marked as weak are statistical flukes: even a random stream of bits can look non-random at times.

Finally, we remark that in the normal execution mode of the generator, in total 56 · 16 bits are XOR’ed together. Hence, even if an attacker can correctly predict the 1 bit per subcarrier with a probability of 98%, our normal execution mode still outputs one bit that is close to uniform. More precisely, by relying on equation 2 and 3, the returned bit equals one with a probability of approximately $0.5 \cdot (1 - 2^{-52})$. Hence, by relying on the large number of measurements returned by the radio chip, even a very powerful attacker is unlikely to predict the final output of the generator. Furthermore, these bits are outputted at a speed of roughly 3125 bits per second. Finally, we believe that our technique can be efficiently implemented in Wi-Fi chips themselves. In practice, implementations can then query the Wi-Fi chip for random samples, and properly and securely manage this collected randomness using a model such as the one proposed by Barak and Halevi [3], or one of its improvements [9].

7 Related Work

While the random number generators that are used in certain browsers [14], OpenSSL [8], Linux [3, 16], GNU Privacy Guard [35], FreeBSD [50], and so on, have been widely studied, we are not aware of any works that study the random number generator of 802.11. More closely related to our work, Lorente et al. discovered that many routers generate weak, and sometimes predictable, default WPA2 passwords [27]. However, the random number generator of 802.11 is not used for this purpose, and hence was not analyzed.

The security of the 4-way handshake has been studied in several works [17, 18, 34]. These works revealed denial-of-service vulnerabilities [17, 34], or proof of the security of an improved design [18]. Additionally, they focus on whether an attacker can perform a downgrade attack against the cipher used to protect traffic transmitted after the handshake. In contrast, we study downgrade attacks against the ciphers used to protect the handshake itself. The 802.11 standard also contains an informative analysis of the handshake [21, 11.6.6.8].

Many researchers have studied RC4 and its usage. Key recovery attacks against WEP were discovered [11], and were later improved in other works [48, 44, 43, 42]. In particular, Mantin and Klein studied whether the WEP key can still be recovered if the initial 256 bytes of RC4 are dropped [28, 26]. We extend this analysis by studying the impact of 16-byte initialization vectors as used in the 4-way handshake, and perform simulations of resulting attacks. AlFardan et al. showed that the initial 256 bytes of RC4 are biased [2]. Vanhoef and Piessens extended this result and showed that bytes between position 256

and 512 are also biased. [47]. In [6] Bricout et al. analyze the structure and exploitation of Mantin’s *ABSAB* bias.

Security of group keys, and the isolation between unicast and group traffic, is briefly mentioned in the Hole 196 vulnerability [1]. However, this attack assumes that an associated (trusted) client will abuse the group key. Therefore it can only be considered an insider threat. Furthermore, it does not discuss how to inject unicast traffic using the group key, nor does it show how all internet traffic can be decrypted using the group key.

Several previous works use the RSSI measurements of 802.11 frames, as returned by commodity Wi-Fi radios, to create secret key agreement protocols [32, 23, 38]. Such a protocol negotiates a shared secret between two stations, that is unpredictable by observers. These works use the average RSSI over all subcarriers, meaning some entropy is lost compared to our per-subcarrier measurements. We use the spectral scan feature to perform RSSI measurements, which makes it possible to generate these measurements even if there is no background traffic. Models to properly collect and manage randomness, such as those contained in RSSI measurements, have also been studied. Examples are Yarrow-160 [25], the model by Barak and Halevi [3], or the model by Dodis et al. [9].

8 Conclusion

Although the generation of pairwise 802.11 keys has been widely analyzed, we have shown the same is not true for group keys. For certain devices the group key is easily predictable, which is caused by the faulty random number generator proposed in the 802.11 standard. This is especially problematic for Wi-Fi stacks in embedded devices, as they generally do not have other (standardized) sources of randomness. Furthermore, we have demonstrated a downgrade attack against the 4-way handshake, resulting in the usage of RC4 to protect the group key. An adversary can abuse this in an attempt to recover the group key.

We also showed that the group key can be used to inject any type of packet, and can even be used decrypt all internet traffic in a network. Combined with the faulty 802.11 random number generator, this enables an adversary to easily bypass both WPA-TKIP and AES-CCMP. To mitigate some of these issues, we also proposed and implemented a strong random number generator tailored for 802.11 platforms.

Abstract

We present DROWN, a novel cross-protocol attack on TLS that uses a server supporting SSLv2 as an oracle to decrypt modern TLS connections.

We introduce two versions of the attack. The more general form exploits multiple unnoticed protocol flaws in SSLv2 to develop a new and stronger variant of the Bleichenbacher RSA padding-oracle attack. To decrypt a 2048-bit RSA TLS ciphertext, an attacker must observe 1,000 TLS handshakes, initiate 40,000 SSLv2 connections, and perform 2^{50} offline work. The victim client never initiates SSLv2 connections. We implemented the attack and can decrypt a TLS 1.2 handshake using 2048-bit RSA in under 8 hours, at a cost of \$440 on Amazon EC2. Using Internet-wide scans, we find that 33% of all HTTPS servers and 22% of those with browser-trusted certificates are vulnerable to this protocol-level attack due to widespread key and certificate reuse.

For an even cheaper attack, we apply our new techniques together with a newly discovered vulnerability in OpenSSL that was present in releases from 1998 to early 2015. Given an unpatched SSLv2 server to use as an oracle, we can decrypt a TLS ciphertext in one minute on a single CPU—fast enough to enable man-in-the-middle attacks against modern browsers. We find that 26% of HTTPS servers are vulnerable to this attack.

We further observe that the QUIC protocol is vulnerable to a variant of our attack that allows an attacker to impersonate a server indefinitely after performing as few as 2^{17} SSLv2 connections and 2^{58} offline work.

We conclude that SSLv2 is not only weak, but actively harmful to the TLS ecosystem.

1 Introduction

TLS [13] is one of the main protocols responsible for transport security on the modern Internet. TLS and its precursor SSLv3 have been the target of a large number of cryptographic attacks in the research community, both on popular implementations and the protocol itself [33]. Prominent recent examples include attacks on outdated or deliberately weakened encryption in RC4 [3], RSA [5], and Diffie-Hellman [1], different side channels including Lucky13 [2], BEAST [14], and POODLE [35], and several attacks on invalid TLS protocol flows [5, 6, 12].

Comparatively little attention has been paid to the SSLv2 protocol, likely because the known attacks are so devastating and the protocol has long been considered obsolete. Wagner and Schneier wrote in 1996 that their attacks on SSLv2 “will be irrelevant in the long term when servers stop accepting SSL 2.0 connections” [41]. Most modern TLS clients do not support SSLv2 at all. Yet in 2016, our Internet-wide scans find that out of 36 million HTTPS servers, 6 million (17%) support SSLv2.

A Bleichenbacher attack on SSLv2. Bleichenbacher’s padding oracle attack [8] is an adaptive chosen ciphertext attack against PKCS#1 v1.5, the RSA padding standard used in SSL and TLS. It enables decryption of RSA ciphertexts if a server distinguishes between correctly and incorrectly padded RSA plaintexts, and was termed the “million-message attack” upon its introduction in 1998, after the number of decryption queries needed to deduce a plaintext. All widely used SSL/TLS servers include countermeasures against Bleichenbacher attacks.

Our first result shows that the SSLv2 protocol is fatally vulnerable to a form of Bleichenbacher attack that enables

decryption of RSA ciphertexts. We develop a novel application of the attack that allows us to use a server that supports SSLv2 as an efficient padding oracle. This attack is a protocol-level flaw in SSLv2 that results in a feasible attack for 40-bit export cipher strengths, and in fact abuses the universally implemented countermeasures against Bleichenbacher attacks to obtain a decryption oracle.

We also discovered multiple implementation flaws in commonly deployed OpenSSL versions that allow an extremely efficient instantiation of this attack.

Using SSLv2 to break TLS. Second, we present a novel *cross-protocol attack* that allows an attacker to break a passively collected RSA key exchange for any TLS server if the RSA keys are also used for SSLv2, possibly on a different server. We call this attack DROWN (*Decrypting RSA using Obsolete and Weakened eNcryption*).

In its *general* version, the attack exploits the protocol flaws in SSLv2, does not rely on any particular library implementation, and is feasible to carry out in practice by taking advantage of commonly supported export-grade ciphers. In order to decrypt one TLS session, the attacker must passively capture about 1,000 TLS sessions using RSA key exchange, make 40,000 SSLv2 connections to the victim server, and perform 2^{50} symmetric encryption operations. We successfully carried out this attack using an optimized GPU implementation and were able to decrypt a 2048-bit RSA ciphertext in less than 18 hours on a GPU cluster and less than 8 hours using Amazon EC2.

We found that 11.5 million HTTPS servers (33%) are vulnerable to this attack, because many HTTPS servers that do not directly support SSLv2 share RSA keys with other services that do. Of servers offering HTTPS with browser-trusted certificates, 22% are vulnerable.

We also present a *special* version of DROWN that exploits flaws in OpenSSL for a more efficient oracle. It requires roughly the same number of captured TLS sessions as the general attack, but only half as many connections to the victim server and no large computations. This attack can be completed on a single core on commodity hardware in less than a minute, and is limited primarily by how fast the server can complete handshakes. It is fast enough that an attacker can perform man-in-the-middle attacks on live TLS sessions before the handshake times out, and downgrade a modern TLS client to RSA key exchange with a server that prefers non-RSA cipher suites. Our Internet-wide scans suggest that 79% of HTTPS servers that are vulnerable to the general attack, or 26% of all HTTPS servers, are also vulnerable to real-time attacks exploiting these implementation flaws.

Our results highlight the risk that continued support for SSLv2 imposes on the security of much more recent TLS versions. This is an instance of a more general phenomenon of insufficient domain separation, where older, vulnerable security standards can open the door to

attacks on newer versions. We conclude that phasing out outdated and insecure standards should become a priority for standards designers and practitioners.

Disclosure. DROWN was assigned CVE-2016-0800. We disclosed our attacks to OpenSSL and worked with them to coordinate further disclosures. The specific OpenSSL vulnerabilities we discovered have been designated CVE-2015-3197, CVE-2016-0703, and CVE-2016-0704. In response to our findings, OpenSSL has made it impossible to configure a TLS server in such a way that it is vulnerable to DROWN. Microsoft had already disabled SSLv2 for all supported versions of IIS. We also disclosed the attack to the NSS developers, who have disabled SSLv2 on the last NSS tool that supported it and have hastened efforts to entirely remove the protocol from their codebase. In response to our disclosure, Google will disable QUIC support for non-whitelisted servers and modify the QUIC standard. We also notified IBM, Cisco, Amazon, the German CERT-Bund, and the Israeli CERT.

2 Background

In the following, $a||b$ denotes concatenation of strings a and b . $a[i]$ references the i -th byte in a . (N, e) denotes an RSA public key, where N has byte-length ℓ_m ($|N| = \ell_m$) and e is the public exponent. The corresponding secret exponent is $d = 1/e \bmod \phi(N)$.

2.1 PKCS#1 v1.5 encryption padding

Our attacks rely on the structure of RSA PKCS#1 v1.5 padding. Although RSA PKCS#1 v2.0 implements OAEP, SSL/TLS still uses PKCS#1 v1.5. The PKCS#1 v1.5 encryption padding scheme [27] randomizes encryptions by prepending a random padding string PS to a message k (here, a symmetric session key) before RSA encryption:

1. The plaintext message is k , $\ell_k = |k|$. The encrypter generates a random byte string PS , where $|PS| \geq 8$, $|PS| = \ell_m - 3 - \ell_k$, and $0x00 \notin \{PS[1], \dots, PS[|PS|]\}$.
2. The encryption block is $m = 00||02||PS||00||k$.
3. The ciphertext is computed as $c = m^e \bmod N$.

To decrypt such a ciphertext, the decrypter first computes $m = c^d \bmod N$. Then it checks whether the decrypted message m is correctly formatted as a PKCS#1 v1.5-encoded message. We say that the ciphertext c and the decrypted message bytes $m[1]||m[2]||\dots||m[\ell_m]$ are PKCS#1 v1.5 conformant if:

$$\begin{aligned} m[1]||m[2] &= 0x00||0x02 \\ 0x00 &\notin \{m[3], \dots, m[10]\} \end{aligned}$$

If this condition holds, the decrypter searches for the first

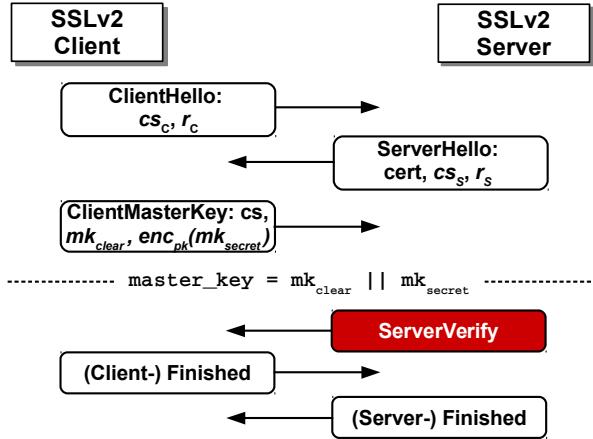

Figure 1: **SSLv2 handshake.** The server responds with a `ServerVerify` message directly after receiving an RSA-PKCS#1 v1.5 ciphertext contained in `ClientMasterKey`. This protocol feature enables our attack.

value $i > 10$ such that $m[i] = 0x00$. Then, it extracts $k = m[i+1] \parallel \dots \parallel m[\ell_m]$. Otherwise, the ciphertext is rejected.

In SSLv3 and TLS, RSA PKCS#1 v1.5 is used to encapsulate the premaster secret exchanged during the hand-shake [13]. Thus, k is interpreted as the premaster secret. In SSLv2, RSA PKCS#1 v1.5 is used for encapsulation of an equivalent key denoted the `master_key`.

2.2 SSL and TLS

The first incarnation of the TLS protocol was the SSL (Secure Socket Layer) protocol, which was designed by Netscape in the 90s. The first two versions of SSL were immediately found to be vulnerable to trivial attacks [40, 41] which were fixed in SSLv3 [17]. Later versions of the standard were renamed TLS, and share a similar structure to SSLv3. The current version of the protocol is TLS 1.2; TLS 1.3 is currently under development.

An SSL/TLS protocol flow consists of two phases: handshake and application data exchange. In the first phase, the communicating parties agree on cryptographic algorithms and establish shared keys. In the second phase, these keys are used to protect the confidentiality and authenticity of the transmitted application data.

The handshake protocol was fundamentally redesigned in the SSLv3 version. This new handshake protocol was then used in later TLS versions up to TLS 1.2. In the following, we describe the RSA-based handshake protocols used in TLS and SSLv2, and highlight their differences.

The SSLv2 handshake protocol. The SSLv2 protocol description [22] is less formally specified than modern RFCs. Figure 1 depicts an SSLv2 handshake. A client initiates an SSLv2 handshake by sending a `ClientHello` message, which includes a list of cipher suites cs_c

supported by the client and a client nonce r_c , termed challenge. The server responds with a `ServerHello` message, which contains a list of cipher suites cs_s supported by the server, the server certificate, and a server nonce r_s , termed `connection_ID`.

The client responds with a `ClientMasterKey` message, which specifies a cipher suite supported by both peers and key data used for constructing a `master_key`. In order to support *export* cipher suites with 40-bit security (e.g., `SSL_RC2_128_CBC_EXPORT40_WITH_MD5`), the key data is divided into two parts:

- mk_{clear} : A portion of the `master_key` sent in the `ClientMasterKey` message as plaintext (termed `clear_key_data` in the SSLv2 standard).
 - mk_{secret} : A secret portion of the `master_key`, encrypted with RSA PKCS#1 v1.5 (termed `secret_key_data`).

The resulting `master_key` mk is constructed by concatenating these two keys: $mk = mk_{clear} || mk_{secret}$. For 40-bit export cipher suites, mk_{secret} is five bytes in length. For non-export cipher suites, the whole `master_key` is encrypted, and the length of mk_{clear} is zero.

The client and server can then compute session keys from the reconstructed `master_key` mk :

$$\begin{aligned} \text{server_write_key} &= MD5(mk||"0"||r_c||r_s) \\ \text{client_write_key} &= MD5(mk||"1"||r_c||r_s) \end{aligned}$$

The server responds with a `ServerVerify` message consisting of the challenge r_c encrypted with the `server_write_key`. Both peers then exchange `Finished` messages in order to authenticate to each other.

Our attack exploits the fact that the server always decrypts an RSA-PKCS#1 v1.5 ciphertext, computes the `server_write_key`, and *immediately* responds with a `ServerVerify` message. The SSLv2 standard implies this message ordering, but does not make it explicit. However, we observed this behavior in every implementation we examined. Our attack also takes advantage of the fact that the encrypted mk_{secret} portion of the `master_key` can vary in length, and is only five bytes for export ciphers.

The TLS handshake protocol. In TLS [13] or SSLv3, the client initiates the handshake with a `ClientHello`, which contains a client random r_c and a list of supported cipher suites. The server chooses one of the cipher suites and responds with three messages, `ServerHello`, `Certificate`, and `ServerHelloDone`. These messages include the server's choice of cipher suite, server nonce r_s , and a server certificate with an RSA public key. The client then uses the public key to encrypt a newly generated 48-byte premaster secret pms and sends it to the server in a `ClientKeyExchange` message. The client and server then derive encryption and MAC keys from the premaster secret and the client and server random nonces. The details of this derivation are not important to our attack. The

client then sends `ChangeCipherSpec` and `Finished` messages. The `Finished` message authenticates all previous handshake messages using the derived keys. The server responds with its own `ChangeCipherSpec` and `Finished` messages.

The two main details relevant to our attacks are:

- The premaster secret is always 48 bytes long, independent of the chosen cipher suite. This is also true for export cipher suites.
- After receiving the `ClientKeyExchange` message, the server waits for the `ClientFinished` message, in order to authenticate the client.

2.3 Bleichenbacher’s attack

Bleichenbacher’s attack is a padding oracle attack—it exploits the fact that RSA ciphertexts should decrypt to PKCS#1 v1.5-compliant plaintexts. If an implementation receives an RSA ciphertext that decrypts to an invalid PKCS#1 v1.5 plaintext, it might naturally leak this information via an error message, by closing the connection, or by taking longer to process the error condition. This behavior can leak information about the plaintext that can be modeled as a cryptographic *oracle* for the decryption process. Bleichenbacher [8] demonstrated how such an oracle could be exploited to decrypt RSA ciphertexts.

Algorithm. In the simplest attack scenario, the attacker has a valid PKCS#1 v1.5 ciphertext c_0 that they wish to decrypt to discover the message m_0 . They have no access to the private RSA key, but instead have access to an oracle \mathcal{O} that will decrypt a ciphertext c and inform the attacker whether the most significant two bytes match the required value for a correct PKCS#1 v1.5 padding:

$$\mathcal{O}(c) = \begin{cases} 1 & \text{if } m = c^d \bmod N \text{ starts with 0x00 02} \\ 0 & \text{otherwise.} \end{cases}$$

If the oracle answers with 1, the attacker knows that $2B \leq m \leq 3B - 1$, where $B = 2^{8(\ell_m - 2)}$. The attacker can take advantage of RSA malleability to generate new candidate ciphertexts for any s :

$$c = (c_0 \cdot s^e) \bmod N = (m_0 \cdot s)^e \bmod N$$

The attacker queries the oracle with c . If the oracle responds with 0, the attacker increments s and repeats the previous step. Otherwise, the attacker learns that for some r , $2B \leq m_0 s - rN < 3B$. This allows the attacker to reduce the range of possible solutions to:

$$\frac{2B + rN}{s} \leq m_0 < \frac{3B + rN}{s}$$

The attacker proceeds by refining guesses for s and r values and successively decreasing the size of the interval containing m_0 . At some point the interval will contain a single valid value, m_0 . Bleichenbacher’s original paper describes this process in further detail [8].

Countermeasures. In order to protect against this attack, the decrypter must not leak information about the PKCS#1 v1.5 validity of the ciphertext. The ciphertext does not decrypt to a valid message, so the decrypter generates a fake plaintext and continues the protocol with this decoy. The attacker should not be able to distinguish the resulting computation from a correctly decrypted ciphertext.

In the case of SSL/TLS, the server generates a random premaster secret to continue the handshake if the decrypted ciphertext is invalid. The client will not possess the session key to send a valid `ClientFinished` message and the connection will terminate.

3 Breaking TLS with SSLv2

In this section, we describe our cross-protocol DROWN attack that uses an SSLv2 server as an oracle to efficiently decrypt TLS connections. The attacker learns the session key for targeted TLS connections but does not learn the server’s private RSA key. We first describe our techniques using a generic SSLv2 oracle. In Section 4.1, we show how a protocol flaw in SSLv2 can be used to construct such an oracle, and describe our general DROWN attack. In Section 5, we show how an implementation flaw in common versions of OpenSSL leads to a more powerful oracle and describe our efficient special DROWN attack.

We consider a server accepting TLS connections from clients. The connections are established using a secure, state-of-the-art TLS version (1.0–1.2) and a `TLS_RSA` cipher suite with a private key unknown to the attacker.

The same RSA public key as the TLS connections is also used for SSLv2. For simplicity, our presentation will refer to the servers accepting TLS and SSLv2 connections as the same entity.

Our attacker is able to passively eavesdrop on traffic between the client and server and record RSA-based TLS traffic. The attacker may or may not be also required to perform active man-in-the-middle interference, as explained below.

The attacker can expect to decrypt one out of 1,000 intercepted TLS connections in our attack for typical parameters. This is a devastating threat in many scenarios. For example, a decrypted TLS connection might reveal a client’s HTTP cookie or plaintext password, and an attacker would only need to successfully decrypt a single ciphertext to compromise the client’s account. In order to collect 1,000 TLS connections, the attacker might simply wait patiently until sufficiently many connections are recorded. A less patient attacker might use man-in-the-middle interference, as in the BEAST attack [14].

3.1 A generic SSLv2 oracle

Our attacks make use of an oracle that can be queried on a ciphertext and leaks information about the decrypted plaintext; this abstractly models the information gained

from an SSLv2 server’s behavior. Our SSLv2 oracles reveal many bytes of plaintext, enabling an efficient attack.

Our cryptographic oracle \mathcal{O} has the following functionality: \mathcal{O} decrypts an RSA ciphertext c and responds with ciphertext validity based on the decrypted message m . The ciphertext is valid only if m starts with 0x00 02 followed by non-null padding bytes, a delimiter byte 0x00, and a master key mk_{secret} of correct byte length ℓ_k . We call such a ciphertext *SSLv2 conformant*.

All of the SSLv2 padding oracles we instantiate give the attacker similar information about a PKCS#1 v1.5 conformant SSLv2 ciphertext:

$$\mathcal{O}(c) = \begin{cases} mk_{secret} & \text{if } c^d \bmod N = 00||02||PS||00||mk_{secret} \\ 0 & \text{otherwise.} \end{cases}$$

That is, the oracle $\mathcal{O}(c)$ will return the decrypted message mk_{secret} if it is queried on a PKCS#1 v1.5 conformant SSLv2 ciphertext c corresponding to a correctly PKCS#1 v1.5 padded encryption of mk_{secret} . The attacker then learns $\ell_k + 3$ bytes of $m = c^d \bmod N$: the first two bytes are 00||02, and the last $\ell_k + 1$ bytes are 00|| mk_{secret} . The length ℓ_k of mk_{secret} varies based on the cipher suite used to instantiate the oracle. For export-grade cipher suites such as `SSL_RSA_EXPORT_WITH_RC2_CBC_40_MD5`, k will be 5 bytes, so the attacker learns 8 bytes of m .

3.2 DROWN attack template

Our attacker will use an SSLv2 oracle \mathcal{O} to decrypt a TLS ClientKeyExchange. The behavior of \mathcal{O} poses two problems for the attacker. First, a TLS key exchange ciphertext decrypts to a 48-byte premaster secret. But since no SSLv2 cipher suites have 48-byte key strengths, this means that a valid TLS ciphertext is invalid to our oracle \mathcal{O} . In order to apply Bleichenbacher’s attack, the attacker must transform the TLS ciphertext into a valid SSLv2 key exchange message. Second, \mathcal{O} is very restrictive, since it strictly checks the length of the unpadded message. According to Bardou et al. [4], Bleichenbacher’s attack would require 12 million queries to such an oracle.¹

Our attacker overcomes these problems by following this generic attack flow:

0. The attacker collects many encrypted TLS RSA key exchange messages.
1. The attacker converts one of the intercepted TLS ciphertexts containing a 48-byte premaster secret to an RSA PKCS#1 v1.5 encoded ciphertext valid to the SSLv2 oracle \mathcal{O} .
2. Once the attacker has obtained a valid SSLv2 RSA ciphertext, they can continue with a modified version of Bleichenbacher’s attack, and decrypt the message after many more oracle queries.

¹See Table 1 in [4]. The oracle is denoted with the term FFF.

3. The attacker then transforms the decrypted plaintext back into the original plaintext, which is one of the collected TLS handshakes.

We describe the algorithmic improvements we use to make each of these steps efficient below.

3.2.1 Finding an SSLv2 conformant ciphertext

The first step for the attacker is to transform the original TLS ClientKeyExchange message c_0 from a TLS conformant ciphertext into an SSLv2 conformant ciphertext.

For this task, we rely on the concept of *trimmers*, which were introduced by Bardou et al. [4]. Assume that the message $m_0 = c_0^d \bmod N$ is divisible by a small number t . In that case, $m_0 \cdot t^{-1} \bmod N$ simply equals the natural number m_0/t . If we choose $u \approx t$, and multiply the original message by $u \cdot t^{-1}$, the resulting number will lie near the original message: $m_0 \approx m_0/t \cdot u$.

This method gives a good chance of generating a new SSLv2 conformant message. Let c_0 be an intercepted TLS conformant RSA ciphertext, and let $m_0 = c_0^d \bmod N$ be the plaintext. We select a multiplier $s = u/t \bmod N = ut^{-1} \bmod N$ where u and t are coprime, compute the value $c_1 = c_0 s^e \bmod N$, and query $\mathcal{O}(c_1)$. We will receive a response if $m_1 = m_0 \cdot u/t$ is SSLv2 conformant.

As an example, let us assume a 2048-bit RSA ciphertext with $\ell_k = 5$, and consider the fraction $u = 7, t = 8$. The probability that $c_0 \cdot u/t$ will be SSLv2 conformant is 1/7,774, so we expect to make 7,774 oracle queries before obtaining a positive response from \mathcal{O} . Appendix A.1 gives more details on computing these probabilities.

3.2.2 Shifting known plaintext bytes

Once we have obtained an SSLv2 conformant ciphertext c_1 , the oracle has also revealed the $\ell_k + 1$ least significant bytes (mk_{secret} together with the delimiter byte 0x00) and two most significant 0x00 02 bytes of the SSLv2 conformant message m_1 . We would like to *rotate* these known bytes around to the right, so that we have a large block of contiguous known most significant bytes of plaintext. In this section, we show that this can be accomplished by multiplying by some shift $2^{-r} \bmod N$. In other words, given an SSLv2 conformant ciphertext $c_1 = m_1^e \bmod N$, we can efficiently generate an SSLv2 conformant ciphertext $c_2 = m_2^e \bmod N$ where $m_2 = s \cdot m_1 \cdot 2^{-r} \bmod N$ and we know several most significant bytes of m_2 .

Let $R = 2^{8(k+1)}$ and $B = 2^{8(\ell_m-2)}$. Abusing notation slightly, let the integer $m_1 = 2 \cdot B + PS \cdot R + mk_{secret}$ be the plaintext satisfying $m_1^e = c_1 \bmod N$. At this stage, the ℓ_k -byte integer mk_{secret} is known and the $\ell_m - \ell_k - 3$ -byte integer PS is not.

Let $\tilde{m}_1 = 2 \cdot B + mk_{secret}$ be the known components of m_1 , so $m_1 = \tilde{m}_1 + PS \cdot R$. We can use this to compute a new plaintext for which we know many most significant

bytes. Consider the value:

$$m_1 \cdot R^{-1} \bmod N = \tilde{m}_1 \cdot R^{-1} + PS \bmod N.$$

The value of PS is unknown and consists of $\ell_m - \ell_k - 3$ bytes. This means that the known value $\tilde{m}_1 \cdot R^{-1}$ shares most of its $\ell_k + 3$ most significant bytes with $m_1 \cdot R^{-1}$.

Furthermore, we can iterate this process by finding a new multiplier s such that $m_2 = s \cdot m_1 \cdot R^{-1} \bmod N$ is also SSLv2 conformant. A randomly chosen $s < 2^{30}$ will work with probability $2^{-25.4}$. We can take use the bytes we have already learned about m_1 to efficiently compute such an s with only 678 oracle queries in expectation for a 2048-bit RSA modulus. Appendix A.3 gives more details.

3.2.3 Adapted Bleichenbacher iteration

It is feasible for all of our oracles to use the previous technique to entirely recover a plaintext message. However, for our SSLv2 protocol oracle it is cheaper after a few iterations to continue using Bleichenbacher’s original attack. We can apply the original algorithm proposed by Bleichenbacher as described in Section 2.3.

Each step obtains a message that starts with the required 0x00 02 bytes after two queries in expectation. Since we know the value of the $\ell_k + 1$ least significant bytes after multiplying by any integer, we can query the oracle only on multipliers that cause the $(\ell_k + 1)$ st least significant byte to be zero. However, we cannot ensure that the padding string is entirely nonzero; for a 2048-bit modulus this will hold with probability 0.37.

For a 2048-bit modulus, the total expected number of queries when using this technique to fully decrypt the plaintext is $2048 * 2 / 0.37 \approx 11,000$.

4 General DROWN

In this section, we describe how to use any correct SSLv2 implementation accepting export-grade cipher suites as a padding oracle. We then show how to adapt the techniques described in Section 3.2 to decrypt TLS RSA ciphertexts.

4.1 The SSLv2 export padding oracle

SSLv2 is vulnerable to a direct message side channel vulnerability exposing a Bleichenbacher oracle to the attacker. The vulnerability follows from three properties of SSLv2. First, the server immediately responds with a `ServerVerify` message after receiving the `ClientMasterKey` message, which includes the RSA ciphertext, without waiting for the `ClientFinished` message that proves the client knows the RSA plaintext. Second, when choosing 40-bit export RC2 or RC4 as the symmetric cipher, only 5 bytes of the `master_key` (mk_{secret}) are sent encrypted using RSA, and the remaining 11 bytes are sent in cleartext. Third, a server implementation that correctly implements the anti-Bleichenbacher countermeasure and receives an RSA key exchange message with invalid padding will generate a random premaster secret

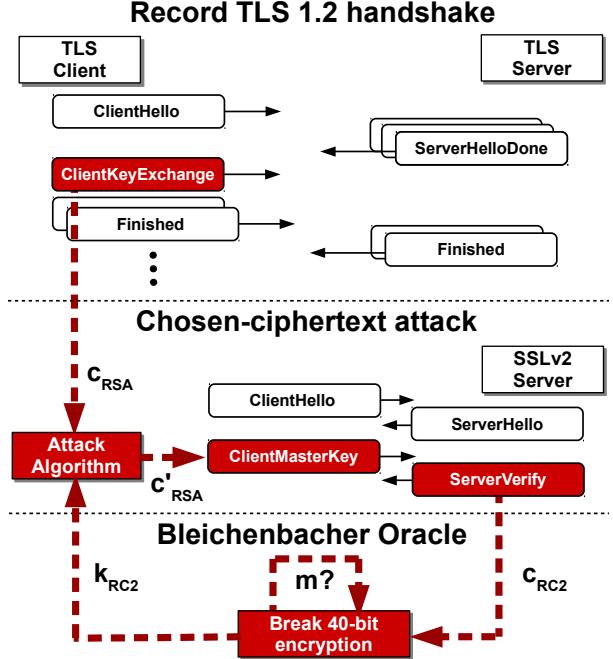

Figure 2: **SSLv2-based Bleichenbacher attack on TLS.** An attacker passively collects RSA ciphertexts from a TLS 1.2 handshake, and then performs oracle queries against a server that supports SSLv2 with the same public key to decrypt the TLS ciphertext.

and carry out the rest of the TLS handshake using this randomly generated key material.

This allows an attacker to deduce the validity of RSA ciphertexts in the following manner:

1. The attacker sends a `ClientMasterKey` message, which contains an RSA ciphertext c_0 and any choice of 11 clear key bytes for mk_{clear} . The server responds with a `ServerVerify` message, which contains the challenge encrypted using the `server_write_key`.
2. The attacker performs an *exhaustive search* over the possible values of the 5 bytes of the `master_key` mk_{secret} , computes the corresponding `server_write_key`, and checks whether the `ServerVerify` message decrypts to `challenge`. One value should pass this check; call it mk_0 . Recall that if the RSA plaintext was valid, mk_0 is the unpadded data in the RSA plaintext c_0^d . Otherwise, mk_0 is a randomly generated sequence of 5 bytes.
3. The attacker re-connects to the server with the same RSA ciphertext c_0 . The server responds with another `ServerVerify` message that contains the current challenge encrypted using the current `server_write_key`. If the decrypted RSA cipher-

text was valid, the attacker can use mk_0 to decrypt a correct challenge value from the ServerVerify message. Otherwise, if the ServerVerify message does not decrypt to challenge, the RSA ciphertext was invalid, and mk_0 must have been random.

Thus we can instantiate an oracle $\mathcal{O}_{\text{SSLv2-export}}$ using the procedure above; each oracle query requires two server connections and 2^{40} decryption attempts in the simplest case. For each oracle call $\mathcal{O}_{\text{SSLv2-export}}(c)$, the attacker learns whether c is valid, and if so, learns the two most significant bytes 0x00 02, the sixth least significant 0x00 delimiter byte, and the value of the 5 least significant bytes of the plaintext m .

4.2 TLS decryption attack

In this section, we describe how the oracle described in Section 4.1 can be used to carry out a feasible attack to decrypt passively collected TLS ciphertexts.

As described in Section 3, we consider a server that accepts TLS connections from clients using an RSA public key that is exposed via SSLv2, and an attacker who is able to passively observe these connections.

We also assume the server supports export cipher suites for SSLv2. This can happen for two reasons. First, the same server operators that fail to follow best practices in disabling SSLv2 [40] may also fail to follow best practices by supporting export cipher suites. Alternatively, the server might be running a version of OpenSSL prior to January 2016, in which case it is vulnerable to the OpenSSL cipher suite selection bug described in Section 7, and an attacker may negotiate a cipher suite of his choice independent of the server configuration.

The attacker needs access to computing power sufficient to perform a 2^{50} time attack, mostly brute forcing symmetric key encryption. After our optimizations, this can be done with a one-time investment of a few thousand dollars of GPUs, or in a few hours for a few hundred dollars in the cloud. Our cost estimates are described in Section 4.3.

4.2.1 Constructing the attack

The attacker can exploit the SSLv2 vulnerability following the generic attack outline described in Section 3.2, consisting of several distinct phases:

0. The attacker passively collects 1,000 TLS handshakes from connections using RSA key exchange.
1. They then attempt to convert the intercepted TLS ciphertexts containing a 48-byte premaster secret to valid RSA PKCS#1 v1.5 encoded ciphertexts containing five-byte messages using the fractional trimmers described in Section 3.2.1, and querying $\mathcal{O}_{\text{SSLv2-export}}$. The attacker sends the modified ciphertexts to the server using fresh SSLv2 connections with weak symmetric ciphers and uses the

ServerVerify messages to deduce ciphertext validity as described in the previous section. For each queried RSA ciphertext, the attacker must perform a brute force attack on the weak symmetric cipher. The attacker expects to obtain a valid SSLv2 ciphertext after roughly 10,000 oracle queries, or 20,000 connections to the server.

2. Once the attacker has obtained a valid SSLv2 RSA ciphertext $c_1 = m_1^e$, they use the shifting technique explained in Section 3.2.2 to find an integer s_1 such that $m_2 = m_1 \cdot 2^{-40} \cdot s_1$ is also SSLv2 conformant. Appendix A.4 contains more details on this step.
3. The attacker then applies the shifting technique again to find another integer s_2 such that $m_3 = m_2 \cdot 2^{-40} \cdot s_2$ is also SSLv2 conformant.
4. They then search for yet another integer s_3 such that $m_3 \cdot s_3$ is also SSLv2 conformant.
5. Finally, the attacker can continue with our adapted Bleichenbacher iteration technique described in Section 3.2.3, and decrypts the message after an expected 10,000 additional oracle queries, or 20,000 connections to the server.
6. The attacker can then transform the decrypted plaintext back into the original plaintext, which is one of the 1,000 intercepted TLS handshakes.

The rationale behind the different phases. Bleichenbacher’s original algorithm requires a conformant message m_0 , and a multiplier s_1 such that $m_1 = m_0 \cdot s_1$ is also conformant. Naïvely, it would appear we can apply the same algorithm here, after completing Phase 1. However, the original algorithm expects s_1 to be of size about 2^{24} . This is not the case when we use fractions for s_1 , as the integer $s_1 = ut^{-1} \bmod N$ will be the same size as N .

Therefore, our approach is to find a conformant message for which we know the 5 most significant bytes; this will happen after multiple rotations and this message will be m_3 . After finding such a message, finding s_3 such that $m_4 = m_3 \cdot s_3$ is also conformant becomes trivial. From there, we can finally apply the adapted Bleichenbacher iteration technique as described in Appendix A.5.

4.2.2 Attack performance

The attacker wishes to minimize three major costs in the attack: the number of recorded ciphertexts from the victim client, the number of connections to the victim server, and the number of symmetric keys to be brute forced. The requirements for each of these elements are governed by the set of fractions to be multiplied with each RSA ciphertext in the first phase, as described in Section 3.2.1.

Table 1 highlights a few choices for F and the resulting performance metrics for 2048-bit RSA keys. Appendix A provides more details on the derivation of these numbers

Optimizing for	Cipher-texts	$ F $	SSLv2 connections	Offline work
offline work	12,743	1	50,421	$2^{49.64}$
offline work	1,055	10	46,042	$2^{50.63}$
compromise	4,036	2	41,081	$2^{49.98}$
online work	2,321	3	38,866	$2^{51.99}$
online work	906	8	39,437	$2^{52.25}$

Table 1: **2048-bit Bleichenbacher attack complexity.**

The cost to decrypt one ciphertext can be adjusted by choosing the set of fractions F the attacker applies to each of the passively collected ciphertexts in the first step of the attack. This choice affects several parameters: the number of these collected ciphertexts, the number of connections the attacker makes to the SSLv2 server, and the number of offline decryption operations.

Key size	Phase 1	Phases 2–5	Total queries	Offline work
1024	4,129	4,132	8,261	$2^{50.01}$
2048	6,919	12,468	19,387	$2^{50.76}$
4096	18,286	62,185	80,471	$2^{52.16}$

Table 2: **Oracle queries required by our attack.** In Phase 1, the attacker queries the oracle until an SSLv2 conformant ciphertext is found. In Phases 2–5, the attacker decrypts this ciphertext using leaked plaintext. These numbers minimize total queries. In our attack, an oracle query represents two server connections.

and other optimization choices. Table 2 gives the expected number of Bleichenbacher queries for different RSA key sizes, when minimizing total oracle queries.

4.3 Implementing general DROWN with GPUs

The most computationally expensive part of our general DROWN attack is breaking the 40-bit symmetric key, so we developed a highly optimized GPU implementation of this brute force attack. Our first naïve GPU implementation performed around 26MH/s, where MH denotes the time required for testing one million possible values of mk_{secret} . Our optimized implementation runs at a final speed of 515MH/s, a speedup factor of 19.8.

We obtained our improvements through a number of optimizations. For example, our original implementation ran into a communication bottleneck in the PCI-E bus in transmitting candidate keys from CPU to GPU, so we removed this bottleneck by generating key candidates on the GPU itself. We optimized memory management, including storing candidate keys and the RC2 permutation table in constant memory, which is almost as fast as a register, instead of slow global memory.

We experimentally evaluated our optimized implementation on a local cluster and in the cloud. We used it to execute a full attack of $2^{49.6}$ tested keys on each platform. The required number of keys to test during the attack is a random variable, distributed geometrically, with an expectation that ranges between $2^{49.6}$ and $2^{52.5}$ depending on the choice of optimization parameters. We treat a full attack as requiring $2^{49.6}$ tested keys overall.

Hashcat. Hashcat [20] is an open source optimized password-recovery tool. The Hashcat developers allowed us to use their GPU servers for our attack evaluation. The servers contain a total of 40 GPUs: 32 Nvidia GTX 980 cards, and 8 AMD R9 290X cards. The value of this equipment is roughly \$18,040. Our full attack took less than 18 hours to complete on the Hashcat servers, with the longest single instance taking 17h9m.

Amazon EC2. We also ran our optimized GPU code on the Amazon Elastic Compute Cloud (EC2) service. We used a cluster composed of 200 variable-price “spot” instances: 150 g2.2xlarge instances, each containing one high-performance NVIDIA GPU with 1,536 CUDA cores and 50 g2.8xlarge instances, each containing four of these GPUs. When we ran our experiments in January 2016, the average spot rates we paid were \$0.09/hr and \$0.83/hr respectively. Our full attack finished in under 8 hours including startup and shutdown for a cost of \$440.

4.4 OpenSSL SSLv2 cipher suite selection bug

General DROWN is a protocol flaw, but the population of vulnerable hosts is increased due to a bug in OpenSSL that causes many servers to erroneously support SSLv2 and export ciphers even when configured not to. The OpenSSL team intended to disable SSLv2 by default in 2010, with a change that removed all SSLv2 cipher suites from the default list of ciphers offered by the server [36]. However, the code for the protocol itself was not removed in standard builds and SSLv2 itself remained enabled. We discovered a bug in OpenSSL’s SSLv2 cipher suite negotiation logic that allows clients to select SSLv2 cipher suites even when they are not explicitly offered by the server. We notified the OpenSSL team of this vulnerability, which was assigned CVE-2015-3197. The problem was fixed in OpenSSL releases 1.0.2f and 1.0.1r [36].

5 Special DROWN

We discovered multiple vulnerabilities in recent (but not current) versions of the OpenSSL SSLv2 handshake code that create even more powerful Bleichenbacher oracles, and drastically reduce the amount of computation required to implement our attacks. The vulnerabilities, designated CVE-2016-0703 and CVE-2016-0704, were present in the OpenSSL codebase from at least the start of the repository, in 1998, until they were unknowingly fixed on March

4, 2015 by a patch [28] designed to correct an unrelated problem [11]. By adapting DROWN to exploit this special case, we can significantly cut both the number of connections and the computational work required.

5.1 The OpenSSL “extra clear” oracle

Prior to the fix, OpenSSL servers improperly allowed the `ClientMasterKey` message to contain `clear_key_data` bytes for *non-export* ciphers. When such bytes are present, the server substitutes them for bytes from the encrypted key. For example, consider the case that the client chooses a 128-bit cipher and sends a 16-byte encrypted key $k[1], k[2], \dots, k[16]$ but, contrary to the protocol specification, includes 4 null bytes of `clear_key_data`. Vulnerable OpenSSL versions will construct the following `master_key`:

```
[00 00 00 00 k[1] k[2] k[3] k[4] ... k[9] k[10] k[11] k[12]]
```

This enables a straightforward key recovery attack against such versions. An attacker that has intercepted an SSLv2 connection takes the RSA ciphertext of the encrypted key and replays it in non-export handshakes to the server with varying lengths of `clear_key_data`. For a 16-byte encrypted key, the attacker starts with 15 bytes of clear key, causing the server to use the `master_key`:

```
[00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 k[1]]
```

The attacker can brute force the first byte of the encrypted key by finding the matching `ServerVerify` message among 256 possibilities. Knowing $k[1]$, the attacker makes another connection with the same RSA ciphertext but 14 bytes of clear key, resulting in the `master_key`:

```
[00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 k[1] k[2]]
```

The attacker can now easily brute force $k[2]$. With only 15 probe connections and an expected $15 \cdot 128 = 1,920$ trial encryptions, the attacker learns the entire `master_key` for the recorded session.

As this oracle is obtained by improperly sending unexpected clear-key bytes, we call it the Extra Clear oracle.

This session key-recovery attack can be directly converted to a Bleichenbacher oracle. Given a candidate ciphertext and symmetric key length ℓ_k , the attacker sends the ciphertext with ℓ_k known bytes of `clear_key_data`. The oracle decision is simple:

- If the ciphertext is valid, the `ServerVerify` message will reflect a `master_key` consisting of those ℓ_k known bytes.
- If the ciphertext is invalid, the `master_key` will be replaced with ℓ_k random bytes (by following the countermeasure against the Bleichenbacher attack), resulting in a different `ServerVerify` message.

This oracle decision requires one connection to the server and one `ServerVerify` computation. After the attacker has found a valid ciphertext corresponding to a

ℓ_k -byte encrypted key, they recover the ℓ_k plaintext bytes by repeating the key recovery attack from above. Thus our oracle $\mathcal{O}_{\text{SSLv2-extra-clear}}(c)$ requires one connection to determine whether c is valid. After ℓ_k connections, the attacker additionally learns the ℓ_k least significant bytes of m . We model this as a single oracle call, but the number of server connections will vary depending on the response.

5.2 MITM attack against TLS

Special DROWN is fast enough that it can decrypt a TLS premaster secret *online*, during a connection handshake. A man-in-the-middle attacker can use it to compromise connections between modern browsers and TLS servers—even those configured to prefer non-RSA cipher suites.

The MITM attacker impersonates the server and sends a `ServerHello` message that selects a cipher suite with RSA as the key-exchange method. Then, the attacker uses special DROWN to decrypt the premaster secret. The main difficulty is completing the decryption and producing a valid `ServerFinished` message before the client’s connection times out. Most browsers will allow the handshake to last up to one minute [1].

The attack requires targeting an average of 100 connections, only one of which will be attacked, probabilistically. The simplest way for the attacker to facilitate this is to use JavaScript to cause the client to connect repeatedly to the victim server, as described in Section 3. Each connection is tested against the oracle with only small number of fractions, and the attacker can discern immediately when he receives a positive response from the oracle.

Note that since the decryption must be completed online, the Leaky Export oracle cannot be used, and the attack uses only the Extra Clear oracle.

5.2.1 Constructing the attack

We will use `SSL_DES_192_EDE3_CBC_WITH_MD5` as the cipher suite, allowing the attacker to recover 24 bytes of key at a time. The attack works as follows:

0. The attacker causes the victim client to connect repeatedly to the victim server, with at least 100 connections.
1. The attacker uses the fractional trimmers as described in Section 3.2.1 to convert one of the TLS ciphertexts into an SSLv2 conformant ciphertext c_0 .
2. Once the attacker has obtained a valid SSLv2 ciphertext c_1 , they repeatedly use the shifting technique described in Section 3.2.2 to rotate the message by 25 bytes each iteration, learning 27 bytes with each shift. After several iterations, they have learned the entire plaintext.
3. The attacker then transforms the decrypted SSLv2 plaintext into the decrypted TLS plaintext.

Using 100 fractional trimmers, this more efficient oracle attack allows the attacker to recover one in 100 TLS session keys using only about 27,000 connections to the server, as described in Appendix A.6. The computation cost is so low that we can complete the full attack on a single workstation in under one minute.

5.3 The OpenSSL ‘leaky export’ oracle

In addition to the extra clear implementation bug, the same set of OpenSSL versions also contain a separate bug, where they do not follow the correct algorithm for their implementation of the Bleichenbacher countermeasure. We now describe this faulty implementation:

- The SSLv2 ClientKeyExchange message contains the mk_{clear} bytes immediately before the ciphertext c . Let p be the buffer starting at the first mk_{clear} byte.
- Decrypt c in place. If the decryption operation succeeds, and c decrypted to a plaintext of a correct padded length, p now contains the 11 mk_{clear} bytes followed by the 5 mk_{secret} bytes.
- If c decrypted to an unpadded plaintext k of incorrect length, the decryption operation overwrites the first $j = \min(|k|, 5)$ bytes of c with the first j bytes of k .
- If c is not SSLv2 conformant and the decryption operation failed, randomize the first five bytes of p , which are the first five bytes of mk_{clear} .

This behavior allows the attacker to distinguish between these three cases. Suppose the attacker sends 11 null bytes as mk_{clear} . Then these are the possible cases:

1. c decrypts to a correctly padded plaintext k of the expected length, 5 bytes. Then the following `master_key` will be constructed:

`[00 00 00 00 00 00 00 00 00 00 k[1] k[2] k[3] k[4] k[5]]`

2. c decrypts to a correctly padded plaintext k of a wrong length. Let r be the five random bytes the server generated. The yielded `master_key` will be:

`[r[1] r[2] r[3] r[4] r[5] 00 00 00 00 00 00 k[1] k[2] k[3] k[4] k[5]]`

when $|k| \geq 5$. If $|k| < 5$, the server substitutes the first $|k|$ bytes of c with the first $|k|$ bytes of k . Using $|k| = 3$ as an example, the `master_key` will be:

`[r[1] r[2] r[3] r[4] r[5] 00 00 00 00 00 00 k[1] k[2] k[3] c[4] c[5]]`

3. c is not SSLv2 conformant, and hence the decryption operation failed. The resulting `master_key` will be:

`[r[1] r[2] r[3] r[4] r[5] 00 00 00 00 00 00 c[1] c[2] c[3] c[4] c[5]]`

The attacker detects case (3) by performing an exhaustive search over the 2^{40} possibilities for r , and checking whether any of the resulting values for the `master_key` correctly decrypts the observed `ServerVerify` message. If no r value satisfies this property, then c^d starts with bytes 0x00 02. The attacker then distinguishes between

cases (1) and (2) by performing an exhaustive search over the five bytes of k , and checking whether any of the resulting values for mk correctly decrypts the observed `ServerVerify` message.

As this oracle leaks information when using export ciphers, we have named it the Leaky Export oracle.

In conclusion, $\mathcal{O}_{\text{SSLv2-export-leaky}}$ allows an attacker to obtain a valid oracle response for all ciphertexts which decrypt to a correctly-padded plaintext of *any* length. This is in contrary to the previous oracles $\mathcal{O}_{\text{SSLv2-extra-clear}}$ and $\mathcal{O}_{\text{SSLv2-export}}$, which required the plaintext to be of a specific length. Each oracle query to $\mathcal{O}_{\text{SSLv2-export-leaky}}$ requires one connection to the server and 2^{41} offline work.

Combining the two oracles. The attacker can use the Extra Clear and Leaky Export oracles together in order to reduce the number of queries required for the TLS decryption attack. They first test a TLS conformant ciphertext for divisors using the Leaky Export oracle, then use fractions dividing the plaintext with both oracles. Once the attacker has obtained a valid SSLv2 ciphertext c_1 , they repeatedly use the shifting technique described in Section 3.2.2 to rotate the message by 25 bytes each iteration while choosing 3DES as the symmetric cipher, learning 27 bytes with each shift. After several iterations, they have learned the entire plaintext, using 6,300 queries (again for a 2048-bit modulus). This brings the overall number of queries for this variant of the attack to $900 + 16 * 4 + 6,300 = 7,264$. These parameter choices are not necessarily optimal. We give more details in Appendix A.7.

6 Extending the attack to QUIC

DROWN can also be extended to a feasible-time man-in-the-middle attack against QUIC [26]. QUIC [10, 39] is a recent cryptographic protocol designed and implemented by Google that is intended to reduce the setup time to establish a secure connection while providing security guarantees analogous to TLS. QUIC’s security relies on a static “server config” message signed by the server’s public key. Jager et al. [26] observe that an attacker who can forge a signature on a malicious QUIC server config once would be able to impersonate the server indefinitely. In this section, we show an attacker with significant resources would be able to mount such an attack against a server whose RSA public keys is exposed via SSLv2.

A QUIC client receives a “server config” message, signed by the server’s public key, which enumerates connection parameters: a static elliptic curve Diffie-Hellman public value, and a validity period. In order to mount a man-in-the-middle attack against any client, the attacker wishes to generate a valid server config message containing their own Diffie-Hellman value, and an expiration date far in the future.

The attacker needs to present a forged QUIC config to the client in order to carry out a successful attack. This is

Protocol	Attack type	Oracle	SSLv2 connections	Offline work	See §
TLS	Decrypt	SSLv2	41,081	2^{50}	4.2
TLS	Decrypt	Special	7,264	2^{51}	5.3
TLS	MITM	Special	27,000	2^{15}	5.2
QUIC	MITM	SSLv2	2^{25}	2^{65}	6.1
QUIC	MITM	Special	2^{25}	2^{25}	6.2
QUIC	MITM	Special	2^{17}	2^{58}	6.2

Table 3: **Summary of attacks.** “Oracle” denotes the oracle required to mount each attack, which also implies the vulnerable set of SSLv2 implementations. SSLv2 denotes any SSLv2 implementation, while “Special” denotes an OpenSSL version vulnerable to special DROWN.

straightforward, since QUIC discovery may happen over non-encrypted HTTP [19]. The server does not even need to support QUIC at all: an attacker could impersonate the attacked server over an unencrypted HTTP connection and falsely indicate that the server supports QUIC. The next time the client connects to the server, it will attempt to connect using QUIC, allowing the attacker to present the forged “server config” message and execute the attack [26].

6.1 QUIC signature forgery attack based on general DROWN

The attack proceeds much as in Section 3.2, except that some of the optimizations are no longer applicable, making the attack more expensive.

The first step is to discover a valid, PKCS conformant SSLv2 ciphertext. In the case of TLS decryption, the input ciphertext was PKCS conformant to begin with; this is not the case for the QUIC message c_0 . Thus for the first phase, the attacker iterates through possible multiplier values s until they randomly encounter a valid SSLv2 message in $c_0 \cdot s^d$. For 2048-bit RSA keys, the probability of this random event is $P_{rnd} \approx 2^{-25}$; see Section 3.2.

Once the first SSLv2 conformant message is found, the attacker proceeds with the signature forgery as they would in Step 2 of the TLS decryption attack. The required number of oracle queries for this step is roughly 12,468 for 2048-bit RSA keys.

Attack cost. The overall oracle query cost is dominated by the $2^{25} \approx 34$ million expected queries in the first phase, above. At a rate of 388 queries/second, the attacker would finish in one day; at a rate of 12 queries/second they would finish in one month.

For the SSLv2 export padding oracle, the offline computation to break a 40-bit symmetric key for each query requires iterating over 2^{65} keys. At our optimized GPU implementation rate of 515 million keys per second, this

would require 829,142 GPU days. Our experimental GPU hardware retails for \$400. An investment of \$10 million to purchase 25,000 GPUs would reduce the wall clock time for the attack to 33 days.

Our implementation run on Amazon EC2 processed about 174 billion keys per g2.2xlarge instance-hour, so at a cost of \$0.09/instance-hour the full attack would cost \$9.5 million and could be parallelized to Amazon’s capacity.

6.2 Optimized QUIC signature forgery based on special DROWN

For targeted servers that are vulnerable to special DROWN, we are unaware of a way to combine the two special DROWN oracles; the attacker would have to choose a single oracle which minimizes his subjective cost. For the Extra Clear oracle, there is only negligible computation per oracle query, so the computational cost for the first phase is 2^{25} . For the Leaky Export oracle, as explained below, the required offline work is 2^{58} , and the required number of server connections is roughly 145,573. Both oracles appear to bring this attack well within the means of a moderately provisioned adversary.

Mounting the attack using Leaky Export. For a 2048-bit RSA modulus, the probability of a random message being conformant when querying $\mathcal{O}_{\text{SSLv2-export-leaky}}$ is $P_{rnd} \approx (1/256)^2 * (255/256)^8 * (1 - (255/256)^{246}) \approx 2^{-17}$. Therefore, to compute c^d when c is not SSLv2 conformant, the attacker randomly generates values for s and tests $c \cdot s^e$ against the Leaky Export oracle. After roughly $2^{17} \approx 131,000$ queries, they obtain a positive response, and learn that $c^d \cdot s$ starts with bytes 0x00 02.

Naively, it would seem the attacker can then apply one of the techniques presented in this work, but $\mathcal{O}_{\text{SSLv2-export-leaky}}$ does not provide knowledge of any least significant plaintext bytes when the plaintext length is not at most the correct one. Instead, the attacker proceeds directly according to the algorithm presented in [4]. Referring to Table 1 in [4], $\mathcal{O}_{\text{SSLv2-export-leaky}}$ is denoted with the term FFT, as it returns a positive response for a correctly padded plaintext of any length, and the median number of required queries for this oracle is 14,501. This number of queries is dominated by the 131,000 queries the attacker has already executed. As each query requires testing roughly 2^{41} keys, the required offline work is approximately 2^{58} .

Future changes to QUIC. In addition to disabling QUIC support for non-whitelisted servers, Google have informed us that they plan to change the QUIC standard, so that the “server config” message will include a client nonce to prove freshness. They also plan to limit QUIC discovery to HTTPS.

Protocol	Port	All certificate			Trusted certificates

Table 4: **Hosts vulnerable to general DROWN.** We performed Internet-wide scans to measure the number of hosts supporting SSLv2 on several different protocols. A host is vulnerable to DROWN if its public key is exposed anywhere via SSLv2. Overall vulnerability to DROWN is much larger than support for SSLv2 due to widespread reuse of keys.

7 Measurements

We performed Internet-wide scans to analyze the number of systems vulnerable to DROWN. A host is directly vulnerable to general DROWN if it supports SSLv2. Similarly, a host is directly vulnerable to special DROWN if it supports SSLv2 and has the extra clear bug (which also implies the leaky export bug). These directly vulnerable hosts can be used as oracles to attack any other host with the same key. Hosts that do not support SSLv2 are still vulnerable to general or special DROWN if their RSA key pair is exposed by any general or special DROWN oracle, respectively. The oracles may be on an entirely different host or port. Additionally, any host serving a browser-trusted certificate is vulnerable to a special DROWN man-in-the-middle if any name on the certificate appears on any other certificate containing a key that is exposed by a special DROWN oracle.

We used ZMap [16] to perform full IPv4 scans on eight different ports during late January and February 2016. We examined port 443 (HTTPS), and common email ports 25 (SMTP with STARTTLS), 110 (POP3 with STARTTLS), 143 (IMAP with STARTTLS), 465 (SMTSPS), 587 (SMTP with STARTTLS), 993 (IMAPS), and 995 (POP3S). For each open port, we attempted three complete handshakes: one normal handshake with the highest available SSL/TLS version; one SSLv2 handshake requesting an export RC2 cipher suite; and one SSLv2 handshake with a non-export cipher and sixteen bytes of plaintext key material sent during key exchange, which we used to detect if a host has the extra clear bug.

We summarize our general DROWN results in Table 4. The fraction of SSL/TLS hosts that directly supported SSLv2 varied substantially across ports. 28% of SMTP servers on port 25 supported SSLv2, likely due to the opportunistic encryption model for email transit. Since SMTP fails-open to plaintext, many servers are config-

ured with support for the largest possible set of protocol versions and cipher suites, under the assumption that even bad or obsolete encryption is better than plaintext [9]. The other email ports ranged from 8% for SMTSPS to 20% for POP3S and IMAPS. We found 17% of all HTTPS servers, and 10% of those with a browser-trusted certificate, are directly vulnerable to general DROWN.

OpenSSL SSLv2 cipher suite selection bug. We discovered that OpenSSL servers do not respect the cipher suites advertised in the SSLv2 ServerHello message. That is, a malicious client can select an *arbitrary* cipher suite in the ClientMasterKey message, regardless of the contents of the ServerHello, and force the use of export cipher suites even if they are explicitly disabled in the server configuration. To fully detect SSLv2 oracles, we configured our scanner to ignore the ServerHello cipher list. The cipher selection bug helps explain the wide support for SSLv2—the protocol appeared disabled, but non-standard clients could still complete handshakes.

Widespread public key reuse. Reuse of RSA key material across hosts and certificates is widespread [21, 23]. Often this is benign: organizations may issue multiple TLS certificates for distinct domains with the same public key in order to simplify use of TLS acceleration hardware and load balancing. However, there is also evidence that system administrators may not entirely understand the role of the public key in certificates. For example, in the wake of the Heartbleed vulnerability, a substantial fraction of compromised certificates were reissued with the same public key [15]. The number of hosts vulnerable to DROWN rises significantly when we take RSA key reuse into account. For HTTPS, 17% of hosts are vulnerable to general DROWN because they support both TLS and SSLv2 on the HTTPS port, but 33% are vulnerable when considering RSA keys used by another service.

Protocol	Port	SSL/TLS	Any certificate		Trusted certificates		
			Special DROWN oracles	Vulnerable key	SSL/TLS	Vulnerable key	Vulnerable name
SMTP	25	3,357 K	855 K (25%)	896 K (27%)	1,083 K	305 K (28%)	398 K (37%)
POP3	110	4,193 K	397 K (9%)	946 K (23%)	1,787 K	485 K (27%)	674 K (38%)
IMAP	143	4,202 K	457 K (11%)	969 K (23%)	1,781 K	498 K (30%)	690 K (39%)
HTTPS	443	34,727 K	4,029 K (12%)	9,089 K (26%)	17,490 K	2,523 K (14%)	3,793 K (22%)
SMTPS	465	3,596 K	334 K (9%)	765 K (21%)	1,641 K	430 K (26%)	630 K (38%)
SMTP	587	3,507 K	345 K (10%)	792 K (23%)	1,657 K	482 K (29%)	667 K (40%)
IMAPS	993	4,315 K	892 K (21%)	1,073 K (25%)	1,909 K	602 K (32%)	792 K (42%)
POP3S	995	4,322 K	897 K (21%)	1,108 K (26%)	1,974 K	641 K (32%)	835 K (42%)
(Alexa Top 1M)	443	611 K	22 K (4%)	52 K (9%)	456 K	33 K (7%)	85 K (19%)

Table 5: **Hosts vulnerable to special DROWN.** A server is vulnerable to special DROWN if its key is exposed by a host with the CVE-2016-0703 bug. Since the attack is fast enough to enable man-in-the-middle attacks, a server is also vulnerable (to impersonation) if any name in its certificate is found in any trusted certificate with an exposed key.

Special DROWN. As shown in Table 5, 9.1 M HTTPS servers (26%) are vulnerable to special DROWN, as are 2.5 M HTTPS servers with browser-trusted certificates (14%). 66% as many HTTPS hosts are vulnerable to special DROWN as to general DROWN (70% for browser-trusted servers). While 2.7 M public keys are vulnerable to general DROWN, only 1.1 M are vulnerable to special DROWN (41% as many). Vulnerability among Alexa Top Million domains is also lower, with only 9% of domains vulnerable (7% for browser-trusted domains).

Since special DROWN enables active man-in-the-middle attacks, any host serving a browser-trusted certificate with at least one name that appears on any certificate with an RSA key exposed by a special DROWN oracle is vulnerable to an impersonation attack. Extending our search to account for certificates with shared names, we find that 3.8 M (22%) hosts with browser-trusted certificates are vulnerable to man-in-the-middle attacks, as well as 19% of the browser-trusted domains in the Alexa Top Million.

8 Related work

TLS has had a long history of implementation flaws and protocol attacks [2, 3, 7, 14, 15, 35, 38]. We discuss relevant Bleichenbacher and cross-protocol attacks below.

Bleichenbacher’s attack. Bleichenbacher’s adaptive chosen ciphertext attack against SSL was first published in 1998 [8]. Several works have adapted his attack to different scenarios [4, 25, 29]. The TLS standard explicitly introduces countermeasures against the attack [13], but several modern implementations have been discovered to be vulnerable to timing-attack variants in recent years [34, 42]. These side-channel attacks are implementation failures and only apply when the attacker is co-located with the victim.

Cross-protocol attacks. Jager et al. [26] showed that a cross-protocol Bleichenbacher RSA padding oracle attack is possible against the proposed TLS 1.3 standard, in spite of the fact that TLS 1.3 does not include RSA key exchange, if server implementations use the same certificate for previous versions of TLS and TLS 1.3. Wagner and Schneier [41] developed a cross-cipher suite attack for SSLv3, in which an attacker could reuse a signed server key exchange message in a later exchange with a different cipher suite. Mavrogiannopoulos et al. [32] developed a cross-cipher suite attack allowing an attacker to use elliptic curve Diffie-Hellman as prime field Diffie-Hellman.

Attacks on export-grade cryptography. Recently, the FREAK [5] and Logjam [1] attacks allowed an active attacker to downgrade a connection to export-grade RSA and Diffie-Hellman, respectively. DROWN exploits export-grade symmetric ciphers, completing the export-grade cryptography attack trifecta.

9 Discussion

9.1 Implications for modern protocols

Although the protocol flaws in SSLv2 enabling DROWN are not present in recent TLS versions, many modern protocols meet a subset of the requirements to be vulnerable to a DROWN-style attack. For example:

1. RSA key exchange. TLS 1.2 [13] allows this.
2. Reuse of server-side nonce by the client. QUIC [10] allows this.
3. Server sends a message encrypted with the derived key before the client. QUIC, TLS 1.3 [37], and TLS False Start [30] do this.
4. Deterministic cipher parameters are generated from the premaster secret and nonces. This is the case for all TLS stream ciphers and TLS 1.0 block ciphers.

DROWN has a natural adaptation when all three properties are present. The attacker exposes a Bleichenbacher oracle by connecting to the server twice with the identical RSA ciphertexts and server-side nonces. If the RSA ciphertext is PKCS conformant, the server will respond with identical messages across both connections; otherwise they will differ.

9.2 Lessons for key reuse

DROWN illustrates the cryptographic principle that keys should be single use. Often, this principle is primarily applied to keys that are used to both sign and decrypt, but DROWN illustrates that using keys *for different protocol versions* can also be a serious security risk. Unfortunately, there is no widely supported way to pin X.509 certificates to specific protocols. While using per-protocol certificates may help defend against passive attacks, an active attacker could still leverage any certificate with a matching name.

9.3 Harms from obsolete cryptography

Recent years have seen a significant number of serious attacks exploiting outdated and obsolete cryptography. Many protocols and cryptographic primitives that were demonstrated to be weak decades ago are surprisingly common in real-world systems.

DROWN exploits a modification of an 18-year-old attack against a combination of protocols and ciphers that have long been superseded by better options: the SSLv2 protocol, export cipher suites, and PKCS #1 v1.5 RSA padding. In fact, support for RSA as a key exchange method, including the use of PKCS #1 v1.5, is mandatory even for TLS 1.2. The attack is made more severe by implementation flaws in rarely used code.

Our work serves as yet another reminder of the importance of removing deprecated technologies before they become exploitable vulnerabilities. In response to many of the vulnerabilities listed above, browser vendors have been aggressively warning end users when TLS connections are negotiated with unsafe cryptographic parameters, including SHA-1 certificates, small RSA and Diffie-Hellman parameters, and SSLv3 connections. This process is currently happening in a piecemeal fashion, primitive by primitive. Vendors and developers rightly prioritize usability and backward compatibility in standards, and are willing to sacrifice these only for practical attacks. This approach works less well for cryptographic vulnerabilities, where the first sign of a weakness, while far from being practically exploitable, can signal trouble in the future. Communication issues between academic researchers and vendors and developers have been voiced by many in the community, including Green [18] and Jager et al. [24].

The long-term solution is to proactively remove these obsolete technologies. There is movement towards this

already: TLS 1.3 has entirely removed RSA key exchange and has restricted Diffie-Hellman key exchange to a few groups large enough to withstand cryptanalytic attacks long in the future. The CA/Browser forum will remove support for SHA-1 certificates this year. Resources such as the SSL Labs SSL Reports have gathered information about best practices and vulnerabilities in one place, in order to encourage administrators to make the best choices.

9.4 Harms from weakening cryptography

Export-grade cipher suites for TLS deliberately weakened three primitives to the point that they are now broken even to enthusiastic amateurs: 512-bit RSA key exchange, 512-bit Diffie-Hellman key exchange, and 40-bit symmetric encryption. All three deliberately weakened primitives have been cornerstones of high-profile attacks: FREAK exploits export RSA, Logjam exploits export Diffie-Hellman, and now DROWN exploits export symmetric encryption.

Like FREAK and Logjam, our results illustrate the continued harm that a legacy of deliberately weakened export-grade cryptography inflicts on the security of modern systems, even decades after the regulations influencing the original design were lifted. The attacks described in this paper are fully feasible against export cipher suites today. The technical debt induced by cryptographic “front doors” has left implementations vulnerable for decades. With the slow rate at which obsolete protocols and primitives fade away, we can expect some fraction of hosts to remain vulnerable for years to come.

Acknowledgements

The authors thank team Hashcat for making their GPUs available for the execution of the attack, Ralph Holz for providing early scan data, Adam Langley for insights about QUIC, Graham Steel for insights about TLS False Start, the OpenSSL team for their help with disclosure, Ivan Ristic for comments on session resumption in a BEAST-styled attack, and Tibor Jager and Christian Mainka for further helpful comments. We thank the exceptional sysadmins at the University of Michigan for their help and support throughout this project, including Chris Brenner, Kevin Cheek, Laura Fink, Dan Maletta, Jeff Richardson, Donald Welch, Don Winsor, and others from ITS, CAEN, and DCO.

A Adaptations to Bleichenbacher’s attack

A.1 Success probability of fractions

For a given fraction u/t , the success probability with a randomly chosen TLS conformant ciphertext can be computed as follows. Let m_0 be a random TLS conformant message, $m_1 = m_0 \cdot u/t$, and let ℓ_k be the expected length of the unpadded message. For $s = u/t \bmod N$ where u and t are coprime, m_1 will be SSLv2 conformant if the following conditions all hold:

1. m_0 is divisible by t . For a randomly generated m_0 , this condition holds with probability $1/t$.
2. $m_1[1] = 0$ and $m_1[2] = 2$, or the integer $m \cdot u/t \in [2B, 3B]$. For a randomly generated m_0 divisible by t , this condition holds with probability

$$P = \begin{cases} 3 - 2 \cdot t/u & \text{for } 2/3 < u/t < 1 \\ 3 \cdot t/u - 2 & \text{for } 1 < u/t < 3/2 \\ 0 & \text{otherwise} \end{cases}$$

3. $\forall i \in [3, \ell_m - (\ell_k + 1)]$, $m_1[i] \neq 0$, or all bytes between the first two bytes and the $(k + 1)$ least significant bytes are non-zero. This condition holds with probability $(1 - 1/256)^{\ell_m - (\ell_k + 3)}$.
4. $m_1[\ell_m - \ell_k] = 0$: the $(\ell_k + 1)$ st least significant byte is 0. This condition holds with probability $1/256$.

Using the above formulas for $u/t = 7/8$, the overall probability of success is $P = 1/8 \cdot 0.71 \cdot 0.37 \cdot 1/256 = 1/7,774$; thus the attacker expects to find an SSLv2 conformant ciphertext after testing 7,774 randomly chosen TLS conformant ciphertexts. The attacker can decrease the number of TLS conformant ciphertexts needed by multiplying each candidate ciphertext by several fractions.

Note that testing random s values until $c_1 = c_0 \cdot s^e \bmod N$ is SSLv2 conformant yields a success probability of $P_{rnd} \approx (1/256)^3 * (255/256)^{249} \approx 2^{-25}$.

A.2 Optimizing the chosen set of fractions

In order to deduce the validity of a single ciphertext, the attacker would have to perform a non-trivial brute-force search over all 5 byte `master_key` values. This translates into 2^{40} encryption operations.

The search space can be reduced by an additional optimization, relying on the fractional multipliers used in the first step. If the attacker uses $u/t = 8/7$ to compute a new SSLv2 conformant candidate, and m_0 is indeed divisible by $t = 7$, then the new candidate message $m_1 = m_0/t \cdot u$ is divisible by $u = 8$, and the last three bits of m_1 (and thus mk_{secret}) are zero. This allows reducing the searched `master_key` space by selecting specific fractions.

More generally, for an integer u , the largest power of 2 by which u is divisible is denoted by $v_2(u)$, and multiplying by a fraction u/t reduces the search space by a factor of $v_2(u)$. With this observation, the trade-off between the 3 metrics: the required number of intercepted ciphertexts, the required number of queries, and the required number of encryption attempts, becomes non-trivial to analyze.

Therefore, we have resorted to using simulations when evaluating the performance metrics for sets of fractions. The probability that multiplying a ciphertext by any fraction out of a given set of fractions results in an SSLv2 conformant message is difficult to compute, since the events are in fact inter-dependent: If $m \cdot 16/15$ is conforming, then m is divisible by 5, greatly increasing the probability that $m \cdot 4/5$ is also conforming. However, it is easy to perform a Monte Carlo simulation, where we randomly generate ciphertexts, and measure the probability that any fraction out of a given set produces a conforming message. The expected required number of intercepted ciphertexts is the inverse of that probability.

Formally, if we denote the set of fractions as F , and the event that a message m is conforming as $C(m)$, we perform a Monte Carlo estimation of the probability $P_F = P(\exists f \in F : C(m \cdot f))$, and the expected number of required intercepted ciphertexts equals $1/P_F$. The required number of oracle queries is simply $1/P_F \cdot |F|$. Accordingly, the required number of server connections is $2 \cdot 1/P_F \cdot |F|$, since each oracle query requires two server connections. And as for the required number of encryption attempts, if we denote this number when querying with a given fraction $f = u/t$ as E_f , then $E_f = E_{u/t} = 2^{40-v_2(u)}$. We further define the required encryption attempts when testing a ciphertext with a given set of fraction F as $E_F = \sum_{f \in F} E_f$. Then the required number of encryption attempts in Phase 1 for a given set of fractions is $(1/P_F) \cdot E_F$.

We can now give precise figures for the expected number of required intercepted ciphertexts, connections to the targeted server, and encryption attempts. The results presented in Table 1 were obtained using the above approach with one billion random ciphertexts per fraction set F .

A.3 Rotation and multiplier speedups

For a randomly chosen s , the probability that the two most significant bytes are 0x00 02 is 2^{-16} ; for a 2028-bit modulus N the probability that the next $\ell_m - \ell_k - 3$ bytes of m_2 are all nonzero is about 0.37 as in the previous section, and the probability that the $\ell_k + 1$ least significant delimiter byte is 0x00 is 1/256. Thus a randomly chosen s will work with probability $2^{-25.4}$ and the attacker expects to try $2^{25.4}$ values for s before succeeding.

However, since the attacker has already learned $\ell_k + 3$ most significant bytes of $m_1 \cdot R^{-1} \pmod{N}$, for $\ell_k \geq 4$ and $s < 2^{30}$ they do not need to query the oracle to learn if the two most significant bytes are SSLv2 conformant; they can compute this themselves from their knowledge of $\tilde{m}_1 \cdot R^{-1}$. They iterate through values of s , test that the top two bytes of $\tilde{m}_1 \cdot R^{-1} \pmod{N}$ are 0x00 02, and only query the oracle for s values that satisfy this test. Therefore, for a 2048-bit modulus they expect to test 2^{16} values offline per oracle query. The probability that a query is conformant is then $P = (1/256) * (255/256)^{249} \approx 1/678$, so they expect to perform 678 oracle queries before finding a fully SSLv2 conformant ciphertext $c_2 = (s \cdot R^{-1})^e c_1 \pmod{N}$.

We can speed up the brute force testing of 2^{16} values of s using algebraic lattices. We are searching for values of s satisfying $\tilde{m}_1 R^{-1} s < 3B \pmod{N}$, or given an offset s_0 we would like to find solutions x and z to the equation $\tilde{m}_1 R^{-1} (s_0 + x) = 2B + z \pmod{N}$ where $|x| < 2^{16}$ and $|z| < B$. Let $X = 2^{15}$. We can construct the lattice basis

$$L = \begin{bmatrix} -B & X\tilde{m}_1 R^{-1} & \tilde{m}_1 R^{-1} s_0 + B \\ 0 & XN & 0 \\ 0 & 0 & N \end{bmatrix}$$

We then run the LLL algorithm [31] on L to obtain a reduced lattice basis V containing vectors v_1, v_2, v_3 . We then construct the linear equations $f_1(x, z) = v_{1,1}/B \cdot z + v_{1,2}/X \cdot x + v_{1,3} = 0$ and $f_2(x, z) = v_{2,1}/B \cdot z + v_{2,2}/X \cdot x + v_{2,3} = 0$ and solve the system of equations to find a candidate integer solution $x = \tilde{s}$. We then test $s = \tilde{s} + s_0$ as our candidate solution in this range.

$\det L = XZN^2$ and $\dim L = 3$, thus we expect the vectors v_i in V to have length approximately $|v_i| \approx (XZN^2)^{1/3}$. We will succeed if $|v_i| < N$, or in other words $XZ < N$. $N \approx 2^{8\ell_m}$, so we expect to find short enough vectors. This approach works well in practice and is significantly faster than iterating through 2^{16} possible values of \tilde{s} for each query.

In summary, given an SSLv2 conformant ciphertext $c_1 = m_1^e \pmod{N}$, we can efficiently generate an SSLv2 conformant ciphertext $c_2 = m_2^e \pmod{N}$ where $m_2 = s \cdot m_1 \cdot R^{-1} \pmod{N}$ and we know several most significant bytes of m_2 , using only a few hundred oracle queries in expectation. We can iterate this process as many times as we like to continue generating SSLv2 conformant ciphertexts c_i for which we know increasing numbers of most

significant bytes, and which have a known multiplicative relationship to our original message c_0 .

A.4 Rotations in the general DROWN attack

After the first phase, we have learned an SSLv2 conformant ciphertext c_1 , and we wish to shift known plaintext bytes from least to most significant bits. Since we learn the least significant 6 bytes of plaintext of m_1 from a successful oracle $\mathcal{O}_{\text{SSLv2-export}}$ query, we could use a shift of 2^{-48} to transfer 48 bits of known plaintext to the most significant bits of a new ciphertext. However, we perform a slight optimization here, to reduce the number of encryption attempts. We instead use a shift of 2^{-40} , so that the least significant byte of $m_1 \cdot 2^{-40}$ and $\tilde{m}_1 \cdot 2^{-40}$ will be known. This means that we can compute the least significant byte of $m_1 \cdot 2^{-40} \cdot s \pmod{N}$, so oracle queries now only require 2^{32} encryption attempts each. This brings the total expected number of encryption attempts for each shift to $2^{32} * 678 \approx 2^{41}$.

We perform two such plaintext shifts in order to obtain an SSLv2 conformant message, m_3 that resides in a narrow interval of length at most $2^{8\ell-66}$. We can then obtain a multiplier s_3 such that $m_3 \cdot s_3$ is also SSLv2 conformant. Since m_3 lies in an interval of length at most $2^{8\ell-66}$, with high probability for any $s_3 < 2^{30}$, $m_3 \cdot s_3$ lies in an interval of length at most $2^{8\ell_m-36} < B$, so we know the two most significant bytes of $m_3 \cdot s_3$. Furthermore, we know the value of the 6 least significant bytes after multiplication. We therefore test possible values of s_3 , and for values such that $m_3 \cdot s_3 \in [2B, 3B]$, and $(m_3 \cdot s_3)[\ell_m - 5] = 0$, we query the oracle with $c_3 \cdot s_3^e \pmod{N}$. The only condition for PKCS conformance which we haven't verified before querying the oracle is the requirement of non-zero padding, which holds with probability 0.37.

In summary, after roughly $1/0.37 = 2.72$ queries we expect a positive response from the oracle. Since we know the value of the 6 least significant bytes after multiplication, this phase does not require performing an exhaustive search. If the message is SSLv2 conformant after multiplication, we know the symmetric key, and can test whether it correctly decrypts the `ServerVerify` message.

A.5 Adapted Bleichenbacher iteration

After we have bootstrapped the attack using rotations, the original algorithm proposed by Bleichenbacher can be applied with minimal modifications.

The original step obtains a message that starts with the required 0x00 02 bytes once in roughly every two queries on average, and requires the number of queries to be roughly $16\ell_m$. Since we know the value of the 6 least significant bytes after multiplying by any integer, we can only query the oracle for multipliers that result in a zero 6th least significant byte, and again an exhaustive search over keys is not required. However, we cannot ensure

that the padding is non-zero when querying, which again holds with probability 0.37. Therefore, for a 2048-bit modulus, the overall expected number of queries for this phase is roughly $2048 * 2 / 0.37 = 11,070$.

A.6 Special DROWN MITM performance

For the first step, the probability that the three padding bytes are correct remains unchanged. The probability that all the intermediate padding bytes are non-zero is now slightly higher, $P_1 = (1 - 1/256)^{229} = 0.41$, yielding an overall maximal success probability $P = 0.1 \cdot 0.41 \cdot \frac{1}{256} = 1/6,244$ per oracle query. Since the attacker now only needs to connect to the server once per oracle query, the expected number of connections in this step is the same, 6,243. Phase 1 now yields a message with 3 known padding bytes and 24 known plaintext bytes.

For the remaining rotation steps, each rotation requires an expected 630 oracle queries. The attacker could now complete the original Bleichenbacher attack by performing 11,000 sequential queries in the final phase. However, with this more powerful oracle it is more efficient to apply a rotation 10 more times to recover the remaining plaintext bits. The number of queries required in this phase is now $10 \cdot 256 / 0.41 \approx 6,300$, and the queries for each of the 10 steps can be executed in parallel.

Using multiple queries per fraction. For the $\mathcal{O}_{\text{SSLv2-extra-clear}}$ oracle, the attacker can increase their chances of success by querying the server multiple times per ciphertext and fraction, using different cipher suites with different key lengths. They can negotiate DES and hope the 9th least significant byte is zero, then negotiate 128-bit RC4 and hope the 17th least significant byte is zero, then negotiate 3DES and hope the 25th least significant is zero. All three queries also require the intermediate padding bytes to be non-zero. This technique triples the success probability for a given pair of (ciphertext, fraction), at a cost of triple the queries. Its primary benefit is that fractions with smaller denominators (and thus higher probabilities of success) are now even more likely to succeed.

For a random ciphertext, when choosing 70 fractions, the probability of the first zero delimiter byte being in one of these three positions is 0.01. Hence, the attacker can use only 100 recorded ciphertexts, and expect to use $100 * 70 * 3 = 21,000$ oracle queries. For the Extra Clear oracle, each query requires one SSLv2 connection to the server. After obtaining the first positive response from the oracle, the attacker proceeds to phase 2 using 3DES.

A.7 Special DROWN with combined oracles

Using the Leaky Export oracle, the probability that a fraction u/t will result in a positive response is $P = P_0 * P_3$, where the formula for computing $P_0 = P((m \cdot u/t)[1, 2] = 00||02)$ is provided in Appendix A.1, and P_3 is, for a

2048-bit modulus:

$$\begin{aligned} P_3 &= P(0x00 \notin \{m_3, \dots, m_{10}\} \wedge \\ &\quad 0x00 \in \{m_{11}, \dots, m_\ell\}) \quad (1) \\ &= (1 - 1/256)^8 * (1 - (1 - 1/256)^{246}) = 0.60 \end{aligned}$$

Phase 1. Our goal for this phase is to obtain a divisor t as large as possible, such that $t|m$. We generate a list of fractions, sorted in descending order of the probability of resulting in a positive response from $\mathcal{O}_{\text{SSLv2-export-leaky}}$. For a given ciphertext c , we then query with the 50 fractions in the list with the highest probability, until we obtain a first positive response for a fraction u_0/t_0 . We can now deduce that $t_0|m$. We then generate a list of fractions u/t where t is a multiple of t_0 , sort them again by success probability, and again query with the 50 most probable fractions, until a positive answer is obtained, or the list is exhausted. If a positive answer is obtained, we iteratively re-apply this process, until the list is exhausted, resulting in a final fraction u^*/t^* .

Phase 2. We then query with all fractions denominated by t^* , and hope the ciphertext decrypts to a plaintext of one of seven possible lengths: $\{2, 3, 4, 5, 8, 16, 24\}$. Assuming that this is the case, we learn at least three least significant bytes, which allows us to use the shifting technique in order to continue the attack. Detecting plaintext lengths 8, 16 and 24 can be accomplished using three Extra Clear oracle queries, employing DES, 128-bit RC4 and 3DES, respectively, as the chosen cipher suite. Detecting plaintext lengths 2, 3, 4 and 5 can be accomplished by using a single Leaky Export oracle query, which requires at most 2^{41} offline computation. In fact, the optimization over the key search space described in Section 3.2.1 is applicable here and can slightly reduce the required computation. Therefore, by initiating four SSLv2 connections and performing at most 2^{41} offline work, the attacker can test for ciphertexts which decrypt to one of these seven lengths.

In practice, choosing 50 fractions per iteration as described above results in a success probability of 0.066 for a single ciphertext. Hence, the expected number of required ciphertexts is merely $1 / 0.066 = 15$. The expected number of fractions per ciphertext for phase 1 is 60, as in most cases phase 1 consists of just a few successful iterations. Since each fraction requires a single query to $\mathcal{O}_{\text{SSLv2-export-leaky}}$, the overall number of queries for this stage is $15 * 60 = 900$, and the required offline computation is at most $900 * 2^{41} \approx 2^{51}$, which is similar to general DROWN. For a 2048-bit RSA modulus, the expected number of queries for phase 2 is 16. Each query consists of three queries to $\mathcal{O}_{\text{SSLv2-extra-clear}}$ and one query to $\mathcal{O}_{\text{SSLv2-export-leaky}}$, which requires at most 2^{41} computation. Therefore in expectancy the attacker has to perform 2^{45} offline computation for phase 2.

All Your Queries Are Belong to Us: The Power of File-Injection Attacks on Searchable Encryption

Yupeng Zhang* Jonathan Katz† Charalampos Papamanthou*

Abstract

The goal of *searchable encryption* (SE) is to enable a client to execute searches over encrypted files stored on an untrusted server while ensuring some measure of privacy for both the encrypted files and the search queries. Most recent research has focused on developing efficient SE schemes at the expense of allowing some small, well-characterized “(information) leakage” to the server about the files and/or the queries. The practical impact of this leakage, however, remains unclear.

We thoroughly study *file-injection attacks*—in which the server sends files to the client that the client then encrypts and stores—on the query privacy of single-keyword and conjunctive SE schemes. We show such attacks can reveal the client’s queries in their entirety using very few injected files, even for SE schemes having low leakage. We also demonstrate that natural countermeasures for preventing file-injection attacks can be easily circumvented. Our attacks outperform prior work significantly in terms of their effectiveness as well as in terms of their assumptions about the attacker’s prior knowledge.

1 Introduction

The goal of *searchable encryption* (SE) is to enable a client to perform keyword searches over encrypted files stored on an untrusted server while still guaranteeing some measure of privacy for both the files themselves as well as the client’s queries. In principle, solutions that leak no information to the server can be constructed based on powerful techniques such as secure

two-party computation, fully-homomorphic encryption, and/or oblivious RAM. Such systems, however, would be prohibitively expensive and completely impractical [15].

In light of the above, researchers have focused on the development of novel SE schemes that are much more efficient, at the expense of allowing some information to “leak” to the server [19, 9, 8, 11, 6, 16, 12, 20, 13, 5]. The situation is summarized, e.g., by Cash et al. [6]:

The premise of [our] work is that in order to provide truly practical SSE solutions one needs to accept a certain level of leakage; therefore, the aim is to achieve an acceptable balance between leakage and performance.

The question then becomes: what sort of leakage is acceptable? Roughly speaking, and focusing on single-keyword search for simplicity, current state-of-the-art schemes leak mainly two things: the *query pattern* (i.e., when a query is repeated) and the *file-access pattern* (namely, which files are returned in response to each query); these are collectively called *L1 leakage* in [4]. The prevailing argument is that L1 leakage is inconsequential in practice, and so represents a reasonable sacrifice for obtaining an efficient SE scheme.

In truth, the ramifications of different types of leakage are poorly understood; indeed, characterizing the real-world consequences of the leakage of existing SE schemes was highlighted as an important open question in [6]. Recently, several groups have shown that even seemingly minor leakage can be exploited to learn sensitive information, especially if the attacker has significant prior knowledge about the client’s files or the keywords they contain. Islam et al. [10] (IKK12), who initiated this line of work, showed that if the server knows (almost) all the contents of the client’s files, then it can determine the client’s queries from L1 leakage. Cash et al. [4] (CGPR15) gave an improved attack that works for larger keyword universes while assuming (slightly) less knowledge about the files of the client. They also ex-

plored the effects of even greater leakage, and showed how query-recovery attacks could serve as a springboard for learning further information about the client’s files.

A different attack for query recovery was given by Liu et al. [14]. The attack assumes a known distribution on the keywords being searched by the client, and works only after the client issues a large number of queries.

1.1 Our Contributions

In this paper, we further investigate the consequences of leakage in SE schemes through the lens of *file-injection attacks*. In such attacks, the server sends files of its choice to the client, who then encrypts and uploads them as dictated by the SE scheme. This attack was introduced by Cash et al. [4], who called it a *known-document attack*. As argued by those authors, it would be quite easy to carry out such attacks: for example, if a client is using an SE scheme for searching email (e.g., Pmail [2]), with incoming emails processed automatically, then the server can inject files by simply sending email to the client (from a spoofed email address, if it wishes to avoid suspicion). We stress that the server otherwise behaves entirely in an “honest-but-curious” fashion.

We show that file-injection attacks are *devastating* for query privacy: that is, a server can learn a very high fraction of the keywords searched by the client, by injecting a relatively small number of files. Compared to prior work [10, 4], our attacks are both more effective in terms of the fraction of queries recovered and far less demanding in terms of the prior information the server knows. Our attacks differ in that the server must inject files, but as argued above this is easy to carry out in practice.

We consider both adaptive and non-adaptive attacks, where adaptivity refers (in part) to whether the server injects files before or after the client’s query is made. In particular, a non-adaptive attack injects files that can be used to break all future queries; An adaptive attack crafts the injected files using leakage of previously-observed queries. Our adaptive attacks are more effective, but assume the SE scheme does not satisfy *forward privacy* [7, 20]. (Forward privacy means that the server cannot tell if a newly inserted file matches previous search queries. With the exception of [7, 20], however, all efficient SE schemes supporting updates do not have forward privacy.) Our work thus highlights the importance of forward privacy in any real-world deployment.

1.2 Organization of the paper

We begin by showing a simple, binary-search attack that allows the server to learn 100% of the client’s queries with *no* prior knowledge about the client’s files. We then propose an easy countermeasure: limiting the number of

keywords that are indexed per file. (We show that this idea is viable insofar as it has limited effect on the utility of searchable encryption.) However, our attacks can be suitably modified to defeat this countermeasure, either using a larger number of injected files (but still no prior knowledge about the client’s files) or based on limited knowledge—as low as 10%—of the client’s files. Our attacks still outperform prior work [10, 4], having a significantly higher recovery rate and requiring a lower fraction of the client’s files to be known.

We additionally investigate the effectiveness of padding files with random keywords (suggested in [10, 4]) as another countermeasure against our attacks. We show that the performance of our attacks degrades only slightly when such padding is used, in contrast to prior attacks that fail completely.

Finally, we initiate a study of the implications of leakage on *conjunctive* queries, and show how to extend our attacks to this setting. Our attacks work against SE schemes having “ideal” leakage, but are even more effective against the scheme of Cash et al. [6] (the most efficient SE scheme allowing conjunctive queries), which suffers from larger leakage.

2 Background

For the purposes of this paper, only minimal background about searchable encryption (SE) is needed. At a high level, an SE scheme allows a client to store encrypted versions of its files on a server, such that at a later point in time the client can retrieve all files containing a certain keyword (or collection of keywords). We assume a set of keywords $K = \{k_0, k_1, \dots\}$ known to an attacker, and for simplicity view a file as an unordered set of keywords. (Although the order and multiplicity of the keywords matter, and a file may contain non-keywords as well, these details are irrelevant for our purposes.)

We assume an SE scheme in which searching for some keyword k is done via the following process (all efficient SE schemes work in this way): first, the client deterministically computes a *token* t corresponding to k and sends t to the server; using t , the server then computes and sends back the *file identifiers* of all files containing keyword k . (These file identifiers need not be “actual” filenames; they can instead simply be pointers to the appropriate encrypted files residing at the server.) The client then downloads the appropriate files.

Because the token is generated deterministically from the keyword, the server can tell when queries repeat and thus learn the *query pattern*; the returned file identifiers reveal the *file-access pattern*. Our attacks rely only on knowledge of the file-access pattern, though we additionally assume that the server can identify when a specific file identifier corresponds to some particular file injected

File 1:		0
File 2:		1
File 3:		0

Figure 1: An example of the binary-search attack with $|K| = 8$. Each file injected by the attacker contains 4 keywords, which are shaded in the figure. If file 2 is returned in response to some token, but files 1 and 3 are not, the keyword corresponding to that token is k_2 .

by the server. (The same assumption is made by Cash et al. [4].) This is reasonable to assume, even if file identifiers are chosen randomly by the client, for several reasons: (1) the server can identify the file returned based on its length (even if padding is used to mitigate this, it is impractical to pad every file to the maximum file length); (2) in SE schemes supporting updates, the server can inject a file F and then identify F with the next (encrypted) file uploaded by the client; (3) if the server can influence the queries of the client, or even if it knows some of the client’s queries, then the server can use that information to identify specific injected files with particular file identifiers. We postpone further discussion to Section 8.

In this paper, we focus only on query-recovery attacks where the server observes various tokens sent by the client followed the file identifiers returned, and the server’s goal is to determine the keywords corresponding to those tokens. This violates *query privacy*, which is important in its own right, and—as noted by Cash et al. [4]—can also be leveraged to violate *file privacy* since it reveals (some of) the keywords contained in (some of) the files. Our attacks show that the leakage of SE schemes should be analyzed carefully when SE is used as part of a larger system.

3 Binary-Search Attack

In this section, we present a basic query-recovery attack that we call the *binary-search attack*. This attack does not require the server to have any knowledge about the client’s files, and recovers all the keywords being searched by the client with 100% accuracy.

3.1 Basic Algorithm

The basic observation is that if the server injects a file F containing exactly half the keywords from the keyword universe K , then by observing whether the token t sent

by the client matches that file (i.e., whether F is returned in response to that token), the server learns one bit of information about the keyword corresponding to t . Using a standard non-adaptive version of binary search, the server can thus use $\lceil \log |K| \rceil$ injected files to determine the keyword exactly. The idea is illustrated in Figure 1 for $|K| = 8$.

The attack is described more formally in the pseudo-code of Figure 2. We assume for simplicity that $|K|$ is a power of 2, and identify K with the set $\{0, \dots, |K| - 1\}$ written in binary. The attack begins by having the server generate a set \mathbf{F} of $\log |K|$ files to be injected, where the i th file contains exactly those keywords whose i th most-significant bit is equal to 1. At some point,¹ the server learns, for each injected file, whether it is returned in response to some token t . We let $R = r_1 r_2 \dots$ denote the search results on the injected files, where $r_i = 1$ if and only if the i th file is returned in response to the token. For this attack, the server can deduce that the keyword corresponding to t is precisely R .

Algorithm $\mathbf{F} \leftarrow \text{Inject_Files}(K)$

- 1: **for** $i = 1, \dots, \log |K|$ **do**
- 2: Generate a file F_i that contains exactly the keywords in K whose i th bit is 1.
- 3: Output $\mathbf{F} = \{F_1, \dots, F_{\log |K|}\}$.

Algorithm $k \leftarrow \text{Recover}(R, K)$

- 1: Return R as the keyword from universe K associated with the token.

Figure 2: The binary-search attack. R denotes the search results for the token to be recovered on the injected files.

We highlight again that for this attack, the files are generated non-adaptively and independent of the token t . We note further that the *same* injected files can be used to recover the keywords corresponding to *any number of tokens*, i.e., once these files are injected, the server can recover the keywords corresponding to any future tokens sent by the client. The number of injected files needed for this attack is quite reasonable; with a 10,000-keyword universe, a server who sends only one email per day to the client can inject the necessary files in just 2 weeks.

Small keyword universe. For completeness and future reference, we note that the binary-search attack can be optimized if the hidden keyword is known to lie in some smaller universe of keywords, or if the server only cares about keywords lying in some subset of the entire keyword universe (and gives up on learning the keyword if

¹This can occur if the files are injected before the token t is sent, or if the files are injected after t is sent and the SE scheme does not satisfy forward privacy.

it lies outside this subset). Specifically, the server can carry out the binary-search attack from Figure 2 based on any subset $K' \subset K$ of the keyword universe using only $\log |K'|$ injected files.

3.2 Threshold Countermeasure

A prominent feature of the binary-search attack is that the files that need to be injected for the attack each contain a large number of keywords, i.e., $|K|/2$ keywords per file. We observe, then, that one possible countermeasure to our attack is to modify the SE scheme so as to limit the number of keywords per indexed file to some threshold $T \ll |K|/2$. This could be done either by simply not indexing files containing more than T keywords (possibly caching such files at the client), or by choosing at most T keywords to index from any file containing more than T keywords.

The threshold T can be set to some reasonably small value while not significantly impacting the utility of the SE scheme. For example, in the Enron email dataset [1] with roughly 5,000 keywords (see Section 5 for further details), the average number of keywords per email is 90; only 3% of the emails contain more than 200 keywords. Using the threshold countermeasure with $T = 200$ would thus affect only 3% of the honest client’s files, but would require the server to inject many more files in order to carry out a naive variant of the binary-search attack. Specifically, the server could replace each file F_i (that contains $|K|/2$ keywords) in the basic attack with a sequence of $|K|/2T$ files $F_{i,1}, \dots, F_{i,|K|/2T}$ each containing T keywords, such that $\cup_j F_{i,j} = F_i$. If any of these files is returned, this is equivalent to the original file F_i being returned in the basic attack. Note, however, that the server must now inject $|K|/2T \cdot \log |K|$ files. Unfortunately, as we explore in detail in the following section, the threshold countermeasure can be defeated using fewer injected files via more-sophisticated attacks.

Note also that the threshold countermeasure does not affect the binary-search attack with small keyword universe $K' \subset K$, as long as $|K'| \leq 2T$.

4 Advanced Attacks

In this section, we present more-sophisticated attacks for when the threshold countermeasure introduced in the previous section is used. In Section 4.1 we show an attack that uses fewer injected files than a naive modification of the binary-search attack, still without any knowledge of the client’s files. Then, in the following section, we show attacks that reduce the number of injected files even further, but based on the assumption that the server has information about some fraction of the client’s files.

4.1 Hierarchical-Search Attack

We noted earlier that the threshold countermeasure does not affect the binary-search attack with small keyword universe $K' \subset K$ if $|K'| \leq 2T$. We can leverage this to learn keywords in the *entire* universe using what we call a *hierarchical search attack*. This attack works by first partitioning the keyword universe into $\lceil |K|/T \rceil$ subsets containing T keywords each. The server injects files containing the keywords in each subset to learn which subset the client’s keyword lies in. In addition, it uses the small-universe, binary-search attack on adjacent pairs of these subsets to determine the keyword exactly. The algorithm is presented in Figure 3.

Algorithm $\mathbf{F} \leftarrow \text{Inject_Files_hierarchical}(K)$

- 1: Partition the universe into $w = \lceil |K|/T \rceil$ subsets K_1, \dots, K_w of T keywords each.
- 2: **for** $i = 1, 2, \dots, w$ **do**
- 3: Generate F_i containing every keyword $k \in K_i$.
- 4: **for** $i = 1, 2, \dots, w/2$ **do**
- 5: $\mathbf{F}_i \leftarrow \text{Inject_Files}(K_{2i-1} \cup K_{2i})$.
- 6: Output $\mathbf{F} = \{F_1, \dots, F_w, \mathbf{F}_1, \dots, \mathbf{F}_{w/2}\}$.

Algorithm $k \leftarrow \text{Recover_hierarchical}(R, K)$

- 1: Parse the search result R as

$$R = \{r_1, \dots, r_w, R_1, \dots, R_{w/2}\},$$

corresponding to the results on the files in \mathbf{F} described above.

- 2: Using the $\{r_i\}$, identify the subset $K_{2x-1} \cup K_{2x}$ the unknown keyword lies in.
- 3: $k \leftarrow \text{Recover}(R_x, K_{2x-1} \cup K_{2x})$.

Figure 3: The hierarchical-search attack. T is the threshold determining the maximum number of keywords in a file. R denotes the search results on the injected files. Inject_Files and Recover are from Figure 2.

We now calculate the number of injected files required by this attack. In Step 3 of $\text{Inject_Files_hierarchical}$, the server injects $\lceil |K|/T \rceil$ files, and in Step 5 it injects $\lceil |K|/2T \rceil \cdot \lceil \log 2T \rceil$ files. The total number of injected files is therefore at most

$$\lceil |K|/2T \rceil \cdot (\lceil \log 2T \rceil + 2).$$

In fact, for each i the first file in the set \mathbf{F}_i generated by $\text{Inject_files}(K_{2i-1} \cup K_{2i})$ is the same as F_{2i-1} and the server does not need to inject it again. Also, the server does not need to generate F_w in Step 3 because if the keyword is not in F_1, \dots, F_{w-1} then the server knows it must be in F_w . So the total number of injected files can

be improved to

$$\lceil |K|/2T \rceil \cdot (\lceil \log 2T \rceil + 1) - 1.$$

When the size of the keyword universe is $|K| = 5,000$ and the threshold is $T = 200$, the server needs to inject only 131 files, and the number of injected files grows linearly with the size of the keyword universe. We highlight again that the same injected files can be used to recover the keywords corresponding to any number of tokens; i.e., once these files are injected, the server can recover the keywords of any future searches made by the client.

We remark that an *adaptive* version of the above attack is also possible. Here, the attacker would first inject $\lceil |K|/T \rceil - 1$ files to learn what subset the unknown keyword lies in, and then carry out the small-universe, binary-search attack on a subset of size T . This requires only $\lceil |K|/T \rceil + \log T - 1$ injected files, but has the disadvantage of being adaptive and hence requires the SE scheme to not satisfy forward privacy. This version of the attack also has the disadvantage of targeting one particular search query of the client; additional files may need to be injected to learn the keyword used in some subsequent search query.

4.2 Attacks Using Partial Knowledge

With the goal of further decreasing the number of injected files required to recover a token in presence of the threshold countermeasure, we now explore additional attacks that leverage prior information that the server might have about some of the client’s files; we refer to the files known to the server as *leaked files*.² A similar assumption is used in prior work showing attacks on SE schemes [10, 4]; previous attacks, however, require the server to know about 90% of the client’s files to be effective (see Section 5), whereas our attacks work well even when the server knows a much smaller fraction of the client’s files.

Our attacks utilize the frequency of occurrence of the tokens and keywords in the client’s files. We define the *frequency* of a token (resp., keyword) as the fraction of the client’s files containing this token (resp., keyword). Similarly, we define the *joint frequency* of two tokens (resp., keywords) as the fraction of files containing *both* tokens (resp., keywords). The server learns the exact frequency (resp., joint frequency) of a token (resp., pair of tokens) based on the observed search results. The server obtains an estimate of the frequencies (resp., joint frequencies) of all the keywords based on the client’s files that it knows. We let $f(t)$ denote the exact (observed) frequency of token t , and let $f(t_1, t_2)$ be the joint frequency

²We stress that our attacks only rely on the *content* of these leaked files; we do not assume the server can identify the file identifiers corresponding to the leaked files after they have been uploaded to the server.

Algorithm $k \leftarrow \text{Inject_Files_Single}(t, K)$

- 1: Let K' be the set of $2T$ keywords with estimated frequencies closest to $f(t)$.
- 2: $\mathbf{F} \leftarrow \text{Inject_Files}(K')$.

Algorithm $k \leftarrow \text{Recover_Single}(R, K')$

- 1: If R contains all 0s, output \perp .
- 2: Else $k \leftarrow \text{Recover}(R, K')$.

Figure 4: Recovering a single keyword using partial file knowledge. T is the threshold determining the maximum number of keywords in a file. R denotes the search results on the injected files. `Inject_Files` and `Recover` are from Figure 2.

of tokens t_1, t_2 . We use $f^*(k)$ to denote the estimated frequency of keyword k , and define $f^*(k_1, k_2)$ analogously. Our attacks use the observation that if the leaked files are representative of all the client’s files, then $f(t)$ and $f^*(k)$ are close when t is the token corresponding to keyword k .

4.2.1 Recovering One Keyword

Say the server obtains a token t sent by the client, having observed frequency $f(t)$. The server first constructs a *candidate universe* K' for the keyword corresponding to t consisting of the $2T$ keywords whose estimated frequencies are closest to $f(t)$. The server then uses the small-universe, binary-search attack to recover the keyword exactly. In this way, the number of injected files is only $\lceil \log 2T \rceil$. The attack is presented in detail in Figure 4.

Differences from attacks in previous sections. The attack just described is *adaptive*, in that it targets a particular token t and injects files whose contents depend on the results of a search using t . This means the attack only applies to SE schemes that do not satisfy forward privacy. It also means that the attack needs to be carried out again in order to learn the keyword corresponding to some other token.

Another difference from our previous attacks is that this attack does not work with certainty. In particular, if the observed and estimated frequencies are far apart, or the number of keywords whose estimated frequencies are close to the observed frequency is larger than $2T$, the server may fail to recover the keyword corresponding to the token. On the other hand, the server can tell whether the attack succeeds or not, so will never associate an incorrect keyword with a token. This also means that if the attack fails, the attacker can re-run the attack with a different candidate universe, or switch to using one of our earlier attacks, in order to learn the correct keyword.

(We rely on this feature to design an attack for multiple tokens in the following section.) This is in contrast to earlier attacks [10, 4], where the attacker cannot always tell whether the keyword was recovered correctly.

4.2.2 Recovering Multiple Keywords

To learn the keywords corresponding to m tokens, the server can repeat the attack above for each token, but then the number of injected files will be (in the worst case) $m \cdot \lceil \log 2T \rceil$. A natural way to attempt to reduce the number of injected files is for the server to determine a candidate universe of size $2T$ for each token and then use the union of those candidate universes when injecting the files. In that case, however, the union would almost surely contain more than $2T$ keywords, in which case the number of keywords in the files produced by the binary-search attack will exceed the threshold T .

A second approach would be for the server to make the size of the candidate universe for each token $2T/m$, so the size of their union cannot exceed $2T$ keywords. Here, however, if m is large then the candidate universe for each token is very small and so the probability of the corresponding keyword not lying in its candidate universe increases substantially. Therefore, the recovery rate of this attack would be low.

Instead, we propose a more-complex attack that recovers multiple tokens by taking into account the joint frequencies for tokens and keywords. Our attack has two main steps (see Figure 5):

1. First, we recover the keywords corresponding to a subset of the tokens, namely the $n \ll m$ tokens with the highest observed frequencies. We recover the keywords using the second approach sketched above, which works (with few injected files) because n is small. This gives us as a set of tokens and their associated keywords as “ground truth.”
2. Given the ground truth, we recover the keyword associated with some other token t' using the following observation: if k' is the keyword corresponding to t' , then the observed joint frequency $f(t, t')$ should be “close” to the estimated joint frequency $f^*(k, k')$ for all pairs (t, k) in our ground-truth set, where “closeness” is determined by a parameter δ . By discarding candidate keywords that do not satisfy this property, we are left with a small set K' of candidate keywords for t' . If the candidate universe of keywords for each token is small enough, then even their union will be small. We then use a small-universe, binary-search attack to recover the corresponding keywords exactly.

Note that in the above attack the ability to tell whether a token is recovered correctly when building the ground

truth is crucial—otherwise the ground-truth set could contain many incorrect associations.

Parameter selection. Our attack has two parameters: n and δ . A larger value of n means that the ground-truth set can potentially be larger, but if n is too large then there is a risk that the candidate universe K_t (comprising the $2T/n$ keywords with estimated frequencies closest to $f(t)$) will not contain the true keyword corresponding to t . In our experiments, we set n heuristically to a value that achieves good performance.

The value of δ is chosen based on statistical-estimation theory. The estimated joint frequency is an empirical average computed from a collection of leaked files assumed to be sampled uniformly from the set of all files. Thus, we set δ such that if keywords k, k' correspond to tokens t, t' , respectively, then the estimated joint frequency $f^*(k, k')$ is within $\pm \delta \cdot f^*(k, k')$ of the true value $f(t, t')$ at least 99% of the time.

Ground-truth set selection. When building the ground-truth set, we recover the keywords associated with those tokens having the highest observed frequencies. We do so because those keywords can be recovered correctly with higher probability, as we explain next.

If the leaked files are chosen uniformly from the set of all files, then using statistical-estimation theory as above the attacker can compute a value δ such that at least 99% of the time it holds that $|f^*(k) - f(t)| \leq \varepsilon \cdot f^*(k)$, where k denotes the (unknown) keyword corresponding to t . Thus, if the attacker sets the candidate universe K_t to be the set of all keywords whose estimated frequencies are within distance $\varepsilon \cdot f^*(k)$ of $f(t)$, the candidate universe will include the keyword corresponding to t at least 99% of the time. The problem with taking this approach is that the set K_t constructed this way may be too large.

If we assume a Zipfian distribution [3] for the keyword frequencies, however, then the size of K_t as constructed above is smallest when $f(t)$ is largest. (This is a consequence of the fact that the Zipfian distribution places high probability on a few items and low probability on many items.) In particular, then, the set of $2T/n$ keywords with estimated frequencies closest to $f(t)$ (as chosen by our algorithm), will “cover” all keywords within distance $\varepsilon \cdot f^*(k)$ of $f(t)$ from $f(t)$ – or, equivalently, the candidate universe will contain the true keyword k – with high probability.

5 Experiments

We simulate the attacks from Section 4. (We do not run any simulations for the binary-search attack described in Section 3, since this attack succeeds with probability 1, injecting a fixed number of emails.) We compare our attacks to our own implementation of the attacks by Cash

$\mathbf{t} = \{t_1, \dots, t_m\}$ is the set of m tokens whose keywords we wish to recover.

Algorithm $\mathbf{k} \leftarrow \text{Attack_Multiple_Tokens}(\mathbf{t}, K)$

Build ground truth set G .

- 1: Sort tokens in \mathbf{t} according to their exact frequencies $f(t)$. Let \mathbf{t}_1 denote the n tokens with highest observed frequencies.
- 2: **for** each token t in \mathbf{t}_1 **do**
- 3: Set its candidate universe K_t as the set of $\frac{2T}{n}$ keywords with estimated frequencies $f^*(k)$ nearest to $f(t)$.
- 4: Define $K' = \cup_{t \in \mathbf{t}_1} K_t$ and inject files generated by $\mathbf{F}_1 \leftarrow \text{Inject_Files}(K')$.
- 5: **for** each token t in \mathbf{t}_1 **do**
- 6: Let R_t be the search result of token t on files \mathbf{F}_1 .
- 7: **if** R_t is not all 0s **then**
- 8: $k_t \leftarrow \text{Recover}(R_t, K')$.
- 9: Add (t, k_t) to G .

Recover the remaining tokens, let \mathbf{t}_2 be the set of unrecovered tokens.

- 10: **for** each token $t' \in \mathbf{t}_2$ **do**
- 11: Set its candidate universe $K_{t'}$ as the set of $2T$ keywords with estimated frequencies $f^*(k)$ nearest to $f(t')$.
- 12: **for** each keyword $k' \in K_{t'}$ **do**
- 13: **for** each token/keyword pair $(t, k) \in G$ **do**
- 14: If $|f(t, t') - f^*(k, k')| > \delta \cdot f^*(k, k')$, remove k' from candidate universe $K_{t'}$.
- 15: Set $K'' = \cup_{t' \in \mathbf{t}_2} K_{t'}$.
- 16: **if** $|K''| \leq 2T$ **then**
- 17: $\mathbf{F}_2 \leftarrow \text{Inject_Files}(K'')$.
- 18: **for** each token $t' \in \mathbf{t}_2$ **do**
- 19: Let $R_{t'}$ be the search result of token t' on files \mathbf{F}_2 .
- 20: $k_{t'} \leftarrow \text{Recover}(R_{t'}, K'')$
- 21: **else**
- 22: $\mathbf{F}_2 \leftarrow \text{Inject_Files_hierarchical}(K'')$.
- 23: **for** each token $t' \in \mathbf{t}_2$ **do**
- 24: Let $R_{t'}$ be the search result of token t' on files \mathbf{F}_2 .
- 25: $k_{t'} \leftarrow \text{Recover_hierarchical}(R_{t'}, K'')$
- 26: Output \mathbf{k} that includes all recovered keywords.

Figure 5: Recovering multiple keywords using partial file knowledge. T is the threshold determining the maximum number of keywords in a file; δ is a parameter. Inject_Files and Recover are from Figure 2.

et al. [4] (CGPR15). We do not compare with the attacks of Islam et al. [10] (IKK12), since their results are strictly dominated by those of CGPR15.

5.1 Setup

For our experiments we use the Enron email dataset [1], consisting of 30,109 emails from the “sent mail” folder of 150 employees of the Enron corporation that were sent between 2000–2002. We extracted keywords from this dataset as in CGPR15: words were first stemmed using the standard Porter stemming algorithm [18], and we then removed 200 stop words such as “to,” “a,” etc. Doing so results in approximately 77,000 keywords in total. In our experiments, we chose the top 5,000 most frequent

keywords as our keyword universe (as in CGPR15).

We assumed the threshold countermeasure with $T = 200$. As discussed earlier, only 3% of the files contained more than this many keywords.

We could not find real-world query datasets for email. Therefore, in our experiments we choose the client’s queries uniformly from the keyword universe, as in CGPR15. (However, our attacks do not use any information about the distribution of the queries.) Leaked files are chosen uniformly from the base set of 30,109 emails, and the percentage of leaked files was varied from 1% to 100%. For each value of the file-leakage percentage, we repeat the attack on 100 uniform sets of queries (containing either one token or 100 tokens) and 10 uniformly sampled sets of leaked files of the appropriate size; we

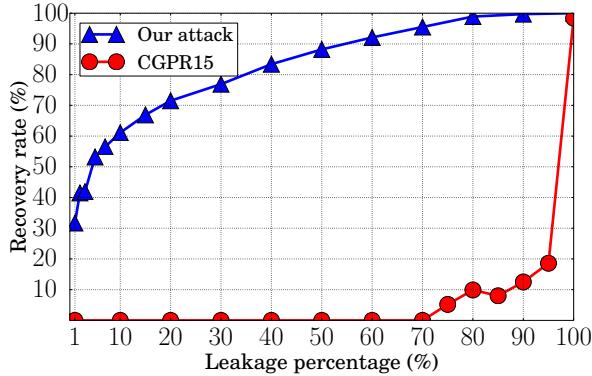

Figure 6: Recovering the keyword corresponding to a single token. Probability of recovering the correct keyword as a function of the percentage of files leaked.

report the average. We do not include error bars in our figures, but have observed that the standard deviation in our experiments is very small (less than 3% of the average).

5.2 Recovery of a Single Token

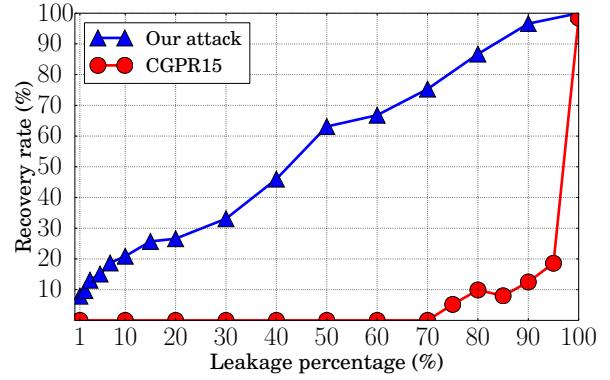

The performance of our attack for recovering the keyword associated with a single token (described in Section 4.2.1) is displayed in Figure 6. The server only needs to inject $\lceil \log 2T \rceil = 9$ files in order to carry out the attack. It can be observed that our attack performs quite well even with only a small fraction of leaked files, e.g., recovering the keyword about 70% of the time once only 20% of the files are leaked, and achieving 30% recovery rate even when given only 1% of the files.

Neither the IKK12 attack nor the CGPR15 attack applies when the server is given the search results of only a single token. To provide a comparison with our results, we run the CGPR15 attack by giving it the search results of 100 tokens (corresponding to uniformly chosen keywords) and then measure the fraction of keywords recovered. As shown in Figure 6, the CGPR15 attack recovers a keyword with probability less than 20% even when 95% of the client’s files are leaked. Of course, our attack model is stronger than the one considered in CGPR15.

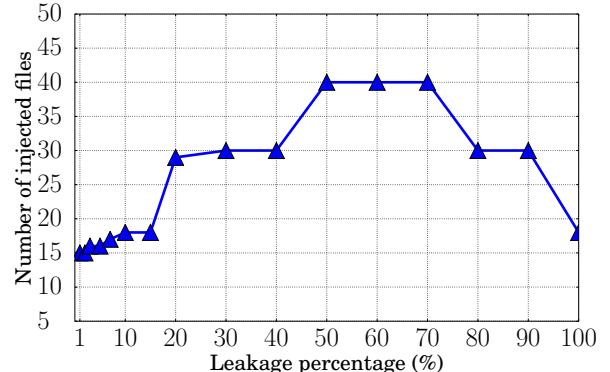

5.3 Recovery of Multiple Tokens

We have also implemented our attack from Section 4.2.2 which can be used to recover the keywords corresponding to multiple tokens. In our experiments, we target the recovery of the keywords associated with $m = 100$ tokens; we choose $n = 10$, and set δ as described in Section 4.2.2.

Figure 7a tabulates the fraction of keywords recovered by our attack, and compares it to the fraction recovered

(a)

(b)

Figure 7: Recovering the keywords corresponding to 100 tokens. (a) Fraction of keywords recovered and (b) number of files injected as a function of the percentage of files leaked.

by the CGPR15 attack. (As noted in the previous section, the CGPR15 attack inherently requires search results for multiple tokens; this explains why the results for the CGPR15 attack in Figure 7a are almost identical to the results for their attack in Figure 6.) Both attacks do well when the fraction of leaked files is large, however the recovery rate of the CGPR15 attack drops dramatically as the fraction of leaked files decreases. In contrast, our attack continues to perform well, recovering 65% of the keywords given access to 50% of the client’s files, and still recovering 20% of the keywords when only 10% of the client’s files have been leaked. We stress that in our attack the server knows which keywords have been recovered correctly and which have not, something that is not the case for prior attacks.

Figure 7b shows the number of files that need to be injected in order to carry out our attack. The number of files injected never exceeds 40, and in many cases it is even less than that. We also highlight that the number of files injected to recover the keywords associated with 100

tokens is more than an order-of-magnitude smaller than $100 \times$ the number of files injected to recover the keyword associated with a single token in the previous section.

The number of files injected by our attack first increases with the fraction of leaked files, and then decreases; we briefly explain why. The number of files injected in step 1 of our attack is independent of the fraction of leaked files. The number of files injected in step 2 of the attack depends on both the number of unrecovered tokens (i.e., the size of \mathbf{t}_2) and the average size of the candidate universe for each unrecovered token t' (i.e., the size of $K_{t'}$). When the fraction of leaked files is very small, the estimated joint frequencies are far from the true frequencies and, in particular, most estimated joint frequencies are 0; thus, many keywords are removed from $K_{t'}$ and hence the size of $K_{t'}$ is low. The net result is that the recovery rate is small, but so is the number of injected files. As the fraction of leaked files increases, more keywords are included in $K_{t'}$, leading to higher recovery rate but also more injected files. When the fraction of leaked files becomes very high, however, the estimated frequencies are very close to the true frequencies and so more keywords are recovered in step 1 of the attack. This leaves fewer unrecovered tokens in step 2, leading to fewer injected files overall even as the recovery rate remains high.

6 Ineffectiveness of Keyword Padding

Prior work [10, 4] suggests *keyword padding* as another potential countermeasure for attacks that exploit the file-access pattern. The basic idea is to distort the real frequency of each keyword k by randomly associating files that do not contain that keyword with k ; this is done at setup time, when the client uploads its encrypted files to the server. One version of the countermeasure [4] ensures that the number of files returned in response to any search result is a multiple of an integer λ . A stronger version of the countermeasure [10] involves performing the padding in such a way that for any keyword k there are at least $\alpha - 1$ other keywords having the same frequency. These countermeasures defeat the attacks in prior work, but we show that they have little effect on our attacks.

We remark that keyword padding seems difficult to apply in the dynamic setting, where new files are uploaded after the initial setup done by the client. The dynamic case is not discussed in [10, 4].

6.1 Binary-/Hierarchical-Search Attacks

Even when keyword padding is used, our binary-search and hierarchical-search attacks will recover the keyword k corresponding to some token t unless one of the

injected files that does not contain k is returned in response to the search using t . We show that the probability of this bad event is small, focusing on the binary-search attack for concreteness. Say ℓ of the files contain k and that, after keyword padding, an additional $\beta \cdot \ell$ random and independently chosen files (in expectation) that do not contain k are returned in response to the search using t . (By setting parameters appropriately, this roughly encompasses both the countermeasures described above.) Now consider some file injected as part of the binary-search attack that does not contain k . The probability that this file is chosen as one of the spurious files returned in response to the search using t is $\beta\ell/(F - \ell)$, where F is the total number of files (including the injected files). Since $\lceil \log |K| \rceil$ files are injected, the overall probability that the bad event occurs is at most

$$1 - \left(1 - \frac{\beta\ell}{(F - \ell)}\right)^{\lceil \log |K| \rceil}.$$

In fact, this is an over-estimate since if k is uniform then on average only half the injected files contain k .

For the Enron dataset with $|K| = 5,000$, $F = 30,109$, $\ell = 560$, and $\beta = 0.6$, and assuming half the injected files contain the keyword in question, the probability that the binary-search attack succeeds is 0.93. (In fact, $\beta = 0.6$ is quite high, as this means that more than 1/3 of the files returned in response to a query do not actually contain the searched keyword.) With $\beta = 0.6$ the IKK12 and CGPR15 attacks recover no keywords at all.

6.2 Attacks with Partial File Leakage

Although our attacks with partial file leakage use information about keyword frequencies and joint frequencies, they are still not significantly affected by the padding countermeasures. The reason is that although the padding ensures that a given frequency no longer suffices to uniquely identify a keyword, the frequency of any particular keyword doesn't change very much. Thus, the exact frequency and the estimated frequency of any keyword remain close even after the padding is done, and the underlying keyword is still likely to be included in the candidate universe of a target token. As long as this occurs, the search step recovers the token with high probability as discussed in the previous section. This is even more so the case with regard to joint frequencies, since these do not change unless two keywords are both associated with the same random file that contains neither of those keywords, something that happens with low probability.

To validate our argument, we implement the padding countermeasure proposed in [4] and repeat the experiments using our attacks. As shown in Figures 8 and 9,

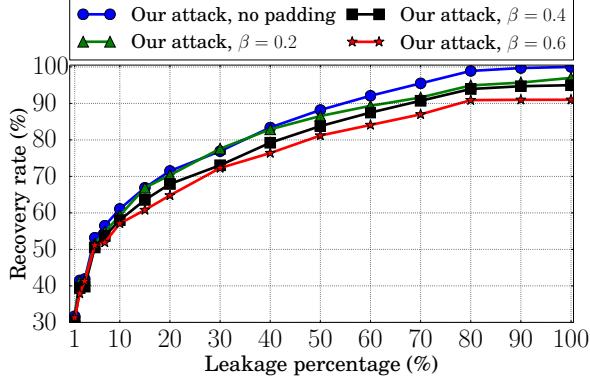

Figure 8: Recovering the keyword corresponding to a single token when keyword padding is used.

the recovery rate of our attacks degrades only slightly when keyword padding is used.

Figure 10 compares the effectiveness of our attack to the CGPR15 attack when keyword padding is used. The recovery rate of the CGPR15 attack drops dramatically in the presence of this countermeasure. In particular, it recovers only 57% of the tokens even with 100% file leakage when $\beta = 0.2$, and recovers nothing even with 100% file leakage when $\beta = 0.6$. In contrast, our attack still recovers almost the same number of keywords as when no padding is used.

7 Extensions to Conjunctive SE

SE schemes supporting conjunctive queries allow the client to request all files containing some collection of keywords k_1, k_2, \dots, k_d . The naive way to support conjunctive queries is to simply have the client issue queries for each of these keywords individually; the server can compute the set of file identifiers S_i containing each keyword k_i and then take their intersection to give the final result. Such an approach leaks more information than necessary: specifically, it leaks each of S_1, \dots, S_d rather than the final result $\cap S_i$ alone. We refer to $\cap S_i$ as the *ideal access-pattern leakage* for a conjunctive query, and show attacks based only on such ideal leakage. We remark, however, that no known efficient SE scheme achieves ideal leakage. For example, the scheme by Cash et al. [6] leaks $S_1, S_1 \cap S_2, S_1 \cap S_3, \dots, S_1 \cap S_d$. Such additional leakage can only benefit our attacks.

Throughout this section, we assume the threshold countermeasure is not used and so injected files can contain any number of keywords. (Our attacks here could be generalized as done previously in case the threshold countermeasure is used.)

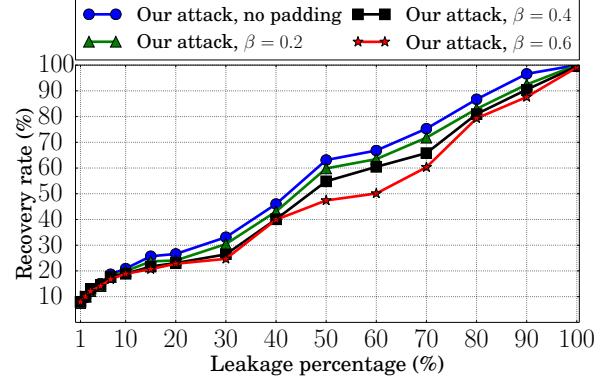

Figure 9: Recovering the keywords corresponding to 100 tokens when keyword padding is used.

7.1 Queries with Two Keywords

We first present a non-adaptive attack to recover the keywords used in a conjunctive query involving two keywords. As in the non-adaptive attacks in prior sections, the attacker can recover the keywords corresponding to any future queries after injecting some initial set of files.

The idea is the following. Say the conjunctive search query involves keywords k_1 and k_2 , and we can partition the universe of keywords into two sets K_1 and K_2 with $k_1 \in K_1$ and $k_2 \in K_2$. We can then use a variant of the binary-search attack in which we inject files generated by `Inject_Files(K_1)`, where we additionally include all keywords in K_2 . Since these files always contain k_2 , the search results of the conjunctive query on these injected files is exactly the same as the search results of k_1 on these files, and we can thus recover k_1 as before. We can proceed analogously to recover k_2 .

The problem with the above is that we do not know, *a priori*, how to partition K into sets K_1, K_2 as required. Instead, we generate a sequence of $\log |K|$ partitions $\{(K_1^i, K_2^i)\}$ such that for some partition i it holds that $k_1 \in K_1^i$ and $k_2 \in K_2^i$. This is done by simply letting K_1^i be the set of all keywords whose i th bit is 0, and K_2^i be the complement. Since k_1 and k_2 are distinct, they must differ on at least one position, say i , and satisfy the desired separation property on the i th partition. By repeating the attack described earlier for each partition, we obtain an attack using $\log^2 |K| + \log |K|$ injected files (after removing duplicates). The attack is described in detail in Figure 11.

Given ideal access-pattern leakage, the above attack above only works for conjunctive queries involving two keywords. For conjunctive searches using the SE scheme of Cash et al. [6], though, the above attack can be extended to work for conjunctive queries involving any number of keywords since the pairwise intersections are leaked as described earlier.

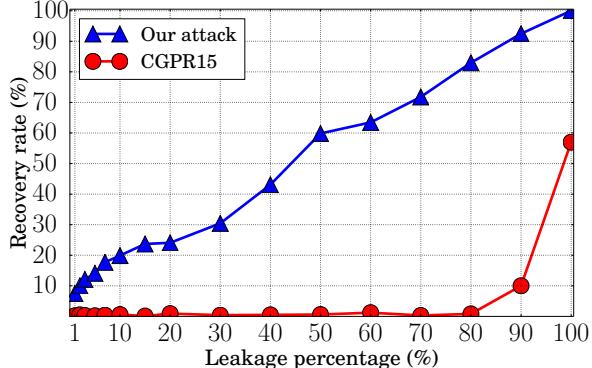

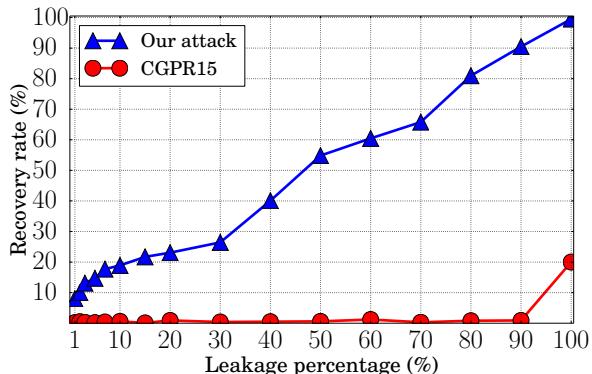

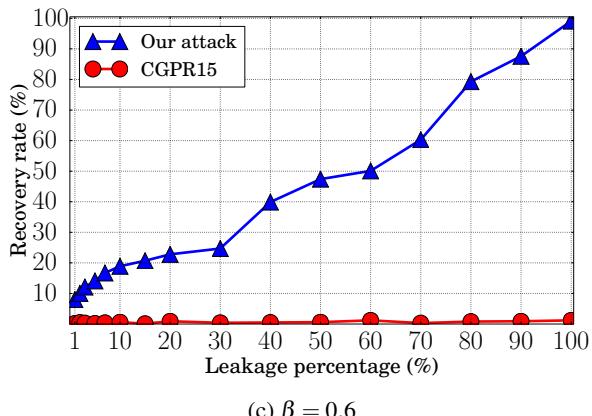

(a) $\beta = 0.2$ (b) $\beta = 0.4$ 

Figure 10: Recovering the keywords corresponding to 100 tokens when keyword padding is used, plotted for different β .

7.2 Queries with Multiple Keywords

The attack in Section 7.1 only works for conjunctive queries involving two keywords, and uses $O(\log^2 |K|)$ injected files. Here we present a non-adaptive attack that can recover conjunctive queries involving any number of keywords using only $O(\log |K|)$ injected files, and still assuming only ideal access-pattern leakage. In contrast

Let q be a conjunctive query with two keywords.

Algorithm F \leftarrow Inject_Files_Disjoint(K_1, K_2)

- 1: $\mathbf{F} \leftarrow$ Inject_Files(K_1).
- 2: Include all keywords in K_2 in every file in \mathbf{F} .

Algorithm F \leftarrow Inject_Files_Conjunctive(K)

- 1: **for** $i = 1, 2, \dots, \log |K|$ **do**
- 2: Let K_1^i contain keywords whose i th bit is 0, and let $K_2^i = K \setminus K_1^i$.
- 3: Generate file F_1^i that contains all keywords in K_1^i and file F_2^i that contains all keywords in K_2^i .
- 4: $\mathbf{F}_1^i \leftarrow$ Inject_Files_Disjoint(K_1^i, K_2^i).
- 5: $\mathbf{F}_2^i \leftarrow$ Inject_Files_Disjoint(K_2^i, K_1^i).
- 6: Output $\mathbf{F} = \{F_1^i, F_2^i, \mathbf{F}_1^i, \mathbf{F}_2^i\}$, for all i .

Algorithm k \leftarrow Recover_Conjunctive(q, K, \mathbf{F})

- 1: Let $R_q = \{r_1^i, r_2^i, R_1^i, R_2^i\}$ for $i = 1, \dots, \log |K|$ be the search result of query q on the files \mathbf{F} described above.
- 2: Find i such that neither F_1^i nor F_2^i is in the search result (i.e., $r_1^i = r_2^i = 0$).
- 3: $k_1 \leftarrow$ Recover(R_1^i, K_1^i).
- 4: $k_2 \leftarrow$ Recover(R_2^i, K_2^i).
- 5: Output (k_1, k_2) .

Figure 11: Non-adaptive attack for a conjunctive query involving two keywords.

to the previous attack, however, this attack does not always succeed.

Consider a conjunctive query q involving d keywords. The basic idea is to inject n files, each containing L keywords selected uniformly and independently from the keyword universe. If parameters are set appropriately, the search result on q will include some of the injected files with high probability. By definition, each of those files contains all d keywords involved in the query, and hence the intersection of those files also contains all those keywords. We claim that when parameters are set appropriately, the intersection contains no additional keywords. Thus, the server recovers precisely the d keywords involved in the query by simply taking the intersection of the injected files returned in response to the query. The following theorem formalizes this idea.

Theorem 1. Let $L = (\frac{1}{2})^{1/d}|K|$ and $n = (2 + \varepsilon)d \log |K|$ with $\varepsilon \geq 0$. Then the success probability of the attack is roughly $e^{-1/|K|^{\varepsilon/4}}$.

Proof. Fix some conjunctive query q involving d keywords. The probability that any particular injected file matches the query is approximately $(L/|K|)^d = 1/2$ since each of the d keywords is included in the file with

probability roughly $L/|K|$. Since each file is generated independently, the expected number of files that match the query is $n/2$; moreover, the number n' of files that match the query follows a binomial distribution and so the Chernoff bound implies

$$\Pr \left[\left| n' - \frac{n}{2} \right| \geq \theta \frac{\sqrt{n}}{2} \right] \leq e^{-\theta^2/2}.$$

Setting $\theta = \frac{\varepsilon\sqrt{n}}{2(2+\varepsilon)}$, we have

$$\Pr \left[n' \leq \left(1 + \frac{\varepsilon}{4} \right) d \log |K| \right] \leq e^{-\frac{\theta^2}{2}}.$$

Thus, $n' > (1 + \frac{\varepsilon}{4})d \log |K|$ with overwhelming probability.

The probability that any *other* keyword is in all these n' files is extremely low. Specifically, for any fixed keyword not involved in the query, the probability that it lies in all n' files is $(L/|K|)^{n'}$. Thus, the probability that *no* other keyword lies in all n' files is

$$\left(1 - \left(\frac{L}{|K|} \right)^{n'} \right)^{|K|-d} \approx \left(1 - \frac{1}{|K|^{1+\varepsilon/4}} \right)^{|K|}$$

(assuming $d \ll |K|$). The above simplifies to $e^{-1/|K|^{\varepsilon/4}}$. \square

Note that for any $\varepsilon > 0$ the bound given by the theorem approaches 1 as $|K|$ tends to infinity. We experimentally verified the bound in the theorem for $|K| = 5,000$ and $d = 3$. For example, setting $\varepsilon = 1$ we obtain an attack in which the server injects $n = 110$ files with $L = 3,969$ keywords each, and recovers all keywords involved in the conjunctive query with probability 0.97. For completeness, we remark that the server can tell whether it correctly recovers all the keywords or not, assuming d is known.

7.3 An Adaptive Attack

We can further reduce the number of injected files using an adaptive attack. The idea is to recover the keywords involved in the query one-by-one, starting with the lexicographically largest, using an adaptive binary search for each keyword. The server first injects a file containing the first $|K|/2$ keywords. There are two possibilities:

1. If this file is in the search result for the query, the server learns that all the keywords involved in the query have index at most $|K|/2$. It will next inject a file containing the first $|K|/4$ keywords.
2. If this file is not in the search result for the query, the server learns that at least one keyword involved in the query has index greater than $|K|/2$. It will next inject a file containing the first $3|K|/4$ keywords.

Proceeding in this way, the server learns the lexicographically largest keyword using $\log |K|$ injected files. Once that keyword k_d is recovered, the server repeats this attack but with k_d always included in the injected files to learn the next keyword, and so on. See Figure 12.

Let q be a conjunctive query with keyword k_1, \dots, k_d .

Algorithm $\mathbf{k} \leftarrow \text{Attack_Conjunctive}(q, K)$

```

1: Initialize  $\mathbf{k} = \emptyset$ .
2: for  $i = d, \dots, 1$  do
3:   Set  $K_i = K \setminus \mathbf{k}$ , set  $b = |K_i|/2$ .
4:   for  $j = 2, \dots, \log |K_i|$  do
5:     Inject  $F$  that contains the first  $b$  keywords
       in  $K_i$  and all keywords in  $\mathbf{k}$ .
6:     Let  $R_q$  be the search result of query  $q$  on  $F$ .
7:     if  $R_q = 1$  then
8:        $b = b - |K_i|/2^j$ .
9:     else
10:       $b = b + |K_i|/2^j$ .
11: Inject  $F$  that contains the first  $b$  keywords in  $K_i$ 
       and all keywords in  $\mathbf{k}$ .
12: Let  $R_q$  be the search result of query  $q$  on  $F$ .
13: if  $R_q = 1$  then
14:   Recover  $k_i$  as the  $b$ th keyword in  $K_i$ .
15: else
16:   Recover  $k_i$  as the  $(b+1)$ th keyword in  $K_i$ .
17:  $\mathbf{k} = \mathbf{k} \cup \{k_i\}$ .

```

Figure 12: An adaptive attack for conjunctive queries involving d keywords.

The number of injected files is $d \log |K|$. We remark that d need not be known in advance, since the attacker can determine d during the course of the attack. It is also worth observing that the number of injected files is essentially optimal for a deterministic attack with success probability 1, because the search results on $d \log |K|$ files contain at most $d \log |K|$ bits of information, which is roughly the entropy of a conjunctive search involving d keywords from a universe of size $|K|$.

8 Additional (Potential) Countermeasures

In this section, we briefly discuss some other potential countermeasures against our attacks.

Semantic filtering. One may be tempted to think that the files injected by our attacks will not “look like” normal English text, and can therefore be filtered easily by the client. We argue that such an approach is unlikely to prevent our attacks. First, although as described our attacks inject files containing arbitrary sets of keywords, the

server actually has some flexibility in the choice of keywords; e.g., the binary-search attack could be modified to group sets of keywords that appear naturally together. Second, within each injected file, the server can decide the order and number of occurrences of the keywords, can choose variants of the keywords (adding “-ed” or “-s,” for example), and can freely include non-keywords (“a,” “the,” etc.) There are several tools (e.g., [21]) that can potentially be adapted to generate grammatically correct text from a given set of keywords by ordering keywords based on *n*-grams trained from leaked files and simple grammatical rules. A detailed exploration is beyond the scope of our paper.

Batching updates. As mentioned in Section 2, even if the client shuffles the file identifiers and pads all files to the same length, the server can identify an injected file based on the time at which it is inserted by the client. This suggests a (partial) countermeasure that can be used in dynamic SE schemes that support updates: rather than uploading each new file as it arrives, the client should wait until there are several (say, B) new files and then upload this “batch” of B files at once. Assuming only one of those files was injected by the server, this means the server only learns that the injected file corresponds to one of B possibilities.

This countermeasure can be trivially circumvented if the server can inject B files before any other new files arrive. (If the server additionally has the ability to mount chosen-query attacks—something we have not otherwise considered in this paper—then the total number of injected files remains the same.) Even if the server can inject only $B' < B$ identical³ files into a single “batch,” the server knows that if fewer than B' files from this batch are returned in response to some query, then the injected files do not match that query. Finally, even if the server can only inject a single file per “batch,” the server can inject the same file repeatedly and with high confidence determine based on the search results whether the file matches some query. We leave a more complete analysis of this countermeasure for future work.

9 Conclusions

Our paper shows that file-injection attacks are devastating for query privacy in searchable encryption schemes that leak file-access patterns. This calls into question the utility of searchable encryption, and raises doubts as to whether existing SE schemes represent a satisfactory tradeoff between their efficiency and the leakage they allow. Nevertheless, we briefly argue that searchable encryption may still be useful in scenarios where

³The files need not be identical; they only need to contain an identical set of keywords.

file-injection attacks are not a concern, and then suggest directions for future research.

We have argued that file-injection attacks would be easy to carry out in the context of searching email. But in “closed systems,” where a client is searching over records generated via some other process, file-injection attacks may not be possible or may be much more difficult to carry out. Additionally, there may be settings—e.g., when all files have the same length because they share some particular format—where even though the server can inject files, it may not be able to associate file identifiers with specific files it has injected. It is worth noting also that there may be applications of SE in which the server is trusted (and so, in particular, can be assumed not to carry out file-injection attacks), and the threat being defended against is an external attacker who compromises the server.⁴

Our work and previous work [10, 4] demonstrate that leaking file-access patterns in their entirety is dangerous, and can be exploited by an attacker to learn a significant amount of sensitive information. We suggest, therefore, that future research on searchable encryption focus on reducing or eliminating this leakage rather than accepting it as the default. Our work also highlights the need to design efficient schemes satisfying forward privacy. Addressing these challenges may require exploring new directions, such as interactive protocols [17] or multiple servers. It would also be of interest to explore lower bounds on the efficiency that searchable encryption can achieve as a function of how much about the file-access pattern is leaked.

Abstract

In this work, we explore the ecosystem of *commercial pay-per-install* (PPI) and the role it plays in the proliferation of unwanted software. Commercial PPI enables companies to bundle their applications with more popular software in return for a fee, effectively commoditizing access to user devices. We develop an analysis pipeline to track the business relationships underpinning four of the largest commercial PPI networks and classify the software families bundled. In turn, we measure their impact on end users and enumerate the distribution techniques involved. We find that unwanted ad injectors, browser settings hijackers, and “cleanup” utilities dominate the software families buying installs. Developers of these families pay \$0.10–\$1.50 per install—upfront costs that they recuperate by monetizing users without their consent or by charging exorbitant subscription fees. Based on Google Safe Browsing telemetry, we estimate that PPI networks drive over 60 million download attempts every week—nearly three times that of malware. While anti-virus and browsers have rolled out defenses to protect users from unwanted software, we find evidence that PPI networks actively interfere with or evade detection. Our results illustrate the deceptive practices of some commercial PPI operators that persist today.

1 Introduction

In recent years, *unwanted software* has risen to the forefront of threats facing users. Prominent strains include ad injectors that laden a victim’s browser with advertisements, browser settings hijackers that sell search traffic, and user trackers that silently monitor a victim’s browsing behavior. Estimates of the incident rate of unwanted software installs on desktop systems are just emerging: prior studies suggest that ad injection affects as many as 5% of browsers [34] and that deceptive extensions escaping detection in the Chrome Web Store affect over 50 million users [17].

Despite the proliferation of unwanted software, the root source of installs remains unclear. One potential explanation is *commercial pay-per-install* (PPI), a monetization scheme where software developers bundle several third-party applications as part of their installation process in return for a payout. We differentiate this from *blackmarket pay-per-install* [4] as commercial PPI relies on a user consent dialogue to operate aboveboard. Download portals are a canonical example, where carelessly installing any of the top applications may leave a system bloated with search toolbars, anti-virus free trials, and registry cleaners [16]. Unfortunately, this all too common user experience is the profit vehicle for a collection of private and publicly companies that commoditize software bundling [15]. While earnings in this space are nebulous, one of the largest commercial PPI outfits reported \$460 million in revenue in 2014 [31].

In this work, we explore the ecosystem of commercial PPI and the role it plays in distributing the most notorious unwanted software families. The businesses profiting from PPI operate *affiliate networks* to streamline buying and selling installs. We identify a total of 15 PPI affiliate networks headquartered in Israel, Russia, and the United States. We select four of the largest to investigate, monitoring each over a year long period from January 8, 2015–January 7, 2016 in order to track the software families paying for installs, their impact on end users, and the deceptive distribution practices involved.

We find that commercial PPI distributes roughly 160 software families each week, 59% of which at least one anti-virus engine on VirusTotal [36] flags as unwanted. For our study, we use this labeling to classify unwanted software. The families with the longest PPI distribution campaigns include ad injectors, like Crossrider, and scareware that dupes victims into paying a subscription fee for resolving “dangerous” registry settings, a hair’s length shy of ransomware. We find that PPI networks support unwanted software as first-class partners: down-

loaders will actively fingerprint a victim’s machine in order to detect hostile anti-virus or virtualized environments, in turn dynamically selecting offers that go undetected. Software developers pay between \$0.10–1.50 per install for these services, where price is dictated by geographic demand.

Via Safe Browsing telemetry, we measure the impact of commercial pay-per-install on end users across the globe. On an average week, Safe Browsing generates over 60 million warnings related to unwanted software delivered via PPI—three times that of malware. Despite these protections, estimates of unwanted software incident rates provided by the Chrome Cleanup Tool [5] indicate there are tens of millions of installs on user systems. Of the top 15 families installed, we find 14 distribute via commercial PPI.

Thousands of PPI affiliates drive these weekly downloads through a battery of distribution practices. We find 54% of sites that link to PPI bundles host content related to freeware, videos, or software cracks. For the long tail of other sites where users are not expecting an installer, PPI networks provide affiliates with “promotional tools” such as butter bars that warn a user their Flash player is out of date, in turn delivering a PPI bundle. In order to avoid detection by Safe Browsing, affiliates churn through domains every 7 hours or actively cloak against Safe Browsing scans. Our findings illustrate the deceptive behaviors present in the commercial PPI ecosystem and the virulent impact it has on end users.

In summary, we frame our contributions as follows:

- We present the first investigation of commercial PPI’s internal operations and its relation to unwanted software.
- We estimate that commercial PPI drives over 60 million download attempts every week.
- We find that 14 of the top 15 unwanted software families distribute via commercial PPI.
- We show that commercial PPI installers and distributors knowingly attempt to evade user protections.

2 Commercial Pay-Per-Install

For the purposes of this study, we define *commercial pay-per-install* (PPI) as the practice of software developers bundling several third-party applications in return for a fee. We present an example bundle in Figure 1, where clicking on “accept” results in a user installing eight *offers* through a single radio dialogue. Some of these offers may be *unwanted software*, where at least one anti-virus engine on VirusTotal marks the application as potentially unwanted, adware, spyware, or a generic category. In contrast to blackmarket pay-per-install which illegally

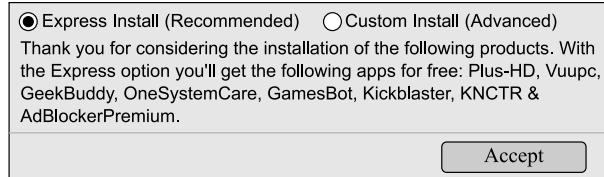

Figure 1: Sample prompt bundling eight commercial pay-per-install offers. Each offer is downloaded and automatically installed upon a user accepting the “Express Install” option. Users may have no knowledge of the behaviors of the bundled offers.

sells access to compromised hosts, deceptive commercial PPI outfits rely on this prompt to nominally satisfy user consent requirements. To simplify the process of buying and selling installs, commercial PPI operates as an affiliate network. We outline this structure and enumerate the major networks in operation during our study.

2.1 PPI Affiliate Structure

The pay-per-install affiliate structure consists of *advertisers*, *publishers*, and *PPI affiliate networks*. Figure 2 presents the typical business role each plays.

Advertiser: In the pay-per-install lingo, advertisers are software owners that pay third-parties to distribute their binaries or extensions. Restrictions on what software advertisers can distribute falls entirely to the discretion of PPI affiliate network operators and their ability (and willingness) to police abuse. As highlighted in Figure 2, advertisers include developers of unwanted software like Conduit, Wajam, or Shopperz that recuperate PPI installation fees by monetizing end users via ad injection, browser settings hijacking, or user tracking. Irrespective of the application’s behavior, PPI networks set a minimum bid price per install that advertisers only pay out upon a successful install. Advertisers may also restrict the geographic regions they bid on.

Publisher: Publishers (e.g., affiliates) are the creators or distributors of popular software applications (irrespective of copyright ownership). An example would be a website hosting VLC player as shown in Figure 2. PPI networks re-wrap a publisher’s application in a *downloader* that installs the original binary in addition to multiple advertiser binaries. This separation of monetization from distribution allows publishers to focus solely on garnering an audience and driving installs through any means. Consequently, advertisers may have no knowledge of the deceptive techniques that publishers employ to obtain installs, nor what their binary is installed alongside. Upon a successful install, the publisher receives a fraction of the advertiser’s bid. We differentiate this from direct distribution licenses such as Java’s agreement to bundle the Ask Toolbar [18], as there is no ambiguity be-

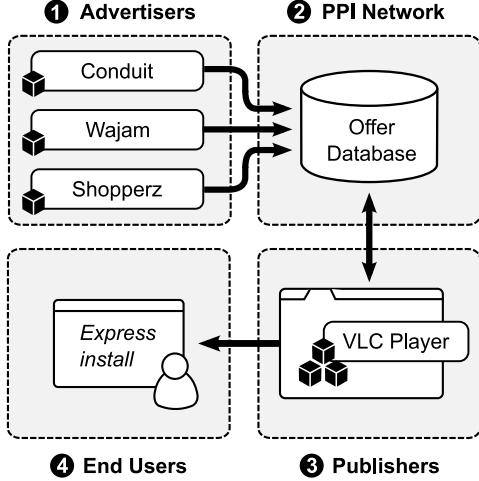

Figure 2: Pay-Per-Install (PPI) business model. Advertisers paying for installs supply their binaries to a PPI affiliate network (1). The PPI network cultivates a set of publishers—affiliates with popular software applications seeking additional monetization (2). The PPI network re-wraps the publisher’s software with a customized downloader that the publisher then distributes (3). When end users launch this downloader, it installs the publisher’s software alongside multiple advertiser binaries (4). The PPI network is paid by the advertisers and the publisher receives a commission.

tween the advertiser and publisher around what packages are co-bundled and the source of installs.

PPI Affiliate Network: PPI affiliate networks serve as a bridge between the specialized roles of advertisers and publishers. The PPI network manages all business relationships with advertisers, provides publishers with custom downloaders, and handles all payments to publishers for successful installs. When a publisher gains access to an end user’s system, the PPI network determines which offers to install. As we show in Section 3, this entails fingerprinting an end user’s system to determine any risk associated with anti-virus as well as to support geo-targeted installations. Similarly, the PPI network dictates the level of user consent when it installs an advertiser’s binary, where consent forms a spectrum between silent installs to opt-out dialogues. In some cases, advertisers can customize the installation dialogue and thus play a role in user consent.

Reselling: With multiple PPI affiliate networks in operation, various PPI operators will aggregate their publishers’ install traffic and resell it to larger PPI affiliate networks. These smaller PPI operators create value for their affiliates by providing promotional tools in the form of landing pages, banner ads, butter bars (e.g., “Your Flash player is out of date”), and generic installers for media players and games—described later in Section 6. These tools simplify the process of monetizing web traf-

fic where a victim is not primed to download a bundle. It is worth noting that these resellers do not operate their own downloader; they rely on sub-affiliate tracking provided by larger PPI networks that effectively enables two-tiered affiliate distribution.

2.2 Identifying PPI Networks

In contrast to blackmarket pay-per-install [4], the affiliate networks driving commercial PPI are largely private companies with venture capital backing such as *Install-Monetizer* and *OpenCandy* [8, 9]. Registering as a publisher with these PPI networks is simple: a prospective affiliate submits her name, website, and an estimate of the number of daily installs she can deliver. Given this porous registration process, underground forums contain extensive discussions on dubious distribution techniques and which PPI affiliate networks offer the best conversion rates and payouts. We tracked these conversations on *blackhatworld.com* and *pay-per-install.com*, enumerating over 50 commercial PPI affiliate programs that exclusively deal with Windows installs. While there are networks that target Mac and mobile installs, we focus our work on the relationship between commercial PPI and unwanted software families that disproportionately impact Windows users as identified by previous studies [17, 34].

2.3 Acquiring PPI Downloader Samples

As part of our initial investigation of PPI, we successfully acquired downloaders for fifteen distinct PPI networks. We list each in Table 1. These networks have been in operation for an average of 2–3 years, with the oldest program dating back to 2008 as gleaned from crawl logs provided by *archive.org*. Based on a preliminary black-

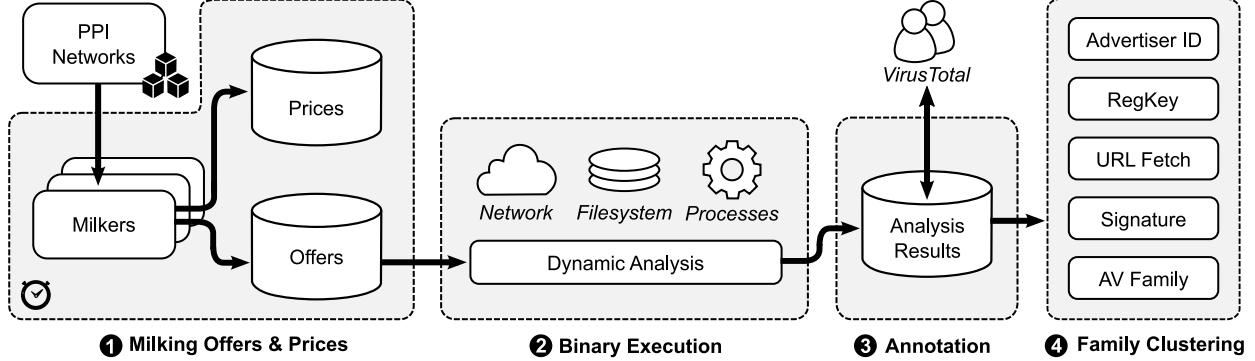

Figure 3: PPI monitoring infrastructure. We collect offers and prices from four PPI networks on a regular basis (❶). We then execute the offer binaries in a sandbox to observe network requests, file system changes, and running processes (❷). We annotate each binary with any known VirusTotal labels (❸) before finally clustering binaries into families (❹).

box test of each downloader, we found six of the fifteen PPI downloaders were merely resellers for other PPI networks in our list. Of the remaining nine, we elect four of the largest—Amonetize, InstallMonetizer, OpenCandy, and Outbrowse—as the basis of our investigation into the role of PPI in unwanted software distribution. We based our initial selection criteria on the complexity of the offer protocols and from preliminary statistics reported by Safe Browsing on which PPI networks delivered the largest number of downloads. We confirm later in Section 5 that these four PPI networks are in fact representative, large operators. We also explore the impact of the PPI ecosystem as a whole on end users.

3 Monitoring the PPI Ecosystem

Using the PPI downloader samples we acquire for Amonetize, InstallMonetizer, OpenCandy, and Outbrowse, we develop a pipeline to track the offers (e.g., advertiser binaries) that each PPI network distributes as well as the regional price per install. We outline our pipeline in Figure 3. We begin by simulating each PPI downloader’s protocol to fetch all possible offers on an hourly basis. We analyze each binary in a sandboxed environment, ultimately clustering the offers into software families based on the behavioral patterns we observe. We discuss the construction of our pipeline and its limitations.

3.1 PPI Downloader Protocol

All four PPI downloaders we study rely on a three-stage protocol for dynamically fetching advertiser binaries. To start, a downloader fingerprints a client’s device to determine the operating system and default browser. The downloader reports these parameters to the PPI server as part of a request for all available offers as shown in Figure 4. In our example, the request embeds the exact

version of the client’s OS and service pack; the Chrome, Firefox, and Internet Explorer version if any are present; whether the system is 32-bit or 64-bit; and finally potentially unique identifiers including a MAC address and a machine identifier such as `HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Cryptography`.

We provide a typical offer response in Figure 5. Each offer contains a unique product identifier, download URL, and additional metadata that dictates how the install process unfolds. Depending on the PPI network, the response will include anywhere from 5–50 offers, filtered by regional requirements imposed by the PPI server based on the client’s IP address.

In the second stage, the downloader verifies that none of the `RegKey` or `AntivirusRegKeys` are present in the device’s registry. This approach serves to prevent multiple installations of the same advertiser’s binary as well as to avoid anti-virus disrupting the installation of an offer. If a client’s machine satisfies the offer criteria, the downloader will display the offer and execute the binary with the command line options specified by the PPI server if accepted. These parameters sometimes reveal the intent of the advertiser (e.g., replacing the default search provider) as well as evasive actions such as remaining dormant for 20 days to prevent unwanted software symptoms (e.g., injected ads) from manifesting immediately after an installation. If a client’s system does not satisfy the criteria, the downloader simply tests another potential offer until all options are exhausted. In total, the downloader will display offers for anywhere from 1–10 advertiser binaries (potentially all as one express install dialogue): the maximum is dictated by the PPI network.

In the final stage, the downloader reports all successfully installed offers along with the publisher’s affiliate id for compensation.

}
```

Figure 5: Example PPI network response for Outbrowse containing an offer and associated metadata.

3.2 Developing Longitudinal Milkers

In order to track bundled offers, we develop *milkers* that replay the first stage of each PPI network’s offer protocol and decode the response. This is largely a time-intensive manual process of blackbox testing each PPI downloader, determining the PPI server’s domain (or those it cycles through), and re-implementing the protocol into a standalone module that generates a network request with the expected downloader User-Agent and custom headers. We provide a sample of the PPI server domains contacted by downloaders in Table 2.

For all requests, we present a device fingerprint associated with a Windows 7 system with Chrome and Internet Explorer installed while randomizing unique identifiers such as the device’s MAC address and machine ID. Upon receiving a response, we decode the list of offers and extract the associated URL of the offer binary. We reiterate that the PPI programs we monitor provide anywhere from 5–50 potential offers along with their installation requirements. For each offer, we detect whether we previously observed the URL of the associated binary. If the URL is fresh, we download the URL’s content; if the URL is redundant, we rely on a cached copy in order to reduce network load on the PPI servers. We note that this caching methodology may reduce the number of unique digests we obtain if advertisers were to cycle binaries referenced by a fixed URL.

We finally store each binary, the offer metadata (e.g., registry requirements, advertiser ids), and the timestamp of execution. We ran our milkers every hour from a col-

PPI Network	Sample Domain
<i>Outbrowse</i>	srv.desk-top-app.info
<i>Amonetize</i>	www.download-way.com
<i>InstallMonetizer</i>	www.stsunwest.com
<i>OpenCandy</i>	api.opencandy.com

Table 2: Sample of PPI server domains contacted by our milkers. In total, we identify 31 domains servicing offer requests for the four PPI networks we study.

PPI Network	Milking Period	Offers	Unique
<i>Outbrowse</i>	1/08/15–1/07/16	107,595	584
<i>Amonetize</i>	1/08/15–1/07/16	231,327	356
<i>InstallMonetizer</i>	1/11/15–1/07/16	30,349	137
<i>OpenCandy</i>	1/09/15–1/07/16	77,581	134
Total	1/08/15–1/07/16	446,852	1,211

Table 3: Breakdown of PPI networks, milking periods, and the unique offers appearing in our dataset.

lection of cloud instances hosted in the United States over a year long period from January 8, 2015–January 7, 2016. During this time, we updated our milker protocols at most once per PPI network, a reflection of the lack of external pressure on commercial PPI practices compared to malware. In total, we collected 446,852 offers. These offers contained 2,841 unique URLs, 1,809 unique digests, and 1,211 unique product identifiers (as determined by the `ProductID` field shown in Figure 5, or its equivalent for other PPI networks, which are consistent across versions.) We provide a detailed breakdown of the offers per PPI network in Table 3.

We faced a separate challenge for tracking regional pricing. In particular, the exact daily prices that advertisers pay per install are available only to publishers delivering successful installs. Unlike previous investigations into blackmarket PPI [4], we elected not to register as commercial PPI affiliates due to potential Terms of Service violations. As such, we lack access to per-advertiser pricing data. Instead, we track the average price per install across the PPI ecosystem as publicly advertised by PPI networks and resellers to attract affiliates. In total, we identify five PPI-related websites that provide a breakdown of the current price per install paid across 219 regions, with rates varying between \$0.01–\$2.09. These sites include cinstaller.com, installmania.com, cashmylinks.com, perinstallbucks.com, and truemediapartner.com. We crawled and parsed these pages (as allowed by robots.txt) on a weekly basis from January 8, 2015–January 7, 2016 to monitor any fluctuations.

3.3 Executing and Annotating Offers

We execute all downloaded binaries in a sandboxed environment similar in flavor to Anubis [2], CWSandbox [38], and GQ [22], the details of which are covered in previous work [17, 29, 34]. During execution, we log all network requests and responses, file system changes, modified registry keys, and spawned processes. We also monitor whether the executable changes any preferences related to Chrome or Internet Explorer such as altering the default browser, dropping an extension, or modifying the startup page.

Independent of our dynamic execution environment, we annotate each binary with third-party intelligence gathered through VirusTotal at the end of our collection period. Mechanically, we submit the hash of each binary to determine which of 61 anti-virus engines report the binary as malicious or unwanted. We also collect any labels, though the value of these is highly variable: some reflect generic ‘Adware’ while others contain a family name potentially unique to an anti-virus engine.

3.4 Clustering and Classifying Offers

At the conclusion of our collection period we classified all of the advertiser binaries in our dataset into distinct families. This canonicalization step is necessary to de-duplicate instances where the same advertiser works with multiple PPI networks or where advertisers introduce polymorphism due to software updates, sub-affiliate programs, or to evade detection by anti-virus engines. Classification is a semi-automated process where we first cluster all binaries based on overlapping registry key modifications, domains contacted during execution, process names, or digital certificates used to sign the advertiser’s software (only 58% of offers were signed). This approach follows similar strategies for clustering malware delivered via drive-by downloads [14] and unwanted software using code-signing [21]. We also cluster offers based on the registry keys present in the installation pre-conditions provided by PPI networks during offer selection. These pre-conditions unambiguously reveal all of the registry paths controlled by a single family, such as *Vitruvian* which goes by 19 other names including *LessTabs*, *SearchSnacks*, *Linksicle*; or *Wajam* which installs under 418 unique registry keys. We present a sample of these pre-conditions in Figure 6. Through all these clustering techniques, we generate 873 non-overlapping clusters (of 1,809 possible).

We manually review all clusters active for more than 150 days (e.g., we examine the timestamp of all milked binaries in a cluster and count the number of distinct dates) totaling 58 distinct clusters. We derive family labels based on the most common naming convention

```
this.bCompExist = g.ami.CheckRegKey(

    "Software\\WajaWebEnhancer",
    ....
    "Software\\Wajam\\affiliate_id")
```

Figure 6: Example offer requirements for Wajam via Amonetize. It contains 418 registry key checks for Wajam variants. We cluster offers that contain the same registry checks.

found in VirusTotal for a cluster. If no public name exists, we fall back to the advertiser name listed in the offer metadata provided by PPI networks. For all clusters lasting less than 150 days, we rely exclusively on the advertiser name. These names serve only to communicate the major software families commonly found in commercial PPI and whether they overlap with the largest unwanted families impacting end users (discussed in Section 5).

3.5 Limitations

Our investigation of the PPI ecosystem faces a number of limitations. First, our pipeline runs exclusively from United States IP addresses. This potentially biases our perspective of PPI offers in the event advertisers distribute exclusively to non-US territories. As we demonstrate later in Section 4, the US is the highest paid region for installs, which makes it one of the most interesting to analyze. Next, because we do not participate directly in the PPI ecosystem, we lack exact pricing details per install. We attempt to extrapolate these values based on public pricing used to attract affiliates, but we cannot verify the accuracy of this data other than to corroborate similar rates cited within the underground. Third, our family classification faces the same challenges of malware phylogeny where there is frequent disagreement between anti-virus naming conventions. We reconcile these discrepancies for the longest running PPI campaigns at the expense of overlooking the long tail of brief campaigns. Finally, our perspective of the PPI ecosystem is restricted to four PPI networks due to the time-intensive

process of building milkers. While there is a risk our findings are not representative of the entire ecosystem, we show in Section 4 there is substantial overlap between the advertisers of each PPI network. This leads us to believe our sample of PPI networks extends to other unexplored commercial PPI operators.

4 Exploring Commercial PPI Offers

We provide a bird’s-eye-view of the business relationships underpinning the commercial PPI ecosystem before diving into the unwanted software families reliant on PPI distribution. We find that ad injectors, browser settings hijackers, and system “clean-up” utilities dominate the advertisers paying for installs. With anti-virus engines flagging 59% of the weekly software families we milk per PPI network, we observe at least 20% of PPI advertisers take advantage of anti-virus and VM detection provided by PPI downloaders to avoid installing in hostile environments.

4.1 High-Level Metrics

Using the 1,211 product identifiers embedded by PPI networks in each offer for accounting purposes, we calculate the total distinct simultaneous offers per PPI network and the duration that advertisers run each offer. On average, we observe 25–60 active offers per PPI network each week, with a fine grained breakdown shown in Figure 7. The spike around July 2015 for Amonetize represents a temporary 2x increase in offers distributed by the PPI network; it is unrelated to any change in our infrastructure. The majority of advertisers for Amonetize and Outbrowse maintain their offers for less than a week before cycling to a new product as shown in Figure 8. In contrast, OpenCandy and InstallMonetizer attract advertisers who run the same product for over 15 days.

4.2 Longest Running Campaigns

With over 873 software families classified by our analysis pipeline, we examine which families consistently appear in the PPI ecosystem and thus sink the most money into installs. Table 4 provides a detailed breakdown of the software families with the longest running distribution campaigns and the PPI networks involved. The families fall into five categories: ad injectors, browser settings hijackers, system utilities, anti-virus, and major brands. We provide sample screenshots of the resulting user experience after installation in the Appendix.

Ad Injectors: Ad injectors modify a user’s browsing experience to replace or insert additional advertisements that otherwise would not appear on a website. Every PPI network we monitor participates in the distribution of ad injectors. Of the top eight programs listed by Thomas

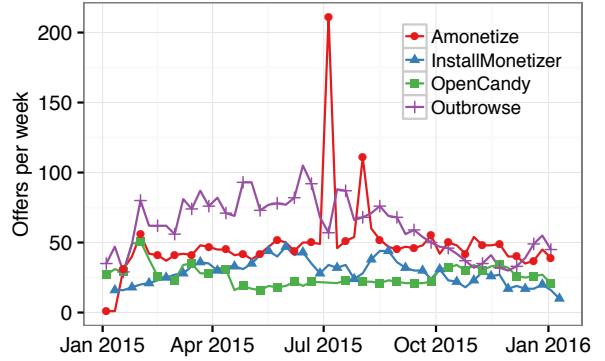

Figure 7: Unique PPI offers operating each week. Amonetize and Outbrowse cultivate a large number of offers compared to OpenCandy and InstallMonetizer.

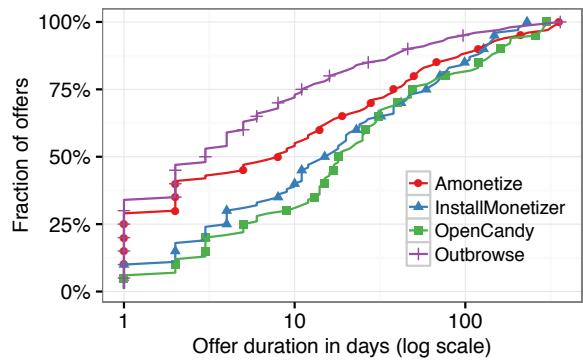

Figure 8: Lifetime of PPI offers. Advertisers run the same offer on OpenCandy and InstallMonetizer for a median of 15 days, while Amonetize and Outbrowse offers quickly churn out of existence to be replaced by new binaries.

et al. as the largest contributors to ad injection in 2014 for Chrome, Firefox, and Internet Explorer [34], we observe six currently in the PPI ecosystem. The companies behind these software products are commercial entities that span the globe: *Wajam* is located in Canada, *Eorezo* is from France, while *Crossrider* originates from Israel. These ad injectors recuperate the initial sunk cost of installs by monetizing users via display ads and shopping helpers until a victim finally uninstalls the injector.

Browser Settings Hijackers: Settings hijackers modify a victim’s default browser behavior, typically to change the default tab or search engine to a property controlled by the hijacker. These companies subsequently monetize victims by selling their traffic to search engines and potentially tracking user behavior. Examples include Conduit Search (e.g., Search Protect) which came pre-installed on Lenovo machines in 2014 [3]. We note that some hijackers also profit by doubling as ad injectors.

System Utilities: System utilities attempt to upsell users using potentially deceptive practices, with some meeting anti-virus definitions of scareware. This category includes “speedup” utilities like *Speedchecker* and *Uniblue* that present nebulous claims such as “Attention! 2203 items are slowing down your PC” or “your system registry health status is dangerous.” These families repeatedly generate pop-up warnings until a victim either pays a subscription fee of \$30–40 or uninstalls the software. This scheme is nearly identical to fake anti-virus, but speedup utilities operate under a veil of legitimacy because they remove files from a client’s machine, thus satisfying some notion of system improvement. Consequently, anti-virus engines do not consider these families to be malicious, only unwanted. Our categorization also includes cloud backup utilities that repeatedly prompt victims to upload their files to the cloud. Adhering to the dialogue requires victims pay a recurring \$120 subscription fee.

All five of the top system utility families are themselves affiliate programs. *Speedchecker* promises affiliates a 30% commission on subscriptions. *Uniblue* advertises a commission of 70%. What emerges is a three-tiered distribution network where system utility affiliates register as advertisers on PPI networks and pay an up-front distribution cost, but reap the commissions on successful subscription conversions. It is also possible that the system utility companies maintain a direct relationship with PPI networks.

Anti-Virus: We observe four anti-virus products distributed via the PPI ecosystem: AVG, LavaSoft, Comodo, and Qihoo. We cannot determine whether these companies directly purchase installs from commercial PPI affiliate networks. We note that all four operate affiliate programs to outsource installs [1, 7, 24, 37]. Assuming all of the installs we observed originate from affiliates, it is unclear how each anti-virus operator polices abuse in the face of an increasingly tangled web of purchased installs and potentially dubious distribution practices. Equally problematic, PPI downloaders simultaneously install these anti-virus products alongside browser settings hijackers and ad injectors—an unenviable user experience.

Major Brands: We observe a small number of major software brands including *Opera*, *Skype*, and browser toolbars distributed via PPI. Based on the affiliate codes embedded in the download URLs for *Opera*, it appears that *Opera* directly interacts with PPI operators to purchase installs rather than relying on intermediate affiliates.¹ The other three programs all operate affiliate pro-

Table 4: Software families with the longest PPI campaigns. We annotate each with the type of software, the days the campaign ran for, the PPI networks involved, and the number of anti-virus engines that flag the family as unwanted. We abbreviate PPI networks as [A]monetize, Open[C]andy, [I]nstallMonetizer, and [O]utbrowse.

grams, yielding a similar distribution pattern to that of anti-virus, though we cannot rule out direct relationships with commercial PPI.

4.3 Long Tail of Campaigns

Outside the top 28 longest running PPI campaigns, a question remains on the mixture of credible and unwanted software that makes up the other 845 short lived campaigns. To explore this, we calculate the fraction of software families distributed per week by commercial PPI where at least one anti-virus engine in VirusTotal flags the family as unwanted. Figure 9 presents our results. On an average week, anti-virus engines label 85% of software families distributed by InstallMonetizer

¹For example, we observe Outbrowse specifically referenced in the target download URL for *Opera*: net.geo.opera.com/opera/

stable?utm_medium=pb&utm_source=outbrowse&utm_campaign=2328

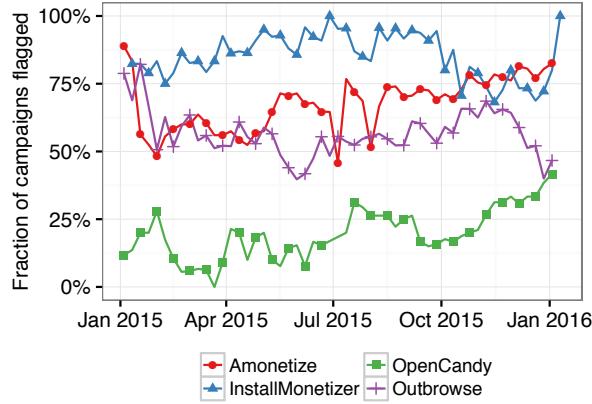

Figure 9: Fraction of software families found each week in PPI networks that were flagged by any anti-virus engine in VirusTotal.

as unwanted, compared to 68% for Amonetize, 57% for Outbrowse, and 20% for OpenCandy. These trends hold true for the entirety of our year-long monitoring. Our findings illustrate that unwanted software dominates both long and short-lived campaigns. The only exception is OpenCandy, which predominantly cultivates advertisers related to games and anti-virus, and to a lesser extent, system utilities and some ad injectors. As a consequence though, OpenCandy has the smallest pool of offers (as discussed previously in Figure 7), while other PPI networks deal with a large number of unwanted software creators and affiliates.

4.4 Contending with Anti-Virus

As discussed in Section 3, each PPI network provides advertisers with a capability to pre-check whether an anti-virus engine is present prior to displaying the advertiser's offer. This pre-check consists of a blacklist of registry keys, file paths, and registry strings specified by the advertiser. We present a sample in Figure 10. To estimate the fraction of offers that take advantage of this capability, we manually collate a list of 58 common anti-virus tokens that appear in a random sample of pre-check requirements, as well as the names of anti-virus companies participating in VirusTotal. We then scanned all offer installation requirements for these tokens.

Of the unique offers in our dataset, 20% take advantage of PPI downloader capabilities that prevent installs from occurring on clients running an anti-virus engine. When anti-virus checks are present, we find advertisers target an average of 3.6 AV families. Our findings suggest that PPI networks support unwanted software developers as first-class partners. We caution our metric is a strict underestimate in the event PPI download-

    "%ProgramFiles%\\Malwarebytes...")

```

Figure 10: Example of anti-virus checks performed by a PPI downloader in order to avoid displaying certain offers to clients running hostile anti-virus engines.

ers scan for side-effects related to anti-virus rather than the exact brand names. We find the most frequently targeted brands include ESET, Avast, AVG, McAfee, Avira, and Symantec. We also observe offers checking for registry keys related to VirtualBox, VMWare, and OpenVPN. There are two possible interpretations of this behavior: advertisers seek to protect themselves from fraudulent installs on virtualized systems; or advertisers actively prevent installations on suspected security testing environments. Given the virtualization checks co-occur with anti-virus evasion, we hypothesize the latter is more likely. Added to our earlier observation that PPI downloaders provide a capability to impose a symptom-free quiet period after installation, a picture emerges of PPI networks actively supporting unwanted software as a first-class partner.

4.5 Regional Pricing Per Install

Far and away, installs from the United States fetch the highest price at roughly \$1.50 each. The United Kingdom is the second most lucrative region at roughly \$0.80 per install. We find that advertisers pay the highest rates for installs from North America, Western Europe, and Japan as shown in Figure 11. Prices outside these regions hover around \$0.02–\$0.10 per install. This holds true throughout the entirety of our investigation as shown in Figure 12 with relatively little volatility in the market. Despite these lower rates, we show in the next Section that commercial PPI impacts clients around the globe.

5 Measuring User Impact

Through Safe Browsing, we estimate the virulent impact that the PPI ecosystem has on end users. Beginning in 2014, Safe Browsing added support to warn users of Chrome and Firefox against downloading PPI-laden

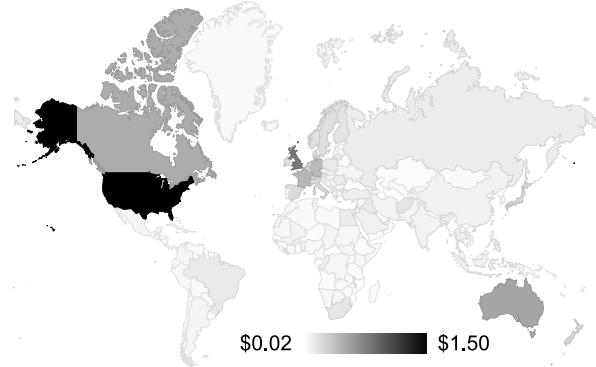

Figure 11: Average price per install across all PPI price monitoring vantage points. Installs from the United States fetch the highest price at \$1.50 each.

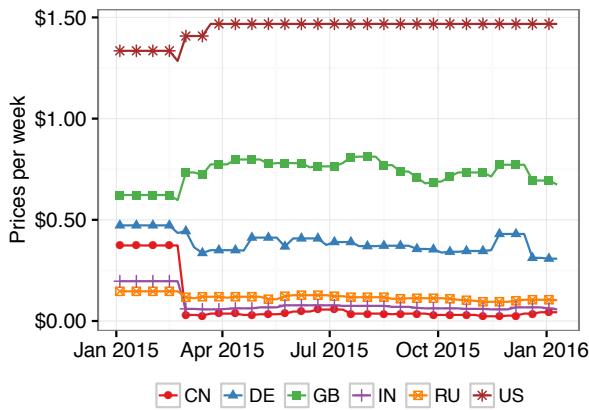

Figure 12: Weekly average price per install for six regions. We observe relatively little volatility for US installs and a slight decline in rates in Europe over time.

software that violates Google’s unwanted software policy [28]. This policy covers a subset of applications flagged by anti-virus engines as unwanted. We map these metrics to the PPI networks we study and find that Safe Browsing generates over 60 million weekly download warnings and browser interstitials. Despite these protections, telemetry Chrome users submit about their systems indicate there are tens of millions of installations of unwanted software, with nearly all of the top families contemporaneously paying for installs.

5.1 Requests for PPI Downloader

We rely on two datasets to estimate the volume of weekly downloads to software monetizing through Amonetize, InstallMonetizer, OpenCandy, and Outbrowse: (1) pings reported by browsers integrated with Safe Browsing for downloaded binaries; and (2) Safe Browsing’s repository of over 75 million binaries (including benign software). When a browser integrated with Safe Browsing fetches a binary from an untrusted source, it generates an API re-

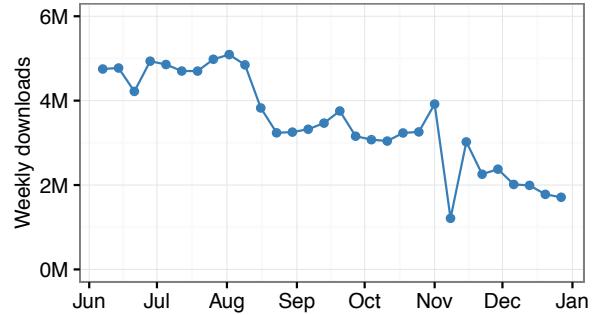

Figure 13: Volume of weekly requests for any of 1.5 million PPI downloaders. We stress this is a lower bound due to missing samples.

quest to Google in order to obtain a verdict for whether the binary is unwanted or malicious. This request contains hosting details about the binary (e.g., URL, IP address) and related metadata including a digest of the binary [27]. In order to map these downloads to digests of known PPI downloaders, we scan Safe Browsing’s repository of dynamic execution traces in search of network requests that match the offer discovery protocol used by each PPI affiliate network (previously discussed in Section 3). From this repository, we identify 1.5 million binaries tied to one of the four PPI networks we study.

We show the total weekly downloads for these 1.5 million binaries between June 1, 2015–January 7, 2016 in Figure 13, irrespective of whether Safe Browsing displayed a warning. We caution these estimates of traffic to PPI networks should serve only as a lower bound as Safe Browsing’s coverage of all possible binaries is incomplete. Similarly, due to Safe Browsing displaying warnings for policy-violating PPI downloaders, operators have an incentive to quickly cycle binaries and hosting pages. Caveats aside, we find publishers for the four PPI networks drive an average of 3.5 million downloads per week, though the volume appears to be in decline. Even as a lower bound, our results illustrate the massive influence that PPI networks have on unwanted software distribution.

5.2 PPI Downloader Warnings

In order to obtain a broader perspective of the entire PPI ecosystem’s impact on end users (not just the four networks we study), we measure the volume of weekly warnings generated by Safe Browsing for PPI downloaders. Users encounter warnings in one of two ways: download warnings that trigger for policy-violating PPI downloaders, and full-page interstitials that appear when users visit websites commonly distributing PPI-laden software. Because affiliate publishers attempt to evade detection (discussed more in Section 6), Safe Browsing

relies on a reputation system called CAMP that builds on incomplete data [29]. The system starts from a seed set of 3 million PPI downloaders that includes samples for all fifteen PPI networks we outlined previously in Section 2. From there, the system scores websites hosting these binaries, common redirect paths, and related binaries. This expands the coverage of sites and binaries involved in pay-per-install, but results in a loss of attribution to individual PPI families. As such, we can only provide an aggregate impact estimate.

We present the volume of PPI downloader warnings and page-level interstitials generated by Safe Browsing between June 1, 2015–January 7, 2016 in Figure 14 and Figure 15 respectively. On an average week, Safe Browsing raises 35 million download warnings and displays 28 million interstitials. Warnings appear as a bursty process, in part due to the arrival of new distribution campaigns and in part due to the ongoing evolutions in the reputation of websites and binaries. In order to place unwanted software in the greater context of threats facing users, we compare the volume of users encountering PPI downloaders versus malware. On average, Safe Browsing raises 13.5 million download warnings and 9 million interstitials to protect users from malware—three times less than that of unwanted software.

The risk of unwanted software is not localized to any single region. We provide a breakdown of the geolocation of users shown a warning related to PPI downloaders in Table 5. We find that Indian users account for 8% of warnings, followed in popularity by Brazil, Vietnam, and the United States. We find no correlation between the price per install and geographic regions with high incident rates. As such, it appears that PPI networks drive installs to any possible user, even when the payout hovers around \$0.10 per install.

5.3 Existing Unwanted Installs

For those PPI downloaders that escape detection and launch on a client’s machine, we estimate the number of users potentially affected. To do this, we tap into metrics kept by the Chrome Cleanup Tool, an opt-in tool that scans a user’s machine for symptoms induced by popular ad injectors, browsing settings hijackers, and system utilities and removes offending programs [5]. Given hundreds of potential unwanted software strains, the tool prioritizes families based on telemetry built into Chrome and system traces supplied by users who file Chrome complaints due to undesirable user experiences. As part of its execution, the tool reports which unwanted software families it identifies as well as those successfully removed. One limitation with the tool is that, for privacy reasons, no unique device identifier is reported per execution. Consequently, if the tool fails to remove a un-

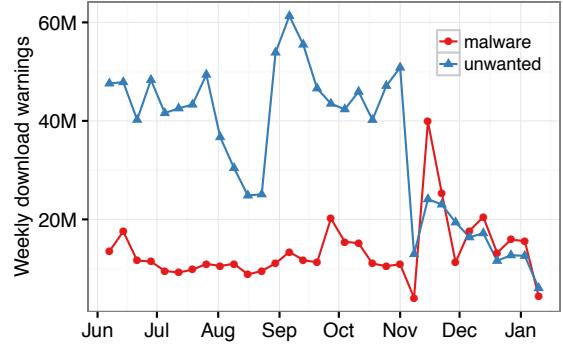

Figure 14: Breakdown of weekly download warnings displayed by Safe Browsing for unwanted software compared to malware. The bursty behavior results from evasion on the part of PPI publishers.

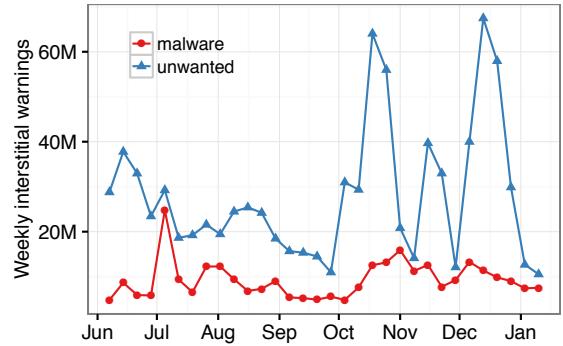

Figure 15: Breakdown of weekly page-level interstitials displayed by Safe Browsing for unwanted software compared to malware. The bursty behavior results from evasion on the part of PPI publishers.

wanted software strain and a user re-runs the tool, they will be counted twice. This may cause us to overestimate the number of infections per family. As the Chrome Cleanup Tool is opt-in, we caution its metrics cover only a subset of all infected machines. While this precludes absolute estimates on the number of unwanted software installs, we can still estimate the relative population of each software family.

Over the last year, the Chrome Cleanup Tool identified *tens of millions* of installations of unwanted software. We present the top 15 most popular strains flagged from January 8, 2015–January 7, 2016 in Table 6. We measure popularity as the total installs per family divided by all known unwanted software installs. To map these families back to the PPI ecosystem, we mark each family known to distribute via any of the four PPI networks we monitor. We arrive at this determination by running the Chrome Cleanup Tool at the completion of the binary execution phase of our analysis pipeline (described in Section 3) to see whether the tool flagged any of the binary’s components.

Country	Frac. Downloads	Price per install
India	8.2%	\$0.09
Brazil	7.2%	\$0.13
Vietnam	6.4%	\$0.06
United States	6.2%	\$1.50
Turkey	5.1%	\$0.11
Thailand	3.3%	\$0.11
Pakistan	3.2%	\$0.08
Mexico	2.6%	\$0.07
Indonesia	2.5%	\$0.09
Philippines	2.5%	\$0.08

Table 5: Top 10 countries receiving the largest volume of Safe Browsing warnings related to unwanted software.

Our results indicate that 14 of the top 15 software families flagged by the Chrome Cleanup Tool simultaneously pay for installs during our monitoring. Conduit, the top family, is a browser settings hijacker that accounts for 20.9% of all unwanted software installs reported by the Chrome Cleanup Tool. Multiplug, the most popular ad injector, accounts for 5.1% of installs. Our results illustrate the virulent affect that unwanted software found in the PPI ecosystem has on end users. We caution we cannot definitively say all of these installs stem from PPI²; there are potentially other sources of installs such as direct downloads via deceptive websites and advertising. However, paired with millions of Safe Browsing warnings for PPI downloaders, we argue that PPI plays a substantial role in unwanted software installation levels.

6 Distribution Techniques

We conclude our investigation with an examination of the affiliates responsible for distributing PPI downloaders, the landing pages they operate, and the deceptive practices that they employ to drive installs.

6.1 Estimating PPI Affiliates

We estimate the number of affiliates participating in Amonetize, InstallMonetizer, OpenCandy, and Outbrowse by scanning for publisher identifiers that each PPI downloader embeds in offer requests for accounting purposes. Based on the dynamic traces of roughly 1.5 million PPI downloaders provided by Safe Browsing (discussed previously in Section 5), we estimate there are 2,518 publishers in the ecosystem, some of which may participate in multiple PPI networks and thus should not be considered unique. We provide a breakdown per PPI network in Table 7. Drawing these estimates into the

²Once a PPI downloader executes, only symptoms related to the bundled advertiser software subsist after the installer completes. The Chrome Cleanup Tool cannot provide us any details for whether unwanted software originated from a PPI downloader.

Unwanted Family	Popularity	PPI Advertiser
<i>Conduit</i>	20.9%	✓
<i>Elex</i>	13.4%	✓
<i>Multiplug</i>	5.1%	✓
<i>Crossrider</i>	4.6%	✓
<i>Browsefox</i>	3.8%	✓
<i>My PC Backup</i>	2.8%	✓
<i>Systweak</i>	2.8%	✓
<i>Mobogenie</i>	2.4%	✓
<i>Smartbar</i>	2.2%	✓
<i>Wajam</i>	1.8%	✓
<i>AnyProtect</i>	1.7%	✓
<i>WinZipper</i>	1.5%	✗
<i>Vopackage</i>	1.2%	✓
<i>ShopperPro</i>	1.2%	✓
<i>Vitruvian</i>	1.1%	✓
Other families	33.5%	—

Table 6: Top 15 software families as detected by the Chrome Cleanup Tool on Windows systems. Popularity is the fraction of all known unwanted software installs.

broader context of PPI, we find a relatively small ecosystem that consists of hundreds of advertisers paying for unwanted software installs that a few thousand publishers distribute. Despite the low number of actors in the space, the end result is still millions of unwanted download attempts on a weekly basis.

6.2 Landing Pages

In order to drive installs, PPI affiliates must present content that either entices or deceives a victim into downloading and executing a PPI downloader. We obtain a sample of these *landing pages* from Safe Browsing which monitors the entire redirect chain behind unwanted software delivery [27]. However, for privacy reasons, our analysis is restricted to a two week period after which these fine-grained details disappear. In total, we sample the top 15,000 most visited landing pages from January 18–February 1, 2016 that direct to one of the four PPI downloaders we monitor. The sites topping this list include large software companies like *utorrent.com*, *bittorrent.com*, and *savefrom.com* (a YouTube downloading service); download portals like *filehippo.com*; and video and media torrent sites like *thepiratebay.se* that display deceptive ads that in fact link to PPI downloaders.

In order to gain a perspective of the category of sites involved in PPI distribution, we crawl all of the landing pages in our sample and supply the non-HTML formatted text to a topic modeling algorithm similar to Gensim’s implementation of LDA [13]. We present the top 10 topics in Table 8, covering 53.6% of all sampled land-

PPI Network	Binary Samples	Affiliates
<i>Outbrowse</i>	1,182,910	1,106
<i>Amonetize</i>	237,660	420
<i>OpenCandy</i>	43,677	747
<i>InstallMonetizer</i>	22,879	245
Total	1,487,126	2,518

Table 7: Estimate of unique affiliates per PPI network. These affiliates drive millions of weekly downloads to PPI networks.

ing pages. Users searching for freeware, video games, torrents, cracks, and even anti-virus are highly likely to encounter PPI downloaders. Most of these sites (58%) cater to an English audience, followed in popularity by Russian (10%). Our results illustrate that popular download portals (or their contributors) fuel a large segment of unwanted software distribution, in turn receiving a kick-back from PPI networks.

6.3 Distribution Pages

After a victim engages with a landing page, PPI affiliates redirect the victim to a *distribution page* that hosts the PPI downloader. This site may be operated by the affiliate or directly by the PPI network, with flavors varying per PPI network. We find that PPI operators rapidly churn through distribution pages, likely to avoid unwanted software warnings from Safe Browsing due to an increasingly negative reputation. During the eight months from June 1, 2015–January 7, 2016, we observed 191,372 distribution pages involved in hosting PPI downloaders. We estimate the lifetime of these pages by measuring the time between the first client that reports a download attempt to Safe Browsing and the last reported download attempt, irrespective of Safe Browsing raising a warning. We find the median lifetime of an Amonetize distribution page is 7 hours, compared to 0.75 hours for Outbrowse. These two stand in contrast to InstallMonetizer and OpenCandy, where distribution pages remain operational for a median of 152 days and 220 days (the entire monitoring window) respectively. This longer lifetime results in part from Safe Browsing not warning on all OpenCandy installs as they do not fall under Google’s unwanted software policy, and in part due to Outbrowse and Amonetize controlling distribution pages, simplifying the process of churning through domains.

6.4 Evasion & Cloaking

Even if PPI operators rapidly cycle through distribution pages, there is a risk that Safe Browsing will scan and detect the PPI downloader itself. We find anecdotal evidence that PPI networks work to actively evade this scanning process. For example, when Safe Browsing first launched its unwanted software detection, it cov-

Site Category	Fraction of Sites
Freeware & Shareware	11.8%
Video Games	10.6%
File Sharing & Hosting	7.3%
Online Video	7.0%
Operating Systems	4.3%
Mobile Apps & Add-Ons	3.7%
Hacking & Cracking	2.7%
Photo & Video Software	2.3%
Game Cheats & Hints	2.1%
Antivirus & Malware	1.9%
Other	46.4%

Table 8: Categorization of the top 15,000 pages driving traffic to PPI downloaders based on topic modeling.

ered only executable files. Shortly after, PPI networks switched to distributing .zip compressed binaries to avoid scanning. When Safe Browsing expanded its scanning coverage, PPI networks moved to more esoteric compression formats including .rar and .ace or doubly compressed files. We also observed PPI networks exploiting a limitation in Chrome, where files downloaded through Flash were not subject to Safe Browsing scans. After a recent Chrome patch to address this, PPI networks switched to password protecting their compressed files, providing instructions for victims on how to access the contents. We provide screenshots of each of these techniques in action in the Appendix. This arms race illustrates that PPI networks opt to actively circumvent user protections rather than ceasing to distribute harmful unwanted software. This behavior likely stems from an incentive structure within PPI where remaining profitable entails racing to the bottom of deceptive install tactics.

6.5 Promotional Tools

For affiliates that do not operate download portals or peer to peer sharing sites, PPI resellers provide deceptive “promotional tools” that socially engineer web visitors into running PPI downloaders. These tools fall into four flavors: butterbars, ad banners, landing pages, and content unlockers.

Butterbars: PPI resellers like NetCashRevenue provide a JavaScript stub to website operators that generates a yellow bar at the top of a page alerting a victim that their “Flash player is out of date!”. This bar can either initiate an auto-download upon visiting the page, or require a victim to click. Either way, the victim receives a PPI downloader.

Content Lockers: Content lockers present victims with an enticing video, song, or PDF. In order to view this content however, a victim must first install a “codec” that

is in fact a PPI downloader. Resellers simplify this process by providing a drop-in script that handles spoofing a fake video player and codec alert.

Ad banners & Landing Pages: Resellers will provide webmasters with ad banners or entire customized landing pages that spoof popular software downloads including uTorrent, Java, Flash, and Firefox that are in fact PPI downloaders.

These techniques highlight that even if the software delivered by a PPI downloader appears benign, the distribution practices of affiliates add an additional layer into the determination of whether software is ultimately unwanted. Consequently, advertisers, publishers, and PPI networks all bear responsibility for the current state of commercial pay-per-install and its ties to unwanted software.

7 Related Work

Blackmarket Pay-Per-Install: Our work is influenced in part by prior explorations of the blackmarket pay-per-install ecosystem that sells access to compromised hosts. Industry reports initially qualitatively described these underground markets as early as 2009 [10,33]. Caballero *et al.* performed the first in-depth investigation by infiltrating the markets and tracking the malware families paying for installs [4]. Prices per install ranged from \$0.02–\$0.18, an order of magnitude less than the prices we observed for commercial PPI. These low rates make blackmarket PPI a better bargain for malware distribution over commercial PPI, though evidence exists of cross-over, such as the commercial PPI network iBarrio recently distributing Sefnit [35]. Other studies have explored the relationships between blackmarket PPI networks and particular malware families [23, 30]. However, all of these studies were limited to establishing a link between the most notorious malware families and their simultaneous distribution in blackmarket PPI; none determined whether PPI was the primary distribution mechanism (as opposed to social engineering or drive-by). Our study went one step further, establishing the volume of weekly download attempts to commercial PPI downloaders.

Unwanted Software: Unwanted software is not a new threat. In 2004, Saroiu *et al.* found at least 5% of computers connected to the University of Washington’s campus network were infected with some form of spyware [32]. In 2005, Edelman tracked multiple purported spyware and adware companies including Claria, WhenU, and 180Solutions to identify their deceptive installation methods and their monetization model [11, 12]. More recently, Thomas *et al.* found that 5% of unique IPs accessing Google websites exhibited symptoms of

ad injection [34], while Jagpal *et al.* identified millions of browsers laden unwanted extensions performing ad injection, search hijacking, and user tracking [17]. Researchers have also explored some of the distribution techniques involved. In 2006, Moshchuk *et al.* crawled and analyzed 21,200 executables from the Internet and found 13.4% contained spyware [25]. Kammerstetter *et al.* repeated a similar study limited to sites purportedly hosting cracks and key generators, though they found the majority bundled malware, not unwanted software [19]. Our work explored the commercialization of these distribution practices as simplified by commercial pay-per-install affiliate networks.

More recently, Kotzias *et al.* explored code-signing techniques of unwanted software that may lead to reduced detection [21]. We rely on a similar technique for clustering advertiser binaries, though we note that only 58% of the 1,809 unique offer digests we identified contained a signature; similarly, only 50% of 1.5 million PPI downloaders distributed by publishers contained a signature. This may lead to a bias in analysis that focus solely on signed unwanted software. Contemporaneous with our own study, Kotzias *et al.* explored the download graph of unwanted software via Symantec’s WINE database and identified 54% of users were affected by unwanted software [20]. Similarly, Nelms *et al.* explored the role of deceptive advertising in enticing victims into running PPI downloaders [26]. Combined with our own work, these three studies present a broad perspective of the number of users affected by unwanted software, an insider perspective of how advertisers, affiliate networks, and publishers coordinate, and the deceptive practices used to entice downloads via advertisements or free software sites.

8 Conclusion

Our work presented the first deep dive into the business practices underpinning the commercial pay-per-install ecosystem that sells access to user systems for prices ranging from \$0.10–\$1.50 per install. Our study illustrated that PPI affiliate networks supported and distributed unwanted software ranging from ad injectors, browser settings hijackers, and system utilities—many of the top families that victims proactively purge from their machines with the aid of the Chrome Cleanup Tool. In aggregate, the PPI ecosystem drove over 60 million weekly download attempts, with tens of million installs detected in the last year. As anti-virus and browsers move to integrate signatures of unwanted software into their malware removal tools and warning systems, we showed evidence that commercial PPI networks actively attempted to evade user protections in order to sustain their business model. These practices demonstrate that

PPI affiliate networks operated with impunity towards the interests of users, relying on a user consent dialogue to justify their actions—though their behaviors may have changed since the conclusion of our study. We hope that by documenting these behaviors the security community will recognize unwanted software as a major threat—one that affects three times as many users as malware.

In response to deceptive behaviors within the commercial PPI ecosystem, members of the anti-virus industry, software platforms, and parties profiting from commercial PPI have formed the Clean Software Alliance [6]. The consortium aims to “champions sustainable, consumer-friendly practices within the software distribution ecosystem.” This includes defining industry standards around deceptive web advertisements, user consent, software functionality disclosure, and software uninstallation. These goals reflect a fundamental challenge of protecting users from unwanted software: it takes only one deceptive party in a chain of web advertisements, publishers, affiliate networks, and advertisers for abuse to manifest. It remains to be seen whether the approach taken by the Clean Software Alliance will yield the right balance between software monetization and user advocacy.

Acknowledgments

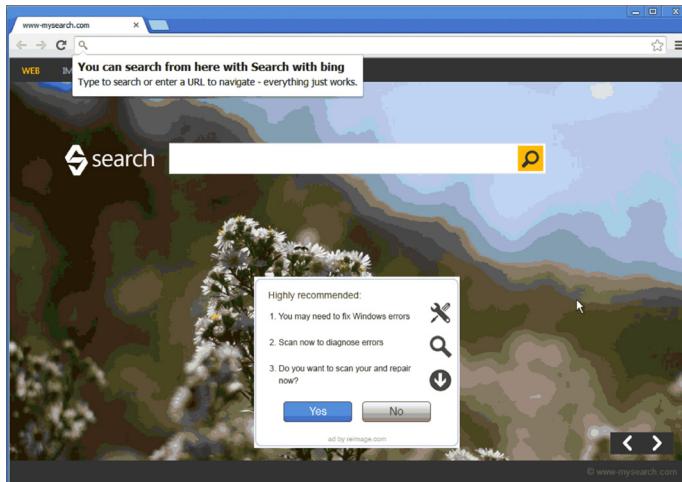

We thank the Safe Browsing and Chrome Security team for their insightful feedback in the development of our study on unwanted software and pay-per-install. Abstract

Potentially unwanted programs (PUP) such as adware and rogueware, while not outright malicious, exhibit intrusive behavior that generates user complaints and makes security vendors flag them as undesirable. PUP has been little studied in the research literature despite recent indications that its prevalence may have surpassed that of malware.

In this work we perform the first systematic study of PUP prevalence and its distribution through pay-per-install (PPI) services, which link advertisers that want to promote their programs with affiliate publishers willing to bundle their programs with offers for other software. Using AV telemetry information comprising of 8 billion events on 3.9 million real hosts during a 19 month period, we discover that over half (54%) of the examined hosts have PUP installed. PUP publishers are highly popular, e.g., the top two PUP publishers rank 15 and 24 amongst all software publishers (benign and PUP). Furthermore, we analyze the who-installs-who relationships, finding that 65% of PUP downloads are performed by other PUP and that 24 PPI services distribute over a quarter of all PUP. We also examine the top advertiser programs distributed by the PPI services, observing that they are dominated by adware running in the browser (e.g., toolbars, extensions) and rogueware. Finally, we investigate the PUP-malware relationships in the form of malware installations by PUP and PUP installations by malware. We conclude that while such events exist, PUP distribution is largely disjoint from malware distribution.

1 Introduction

Potentially unwanted programs (PUP) are a category of undesirable software that includes adware and rogue

software (i.e., rogueware). While not outright malicious (i.e., malware), PUP behaviors include intrusive advertising such as ad-injection, ad-replacement, pop-ups, and popunders; bundling programs users want with undesirable programs; tracking users' Internet surfing; and pushing the user to buy licenses for rogueware of dubious value, e.g., registry optimizers. Such undesirable behaviors prompt user complaints and have led security vendors to flag PUP in ways similar to malware.

There exist indications that PUP prominence has quickly increased over the last years. Already in Q2 2014, AV vendors started alerting of a substantial increase in collected PUP samples [59]. Recently, Thomas et al. [64] showed that ad-injectors, a popular type of PUP that injects advertisements into user's Web surfing, affects 5% of unique daily IP addresses accessing Google [64]. And, Kotzias et al. [35] measured PUP steadily increasing since 2010 in (so-called) malware feeds, to the point where nowadays PUP samples outnumber malware samples in those feeds. Still, the prevalence of PUP remains unknown.

A fundamental difference between malware and PUP is distribution. Malware distribution is dominated by *silent* installation vectors such as drive-by downloads [22, 53], where malware is dropped through vulnerability exploitation. Thus, the owner of the compromised host is unaware a malware installation happened. In contrast, PUP does not get installed silently because that would make it malware for most AV vendors. A property of PUP is that it is installed with the consent of the user, who (consciously or not) approves the PUP installation on its host.

In this work, we perform the first systematic study of PUP prevalence and its distribution through pay-per-install (PPI) services. PPI services (also called PPI net-

works) connect advertisers willing to buy installs of their programs with affiliate publishers selling installs. The PPI services used for distributing PUP are disjoint from silent PPI services studied by prior work [7]. Silent PPI services are exclusively used for malware distribution, while the PPI services we study are majoritarily used for distributing PUP and benign software. In the analyzed PPI services, an affiliate publisher owns an original program (typically freeware) that users want to install. To monetize installations of its free program, the affiliate publisher bundles (or replaces) it with an installer from a PPI service, which it distributes to users looking for the original program. During the installation process of the original program, users are prompted with offers to also install other software, belonging to advertisers that pay the PPI service for successful installs of their advertised programs.

To measure PUP prevalence and its distribution through PPI services we use AV telemetry information comprising 8 billion events on 3.9 million hosts during a 19 month time period. This telemetry contains events where parent programs installed child programs and we focus on events where the publishers of either parent or child programs are PUP publishers. This data enables us to measure the prevalence of PUP on real hosts and to map the who-installs-who relationships between PUP publishers, providing us with a broad view of the PUP ecosystem.

We first measure PUP prevalence by measuring the installation base of PUP publishers. We find that programs from PUP publishers are installed in 54% of the 3.9M hosts examined. That is, more than half the examined hosts have PUP. We rank the top PUP publishers by installation base and compare them with benign publishers. The top two PUP publishers, both of them PPI services, are ranked 15 and 24 amongst all software publishers (benign or not). The top PUP publisher is more popular than NVIDIA, a leading graphics hardware manufacturer. The programs of those two top PUP publishers are installed in 1M and 533K hosts in our AV telemetry dataset, which we estimate to be two orders of magnitude higher when considering all Internet-connected hosts. We estimate that each top 20 PUP publisher is installed on 10M–100M hosts.

We analyze the who-installs-who relationships in the publisher graph to identify and rank top publishers playing specific roles in the ecosystem. This enables us to identify 24 PPI services distributing PUP in our analyzed time period. We also observe that the top PUP advertisers predominantly distribute browser add-ons involved

in different types of advertising and by selling software licenses for rogueware. We measure PUP distribution finding that 65% of PUP downloads are performed by other PUP, that the 24 identified PPI services are responsible for over 25% of all PUP downloads, and that advertiser affiliate programs are responsible for an additional 19% PUP downloads.

We also examine the malware-PUP relationships, in particular how often malware downloads PUP and PUP downloads malware. We find 11K events (0.03%) where popular malware families install PUP for monetization and 5,586 events where PUP distributes malware. While there exist cases of PUP publishers installing malware, PUP–malware interactions are not prevalent. Overall, it seems that PUP distribution is largely disjoint from malware distribution. Finally, we analyze the top domains distributing PUP, finding that domains from PPI services dominate by number of downloads.

Contributions:

- We perform the first systematic study of PUP prevalence and its distribution through PPI services using AV telemetry comprising 8B events on 3.9M hosts over a 19-month period.
- We measure PUP prevalence on real hosts finding that 54% have PUP installed. We rank the top PUP publishers by installation base, finding that the top two PUP publishers rank 15 and 24 amongst all (benign and PUP) software publishers. We estimate that the top 20 PUP publishers are each installed on 10M–100M hosts.
- We build a publisher graph that captures the who-installs-who relationships between PUP publishers. Using the graph we identify 24 PPI services and measure that they distribute over 25% of the PUP.
- We examine other aspects of PUP distribution including downloads by advertiser affiliate programs, downloads of malware by PUP, downloads of PUP by malware, and the domains from where PUP is downloaded. We conclude that PUP distribution is largely disjoint from malware distribution.

2 Overview and Problem Statement

This section first introduces the PPI ecosystem (Section 2.1), then details the datasets used (Section 2.2), and finally describes our problem and approach (Section 2.3).

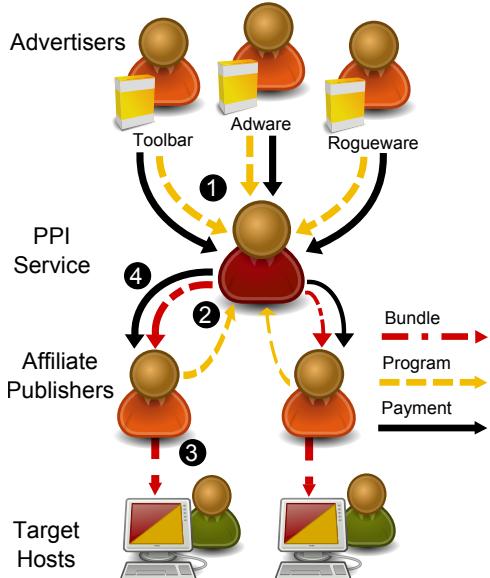

Figure 1: Typical transactions in the PPI market. (❶) Advertisers provide software they want to have installed, and pay a PPI service to distribute it. (❷) Affiliate publishers register with the PPI service, provide their program, and receive a bundle of their program with the PPI installer. (❸) Affiliate publishers distribute their bundle to target users. (❹) The PPI service pays affiliate publishers a bounty for any successful installations they facilitated.

2.1 Pay-Per-Install Overview

The PPI market, as depicted in Figure 1, consists of three main actors: *advertisers*, *PPI services/networks*, and *affiliate publishers*. *Advertisers* are entities that want to install their programs onto a number of target hosts. They wish to *buy installs* of their programs. The PPI service receives money from advertisers for the service of installing their programs onto the target hosts. They are called advertisers because they are willing to pay to promote their programs, which are offered to a large number of users by the PPI service. Advertiser programs can be benign, potentially unwanted (PUP), and occasionally malware.

Affiliate publishers are entities that *sell installs* to PPI services. They are often software publishers that own programs (e.g., freeware) that users may want to install, and who offer the advertiser programs to those users installing their programs. This enables affiliate publishers to monetize their freeware, or to generate additional income on top of the normal business model of their programs. They can also be website owners that offer visi-

Country	Avg	Range
United States	\$1.30	\$0.70-\$2.00
United Kingdom	\$0.80	\$0.40-\$1.50
Australia	\$0.40	\$0.30-\$0.50
Canada	\$0.40	\$0.30-\$0.50
France	\$0.28	\$0.15-\$0.50
Germany	\$0.25	\$0.10-\$0.40
New Zealand	\$0.23	\$0.15-\$0.35
Ireland	\$0.19	\$0.15-\$0.25
Denmark	\$0.18	\$0.15-\$0.20
Austria	\$0.16	\$0.15-\$0.20
Netherlands	\$0.16	\$0.10-\$0.20
Finland	\$0.15	\$0.10-\$0.20
Norway	\$0.15	\$0.05-\$0.20
Switzerland	\$0.12	\$0.03-\$0.20
Spain	\$0.11	\$0.03-\$0.20

Table 1: Top 15 countries with the highest average price per install collected from 3 PPI services [8, 9, 50] on June 2016.

tors to download an installer from the PPI service, thus selling installs on the visitor’s machines. Affiliate publishers are often referred simply as publishers, but we use publishers to refer to software owners, and affiliate publishers for those signing up to PPI services.

The PPI service acts as a middle man that buys installs from affiliate publishers and sells installs to advertisers. The PPI service credits the affiliate publisher a *bounty* for each confirmed installation, i.e., affiliate displays an offer for an advertised program *and* the user approves and successfully installs the advertised program.

Affiliate publishers are paid between \$2.00 and \$0.01 per install depending on the geographic location. Prices vary over time based on offer and demand and the current price is typically only available to registered affiliate publishers. Table 1 shows the prices paid to affiliate publishers for the most demanded countries on June 25th, 2016 by 3 PPI services that publicly list their prices to attract affiliate publishers. The highest paid country is the United States with an average install price of \$1.30, followed by the United Kingdom (\$0.80), Australia and Canada (\$0.40), and European countries starting at \$0.30 for France. The cheapest installs are \$0.03–\$0.01 for Asian and African countries (typically part of a “Rest of the World” region). In comparison, prices paid to affiliate publishers by silent PPI services that distribute malware range \$0.18–\$0.01 per install [7]. This shows that malware distribution can be an order of magnitude cheaper for the most demanded countries.

A common PPI model (depicted in Figure 1) is that the affiliate publisher provides the PPI service with its program executable and the PPI service *wraps* (i.e., bundles) the affiliate’s program with some *PPI installer* software, and returns the bundle/wrapper to the affiliate publisher. The affiliate publisher is then in charge of distributing the bundle to users interested in the affiliate’s program. The distribution can happen through different vectors such as websites that belong to the affiliate publisher or uploading the bundle to *download portals* such as Download.com [15] or Softonic [61]. When a user executes the wrapper, the wrapper installs the affiliate’s program and during this installation it offers the user to install other advertised programs. If the user downloads and installs one of the offers, the PPI service pays a bounty to the affiliate’s account.

An affiliate publisher can register with a PPI service even if it does not own programs that users want to install. Some PPI services look for affiliate website owners whose goal is to convince visitors of their websites to download and run an installer from the PPI service. Furthermore, some PPI services offer a *pre-wrapped software* model where the PPI service wraps its own software titles with the advertiser offers, and provides the bundle to the affiliate publishers [29]. Some PPI services even allow affiliate publishers to monetize on third-party free programs (e.g., GNU).

Some download portals such as Download.com run their own PPI service. When publishers upload their programs to the portal (e.g., through Upload.com) they are offered if they want to monetize their programs. If so, the download portal wraps the original program and makes the bundle available for download. In this model the download portal is in charge of distribution.

Another distribution model are *affiliate programs* where an advertiser uses affiliate publishers to distribute its software directly, without a PPI service. This is a one-to-many distribution model, in contrast with the many-to-many distribution model of PPI services.

2.2 Datasets

Our paper leverages several datasets to conduct a systematic investigation about PUP prevalence and distribution. We analyze WINE’s binary downloads dataset [16] to trace PUP installations by real users and their parent/child (downloader/downloadee) relationships, the list of signed malicious executables from the Malsign project [35] to cluster together executables signed by different signers that belong to the same publisher,

Dataset	Data	Count
WINE	Events Analyzed	8 B
01/2013 – 07/2014	Events with Parent	90 M
	Total number of Machines	3.9 M
	All Files	2.6 M
	Parent Files	657 K
	Child Files	2 M
	Signed Files	982 K
	Publishers	6 K
	Parent Publishers	1.4 K
	Child Publishers	6 K
	Events with URL	1.1 M
	URLs	290 K
	FQDNs	13.4 K
	ESLDs	7.5 K
Malsign	Signed executables	142 K
VirusTotal	Reports	12 M
	Feed Reports	11 M
	WINE Reports	1.1 M
	Malsign Reports	142 K

Table 2: Summary of datasets used.

and VirusTotal [67] reports for enriching the previous datasets with additional file meta-data (e.g., AV detections, file certificates for samples not in Malsign). Table 2 summarizes these datasets.

WINE. The Worldwide Intelligence Network Environment (WINE) [17] provides researchers a platform to analyze data collected from Symantec customers that opt-in to the collection. This data consists of anonymous telemetry reports about security events (e.g., AV detections, file downloads) on millions of real computers in active use around the world.

In this work, we focus on the *binary downloads* dataset in WINE, which records meta-data about all executable files (e.g., EXE, DLL) and compressed archives (e.g., ZIP, RAR, CAB) downloaded by Windows hosts regardless if they are malicious or benign. Each *event* in the dataset can correspond to (1) a download of an executable file or compressed archive over the network, or (2) the extraction of a file from a compressed archive. For our work, we analyze the following fields: the server-side timestamp of the event, the unique identifier for the machine where the event happens, the SHA256 hash of the child file (i.e., downloaded or extracted), the SHA256 hash of the parent process (i.e., downloader program or decompressing tool), the certificate subject for the parent and child files if they are signed, and, when available, the URL from where the child file was downloaded. The files themselves are not included in the dataset.

We focus our analysis on the 19 months between January 1st 2013 and July 23rd 2014. As our goal is to analyze PUP (i.e., executables from PUP publishers), we only monitor the downloads of PUP and the files that are downloaded by PUP, i.e., events where either the child or the parent is PUP. This data corresponds to 8 billion events. The details of the data selection methodology are explained in Section 3. Out of 8 B events, 90 M events have information about the parent file that installed the PUP. Those events comprise 2.6 M distinct executables out of which 982 K (38%) are signed by 6 K publishers.

A subset of 1.1 M events provide information about the URL the child executable was downloaded from. These events contain 290 K unique URLs from 13.4 K fully qualified domain names (FQDNs). To aggregate the downloads initiated from the same domain owner, we extract the effective second-level domain (ESLD) from the FQDN. For example, the ESLD of `www.google.com` is the 2LD `google.com`, however, the ESLD of `www.amazon.co.uk` is the 3LD `amazon.co.uk` since different entities can request `co.uk` subdomains. We extract the ESLDs of the domains by consulting Mozilla’s public suffix list [54].

Malsign. To cluster executables in the WINE binary downloads dataset signed by different entities that belong to the same publisher, we leverage a dataset of 142 K signed malware and PUP from the Malsign project [35]. This dataset includes the samples and their clustering into families. The clustering results are based on statically extracted features from the samples with a focus on features from the Windows Authenticode signature [39]. These features include: the leaf certificate hash, leaf certificate fields (i.e., public key, subject common name and location), the executable’s hash in the signature (i.e., Authentihash), file metadata (i.e., publisher, description, internal name, original name, product name, copyright, and trademarks), and the PEhash [68]. From the clustering results we extract the list of publisher names (subject common name in the certificates) in the same cluster, which should belong to the same publisher.

VirusTotal. VirusTotal [67] is an online service that analyzes files and URLs submitted by users. One of its services is to scan the submitted binaries with anti-virus products. VirusTotal also offers a web API to query meta-data on the collected files including the AV detection rate and information extracted statically from the files. We use VirusTotal to obtain additional meta-data about the WINE files, as well as from 11 M malicious/undesirable executables from a feed. In particular, we obtain: AV detection labels for the sample, first seen

timestamp, detailed certificate information, and values of fields in the PE header. This information is not available otherwise as we do not have access to the WINE files that are not in Malsign, but we can query VirusTotal using the file hash. We consider that a file is malicious if at least 4 AV engines in the VT report had a detection label for it, a threshold also used in prior works to avoid false positives [35].

2.3 Problem Statement

In this paper we conduct a systematic analysis of PUP prevalence and its distribution through PPI services. We split our measurements in two main parts. First, we measure how prevalent PUP is. This includes what fraction of hosts have PUP installed, which are the top PUP publishers, and what is the installation base of PUP publishers in comparison with benign publishers. Then, we measure the PPI ecosystem including who are the top PPI services and PUP advertisers, what percentage of PUP installations are due to PPI services and advertiser affiliate programs, what are the relationships between PUP and malware, and what are the domains from where PUP is downloaded.

We do not attempt to differentiate what behaviors make a program PUP or malware, but instead rely on AV vendors for this. We leverage the prior finding that the majority of PUP (and very little malware) is properly signed. In particular, signed executables flagged by AV engines are predominantly PUP, while malware rarely obtains a valid code signing chain due to identity checks implemented by CAs [35]. Using that finding, we consider PUP any signed file flagged by at least 4 AV engines. Thus, the term PUP in this paper includes different types of files that AV vendors flag as PUP including undesirable advertiser programs, bundles of publisher programs with PPI installers, and stand-alone PPI installers.

To measure PUP prevalence, we first identify a list of dominant PUP publishers extracted from the code signing certificates from the 11M VT reports from the malware feed (Section 3). Then, we group publisher names (i.e., subject strings in code signing certificates) from the same entity into publisher clusters (Section 4). Finally, we use the WINE binary reputation data to measure the PUP installation base, as well as the installation base of individual PUP and benign publisher clusters (Section 5). Since we focus on signed executables, our numbers constitute a lower bound on PUP and publisher prevalence.

To measure the PPI ecosystem, we build a publisher graph that captures the who-installs-who relationships

among PUP publishers. We use the graph for identifying PPI services and PUP advertisers (Section 6). Then, we measure the percentage of PUP installations due to PPI services and advertiser affiliate programs (Section 7). Next, we analyze the downloads of malware by PUP and the downloads of PUP by malware (Section 8). Finally, we examine the domains from where PUP is downloaded (Section 9).

3 Identifying PUP Publishers

The first step in our approach is to identify a list of dominant PUP publishers. As mentioned earlier, prior work has shown that signed executables flagged by AV engines are predominantly PUP, while malware is rarely properly signed. Motivated by this finding, we identify PUP publishers by ranking publishers of signed binaries flagged by AV vendors, by the number of samples they sign.

For this, we obtain a list of 11M potentially malicious samples from a “malware” feed and query them in VirusTotal to collect their VT reports. From these reports, we keep only executables flagged by at least 4 AV vendors to make sure we do not include benign samples in our study. We further filter out executables with invalid signatures, i.e., whose publisher information cannot be trusted. These filtering steps leave us with 2.5M binaries whose signatures validated at the time of signing. These include executables whose certificate chain still validates, those with a revoked certificate, and those with expired certificates issued by a valid CA.

From each of the 2.5M signed executables left, we extract the publisher’s subject common name from the certificate information in its VT report. Hereinafter, we will refer to the publisher’s subject common name as publisher name. Oftentimes, publisher names have some variations despite belonging to the same entity. For example, MyRealSoftware could use both “MyRealSoftware S.R.U” and “MyRealSoftware Inc” in the publisher name. Thus, we perform a normalization on the publisher names to remove company suffixes such as Inc., Ltd. This process outputs a list of 1,440 normalized PUP publisher names. Table 11 in the Appendix shows the top 20 normalized PUP publisher names by number of samples signed in the feed. These 20 publishers own 56% of the remaining signed samples after filtering.

Clearly, our list does not cover all PUP publishers in the wild. This would not be possible unless we analyzed all existing signed PUP. However, the fact that we analyze 2.5M of undesirable/malicious signed samples gives us confidence that we cover the top PUP publishers.

Those 1,440 PUP publisher names are used to scan the file publisher field in WINE’s binary downloads dataset to identify events that involve samples from those PUP publishers, i.e., where a parent or child file belongs to the 1,440 PUP publishers. As shown in Table 2, there are 8 B such events.

Note that at this point we still do not know whether different publisher names (i.e., entries in Table 11) belong to the same PUP publisher. For example, some popular publisher names such as Daniel Hareuveni, Stepan Rybin, and Stanislav Kabin are all part of Web Pick Internet Holdings Ltd, which runs the InstalleRex PPI service. The process to cluster publisher names that belong to the same publisher is described in Section 4.

4 Clustering Publishers

PUP authors use certificate polymorphism to evade detection by certification authorities and AV vendors [35]. Two common ways to introduce certificate polymorphism are applying small variations to reuse the same identity / publisher name (e.g. apps market ltd, APPS Market Inc., Apps market Incorporated) and using multiple identities (i.e., companies or persons) to obtain code signing certificates. We cluster publisher names that belong to the same publisher according to similarities on the publisher names, domain names in events with URLs, and Malsign clustering results.

Publisher name similarity. This feature aims to group together certificates used by the same identity that have small variations on the publisher name. Since the WINE binary downloads dataset contains the publisher name for parent and child files, this feature can be used even when a signed sample has no VT report and we do not have the executable (i.e., not in Malsign). The similarity between two publisher names is computed in two parts: first derive a list of normalized tokens from each publisher name through four steps and then compute similarity between the token lists.

To obtain the token list of a publisher name, the first step is to extract parenthesized strings as separate tokens. For example, given the publisher name “Start Playing (Start Playing (KnockApps Limited))” this step produces 3 tokens: “Start Playing”, “Start Playing”, and “KnockApps Limited”. The second step converts each token to lowercase and removes all non-alphanumeric characters from the token. The third step removes from the tokens company extensions (e.g., ltd, limited, inc, corp), geographical locations (e.g., countries, cities), and the string

Publishers	Clusters	Singletons	Largest	Median
6,066	5,074	4,534	103	1

Table 3: Publisher clustering results.

“Open Source Developer”, which appears in code signing certificates issued to individual developers of open source projects. Finally, tokens that have less than 3 characters and duplicate tokens are removed.

To compute the similarity between two token lists, for each pair of publisher names P_1 and P_2 , we calculate the normalized edit distance among all token pairs (t_i, t_j) where t_i belongs to P_1 and t_j to P_2 . If the edit distance between P_1 and P_2 is less than 0.1, we consider these two publishers to be the same. We selected this threshold after experimenting with different threshold values over 1,157 manually labeled publisher names. The edit distance threshold of 0.1 allowed us grouping the 1,157 publisher names into 216 clusters with 100% precision, 81.9% recall, and 86.4% F1 score.

Child download domains. If child executables signed by different publisher names are often downloaded from the same domains, that is a good indication that the publisher names belong to the same entity. To capture this behavior, we compute the set of ESLDs from where files signed by the same publisher name have been downloaded. Note that we exclude ESLDs that correspond to file lockers and download portals as they are typically used by many different publishers. The publisher names whose Jaccard Index of their ESLD sets is over 0.5 are put to the same cluster.

Parent download domains. Similarly, if parent files signed by different publisher names download from a similar set of domains, this indicates the publisher names likely belong to the same entity. This feature first computes the set of ESLDs from where parent files signed by the same publisher name download (excluding file lockers and download portals). Publisher names whose Jaccard Index is over 0.5 are put to the same cluster.

Malsign clustering. For each Malsign cluster we extract the list of distinct publisher names used to sign executables in the cluster, i.e., Subject CN strings extracted from certificates for files in the cluster. We consider that two publisher names in the same Malsign cluster belong to the same publisher.

Final clustering. We group publisher names into the same cluster if they satisfy at least one of the first 3 features explained above or are in the same Malsign cluster. Table 3 summarizes the clustering, which produces 5,074 clusters from 6,066 publisher names.

5 PUP Prevalence

In this Section, we measure the prevalence of PUP, based on the number of hosts in the WINE binary downloads dataset (i.e., WINE hosts) that have installed programs from PUP publishers. We measure the total number of WINE hosts affected by PUP, rank PUP publishers by installation base, and compare the installation base of PUP publishers to benign publishers.

We first compute the *detection ratio* (DR) for each cluster, which is the number of samples signed by publishers in the cluster flagged by at least 4 AVs, divided by the total number of samples in the cluster for which we have a VT report. We mark as PUP those clusters with $DR > 5\%$, a threshold chosen because is the lowest that leaves out known benign publishers. From this point on, when we refer to PUP publishers, we mean the 915 publisher clusters with $DR > 5\%$.

Note that the number of WINE hosts with installed programs from a publisher cluster constitutes a quite conservative lower bound on the number of hosts across the Internet that have programs installed from that publisher. It captures only those Symantec customers that have opted-in to share data and have been sampled into WINE. If we take into account that Symantec only had 8% of the AV market share in January 2014 [47] and that only $\frac{1}{16}$ of Symantec users that opt-in to share telemetry are sampled into WINE [6], we estimate that the number of WINE hosts is two orders of magnitude lower than the corresponding number of Internet-connected hosts. Furthermore, we do not count WINE hosts with only unsigned PUP executables installed.

PUP prevalence. We find 2.1M WINE hosts, out of a total 3.9M WINE hosts in our time period, with at least one executable installed from the 915 PUP clusters. Thus, 54% of WINE hosts have PUP installed. This ratio is a lower bound because we only count signed PUP executables (i.e., we ignore unsigned PUP executables) and also because our initial PUP publisher list in Section 3 may not be complete. Thus, PUP is prevalent: more than half of the hosts examined have some PUP installed.

Top PUP publishers. Table 4 shows the top 20 PUP publishers by WINE installation base and details the cluster name, whether the publisher is a PPI service (this classification is detailed in Section 6), the number of publisher names in the cluster, detection ratio, and host installation base. The number of publishers ranks from singleton clusters up to 48 publishers for IronSource, an Israeli PPI service. The installation bases for the top 20 PUP publishers range from 200K up to over 1M for Pe-

Table 4: Top 20 PUP publishers by installation base.

riion Network, an Israeli PPI service that bought the operations of the infamous Conduit toolbar in 2013. As explained earlier, these numbers are a quite conservative lower bound. We estimate the number of Internet-connected computers for these publishers to be two orders of magnitude larger, in the range of tens of millions, and up to a hundred million, hosts. We have found anecdotal information that fits these estimates. For example, an adware developer interviewed in 2009 claimed to have control over 4M machines [12].

Comparison with benign publishers. Table 5 shows the top 20 publisher clusters, benign and PUP, in WINE. The most common publishers are Microsoft and Symantec that are installed in nearly all hosts. The Perion Network / Conduit PPI network ranks 15 overall. That is, there are only 14 benign software publishers with a larger installation base than the top PUP publisher. Perion Network is more prevalent than well known publishers such as Macrovision and NVIDIA. The second PUP publisher (Mindspark Interactive Network) has the rank 24. This highlights that top PUP publishers are among the most widely installed software publishers.

A reader may wonder if we could also compute the installation base for malware families. Unfortunately, due to malware being largely unsigned and highly polymorphic, we would need to first classify millions of files in WINE (without having access to the binaries) before we can perform the ranking.

#	Cluster	PUP	Hosts

Table 5: Top publishers by install base (benign and PUP).

6 Classifying Publishers

Among the 5,074 PUP publisher clusters obtained in Section 4 we want to identify important clusters playing a specific role in the ecosystem. In particular, we want to identify clusters that correspond to PPI services and to examine the type of programs distributed by the dominant advertisers. For this, we first build a *publisher graph* that captures the who-installs-who relationships. Then, we apply filtering heuristics on the publisher graph to select a subset of publishers that likely hold a specific role, e.g., PPI service. Finally, we manually classify the filtered publishers into roles by examining Internet resources, e.g., publisher web pages, PPI forums, and the Internet Archive [32].

Publisher graph. The publisher graph is a directed graph where each publisher cluster is a node and an edge from cluster C_A to cluster C_B means there is at least one event where a parent file from C_A installed a child file from C_B . Self-edges are excluded, as those indicate program updates and downloads of additional components from the same publisher. Note that an edge captures download events between parent and child clusters across all hosts and the 19 months analyzed. Thus, the publisher graph captures the who-installs-who relationships over that time period, enabling a birds-eye view of the ecosystem.

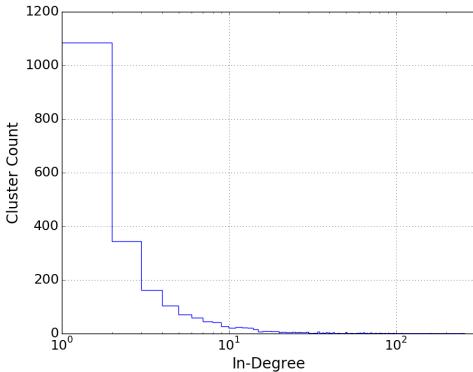

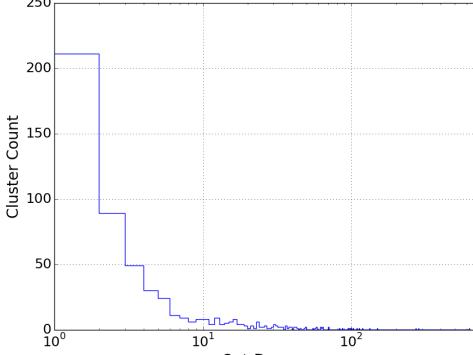

Figure 2: Cluster in-degree distribution.

#	Cluster	PPI Service	ID	OD	Hosts	DR	Pub.

Table 6: PPI services services identified sorted by installation base.

(or gained popularity) after the end of our observation period (e.g., AdGazelle). Third, some PPI services may distribute unsigned bundles or downloaders. For example, we examined over 30K samples that AV engines label as belonging to the InstallMonetizer PPI service, of which only 8% were signed. Finally, some PPI services may have so low volume that they were not observed in our initial 11 M sample feed.

Advertisers. To identify advertisers in the publisher graph, we first select PUP clusters with high in-degree, low out-degree, and for which at least one parent is one of the 24 PPI services (i.e., $DR \geq 5\% \wedge ID \geq 10 \wedge OD \leq 9 \wedge PPPI > 0$). Advertisers pay to have their products installed (i.e., buy installs) and may not install other publishers for monetization as they know how to monetize the machines themselves. Since buying installs costs money, they need to generate enough income from the installations to offset that cost. This filtering identifies 77 clusters, which we manually examine to identify the main product they advertise (they can advertise multiple ones) and whether they run an affiliate program where they pay affiliates to distribute their programs. We also include in this analysis the 20 advertiser clusters manually identified in the PPI service identification above.

Table 7 shows the top 30 advertiser clusters by installation base. The table shows the cluster name, whether it runs an affiliate program, in-degree, out-degree, detection ratio, installation base, the number of parent PPI service nodes, the number of child PPI service nodes, the main product they install, and whether they install browser add-ons (BAO). The latter includes any type of browser add-ons such as toolbars, extensions, plugins, browser helper objects, and sidebars.

The data shows that 18 of the 30 top advertisers install browser add-ons. Those browser add-ons enable monetization through Web traffic, predominantly through different types of advertisement. Common methods are modifying default search engines to monetize searches (e.g., SearchResults, Delta Toolbar, Imminent Toolbar), shopping deals and price comparisons (e.g., PriceGong, PricePeep, DealPLY, SupremeSavings), and other types of advertisement such as pay-per-impression and pay-per-action (e.g., Widgi Toolbar, Inbox Toolbar).

The 12 advertisers that focus on client applications monetize predominantly through selling licenses and subscriptions. The main group is 6 publishers advertising rogueware claiming to improve system performance (Regclean Pro, Optimizer Pro, SpeedUpMyPC,

Table 7: Top 30 advertiser clusters by installation base. For each publisher cluster it shows: whether we found an affiliate program (Aff), the in-degree (IN), out-degree (OD), detection ratio (DR), installation base (Hosts), number of parent PPI services (PPPI), number of child PPI services (CPPI), the main product advertised, and whether that product is a browser add-on (BAO) including toolbars, extensions, sidebars, and browser helper objects.

Event Type	Count
All PUP downloads	40.1M
Unsigned parent	11.5M
Signed parent	28.6M
Benign parent	7.4M
PUP parent	21.2M
PPI	7.3M
Adv. affiliate program	5.5M

Table 8: Analysis of PUP download events.

PC Speed Maximizer, Advanced System Care, DAEMON Tools). These rogueware try to convince users to buy the license for the full version. We also observe multimedia tools (Free Studio, GOM Player), backup tools (MyPC Backup), game promotion (EpicPlay), compressors (BitZipper), and presentation tools (Visual Bee).

7 PUP Distribution Methods.

This section measures the distribution of PUP through PPI services and affiliate programs. The relevant data is provided in Table 8. From the 90 M events with parent information, we first find the events with child files that are signed by PUP publishers (40.1M events). Then, we investigate the parents that installed them. In 28.6M (71%) of these events, parents were signed, therefore allowing us to go further in our search for finding the parents who are PPIs. 7.4M (35%) of these parents correspond to Web browsers and other benign download programs such as BitTorrent clients and Dropbox. The remaining 21.2M (65%) events have a PUP parent. This indicates that the majority of PUP is installed by other PUP. In particular, for 7.3M out of 21.2M events (34%)

with PUP parent, the parent corresponds to one of the 24 PPI services identified in Table 6. And, for another 5.5M (26%) events the parent corresponds to one of the 21 affiliate programs identified in Section 6. From these statistics, we can conclude that PUPs are generally installed by other PUPs and moreover, over 25% of the PUP download events are sourced by PPI services, and another 19% by advertisers with affiliate programs.

8 PUP–Malware Relationships

We are interested in understanding if there is any form of relationship between PUP and malware and if malware uses the PPI services we identified. In particular we would like to measure the percentage of PUP that installs malware or is installed by malware. Here, the obvious challenge is to accurately label malware in the WINE dataset. While the majority of properly signed executables flagged by AV engines are PUP, unsigned executables flagged by AV engines can be PUP or malware and there are a few malware that are signed.

To address these issues, we use AVClass, a recently released malware labeling tool [58]. Given the VT reports of a large number of executables, AVClass addresses the most important challenges in extracting malware family information from AV labels: label normalization, generic token detection, and alias detection. For each sample, it outputs a ranking of the most likely family names ranked by the number of AV engines assigning that family to the sample. Since AV labels can be noisy [4], we focus on executables for which the top family AVClass outputs is in a precomputed list of 70 malware families that includes prevalent families such as zbot, zeroaccess, reveton, virut, sality, shylock, and vobfus. Clearly, our methodology is not 100% accurate, but allows us to gain insight on the relationships between malware and PUP.

PUP downloading malware. One way malware authors could relate to PUP could be by signing up as advertisers to PPI services to distribute their malware. To identify such cases, we look for PUP publishers that download executables from one of the 70 malware families considered. What we have found out is that there is a link between 71 of the PUP publisher clusters to malware. Those publishers distribute malware from 40 families through 5,586 download events. Out of those 71 clusters, 11 are classified as PPI services in Section 6. Those PPI services generate 35% of the 5,586 malware downloads by PUP. For example, Perion Network, the most popular PPI service, downloads instances of zbot, shylock, and andromeda trojans. We also observe at the

end of 2013 iBaro downloading instances of sefnit click-fraud malware as reported by TrendMicro [38]. Clearly, 5,586 downloads is a low number, which may indicate that malware favors silent distribution vectors and that PPI services are careful to avoid malware to preserve their reputation towards security vendors. We only observe occasional events spread amongst multiple PPI services, possibly due to insufficient checks by those PPI services. Another factor of influence may be that installs through these PPIs can be an order of magnitude more expensive than those from silent PPIs, as shown in Section 2.1.

Malware downloading PUP. Malware authors could also sign up as affiliate publishers to PPI services to monetize the compromised machines by selling installs. To capture this behavior, we analyzed PUP downloaded by samples from the 70 malware families considered. We found 11K downloads by malware from 25 families. These malware samples downloaded executables from 98 PUP publisher clusters. 88% of these downloads were generated by 3 malware families: vobfus, badur, and delf. 7 of the 98 PUP publisher clusters belong to the PPI services category. For example, we observe zeroaccess installing files from the DomaIQ PPI service. Overall, malware downloading PUP is a more common event than PUP downloading malware, but still rare, affecting only 0.03% of all events where PUP is downloaded.

The conclusion of this analysis is that while PUP–malware interactions exist, they are not prevalent and malware distribution seems disjoint from PUP distribution. Observed malware–PPI service interactions do not focus on a few misbehaving PPI services, but rather seem to occasionally affect many PPI services.

9 Domain Analysis

In this section we analyze the 1.1 M events that contain a URL, and in particular the domains (ESLDs) in those URLs. The events that contain a URL allow us to identify publishers that download from and are downloaded from a domain. Note that the domains we extract from this dataset are used for hosting and distributing executables and do not cover all of the domains used by PUP. We identify 3 main types of domains from our analysis:

- **File lockers.** Cloud storage services used for backup or sharing executables between users. They exhibit a high number of client publishers being downloaded from them, most of which are benign (e.g., Microsoft, Adobe, AutoDesk). These ESLDs also host a front-end website for users.

- **Download portals.** They also distribute programs from a high number of publishers, predominantly free software publishers and their own PPI services. They also host a front-end website.
- **PPI services.** Used by PPI services to host their wrappers and advertised programs. These ESLDs do not host a front-end website as they are accessed by PPI installers, rather than humans.

Rank by downloaded publishers. Table 9 shows the top 20 ESLDs by number of child publishers signing files downloaded from that ESLD. The 4 tick-mark columns classify the domain as file locker (FL), download portal (DP), PPI service (PPI), or other (Oth). Of the 20 ESLDs, 15 correspond to file lockers, 2 to download portals, and another 2 to PPI services. The remaining domain is `file.org`, a portal where users can enter a file extension to find a tool that can open files with that extension. The publisher behind this portal uses it to promote its own free file viewer tool, which is offered as the best tool to handle over 200 file extensions.

If we give a vote to the top 3 publishers downloaded from each of the 15 file lockers (45 votes), Microsoft gets 13, Adobe 11, Cyberlink 4, and AutoDesk 3. The rest are popular benign publishers such as Ubisoft, VMWare, and Electronic Arts. Thus, file lockers predominantly distribute software from reputable publishers.

For the two download portals, the publishers downloaded from them correspond to their own PPI service (i.e., bundles signed by “CBS Interactive” from `cnet.com`), free software publishers, and PPI services. For `edgecastcdn.net` all 67 publishers are part of the same PPI service run by the Yontoo group. The domain `d3d6wi7c7pa6m0.cloudfront.net` belongs to the Adknowledge PPI service and distributes their advertiser programs. Among those advertiser programs we observe bundles signed by other PPI services, which may indicate arbitrageurs who try to take advantage of pricing differentials among PPI services [7].

Rank by downloads. Table 10 ranks the top 20 domains by number of downloads. It shows the ESLD, the type (file locker, download portal, PPI service, advertiser, other), the cluster that owns the domain, the number of downloads, the number of publishers of the downloaded executables, and the number of distinct files downloaded. We label each domain as belonging to the cluster that signs most executables downloaded from the domain. The publisher in the other category is Frostwire, which distributes a popular free BitTorrent client.

Table 9: Top 20 ESLDs by number of distinct publishers of downloaded executables. FL means file locker, DP download portal, PPI pay-per-install service, and Oth other. For brevity, `d3d6wi7c7pa6m0.cf` stands for `d3d6wi7c7pa6m0.cloudfront.net`.

Table 10 shows that PPI domains dominate in terms of downloads, but distribute a smaller number of child publishers compared to file lockers and download portals that dominate Table 9. It also shows that it is possible to link download domains to the publishers that own them based on the signature of files they distribute, despite the domains being typically registered by privacy protection services.

10 Discussion

Unsigned PUP. Our work focuses on signed PUP executables based on the prior observation that most signed samples flagged by AV engines are PUP [35]. However, this means that we will miss PUP publishers if they distribute only unsigned executables. Also, our PUP prevalence measurements are only a lower bound since there may be hosts with only unsigned PUP installed. In concurrent work, Thomas et al. [65] infiltrate 4 PPI services observing that only 58% of the advertiser software they distribute is signed. Thus, we could be missing as much as 42% of PUP software, but we expect a much smaller number of hosts will only have unsigned PUP installed.

Table 10: Top ESLDs by number of downloads from them. The two rightmost columns are the number of publishers and files of the downloads.

Affiliate publisher analysis. We have classified publisher clusters as PPI services and advertisers, but we have not examined affiliate publisher clusters. One challenge with affiliate publishers is that when distribution happens through a stand-alone PPI installer (rather than bundles) both the advertiser program and the affiliate publisher program may appear as children of the PPI service in the publisher graph. It may be possible to measure the number of affiliates for some PPI services by analyzing URL parameters of download events. We leave this analysis to future work.

Other distribution models. We have examined PUP distribution through PPI services and advertiser affiliate programs. However, other distribution models exist. These include bilateral distribution agreements between two parties (e.g., Oracle’s Java distributing the Ask toolbar [34]) and pre-installed PUP (e.g., Superfish on Lenovo computers [21]). We observe Superfish distributed through PPI services prior to the Lenovo agreement, which started in September 2014 after our analysis period had ended. We leave the analysis of such distribution models to future work.

Observation period. Our observation period covers 19 months from January 2013 to July 2014. Unfortunately, WINE did not include newer data at the time of our study. Thus, we miss newer PUP publishers that joined the ecosystem after our observation period. However, the

vast majority of PUP publishers examined are still alive at the time of writing.

Internet population. We have measured the installation base of PUP (and benign) publishers on WINE hosts. We have also estimated that our measured WINE population may be two orders of magnitude lower than that of hosts connected to the Internet. But, we concede that this estimation is rough and could be affected by different factors such as selection bias.

11 Related Work

PUP. Potentially unwanted programs have received little attention from academia. In 2005–2007 Edelman studied the deceptive installation methods by spyware and other unwanted software [19]. In 2012, Pickard and Mladinov [52] studied a PUP rogue anti-malware software concluding that while not malicious, it only detected 0.3% of the malware and its main purpose was convincing the user to pay the license. Recently, some works have hinted at the increased prevalence and importance of PUP. Thomas et al. [64] study ad injectors, a type of PUP that modifies browser sessions to inject advertisements, finding that 5% of unique daily IP addresses accessing Google are impacted. In follow up work, Jagpal et al. [33] design WebEval, a system to identify mali-

cious extensions at the core of ad injection. Kotzias et al. [35] analyze abuse in Windows Authenticode by analyzing 356K samples from malware feeds. They find that PUP has been quickly increasing feeds since 2010, that the vast majority of properly signed samples are PUP, and that PUP publishers use high file and certificate polymorphism to evade security tools and CA defenses such as identity validation and revocation.

In concurrent work, Thomas et al. [65] analyze the advertiser software distributed to US hosts by 4 PPI services (OutBrowse, Amonetize, OpenCandy, InstallMonetizer). They also use SafeBrowsing data to measure that PPI services drive over 60 million download events every week, nearly three times that of malware. Both works are complementary in their study of PPI services and measuring users affected by PUP. They use a top-to-bottom approach of infiltrating a few PPI services plus SafeBrowsing data, while we perform a bottom-to-top approach starting from files installed on end hosts. We analyze 19 months from January 2013 to July 2014, while they analyze 12 months from August 2015 to July 2016. By examining download events on 3.9M WINE hosts in different countries, our approach enables us to measure PUP prevalence and achieves a broader coverage of the PPI ecosystem. We observe 23 PPI services including 3 of the 4 in their study. The missing PPI service is InstallMonetizer, which distributes mostly unsigned installers.

Also in concurrent work, Nelms et al. [42] analyzed web-based social engineering attacks that use deceiving advertisements to convince users to download unwanted software. They find that most programs distributed this way are bundles of free software with PUP.

Malware distribution. Prior work has studied malware distribution through different vectors, which differs from our focus on PUP distribution. Moschuk et al. [40] crawl 18M URLs finding that 5.9% were drive-by downloads and 13.4% lead to spyware. Provos et al. [53] study the prevalence of distribution through drive-by downloads. Grier et al. [22] analyze the commoditization of drive-by downloads and compare malware distribution through different vectors, concluding that drive-by downloads dominate. Caballero et al. [7] study malware distribution through PPI services. The PPI services we study differ in that installations are not silent and are mostly used by PUP and benign software. Kwon et al. [36] recently use WINE data to investigate malware distribution through downloaders. Their work differs in that they do not distinguish malware from PUP and in that they analyze file download graphs for individual machines. Instead, we

analyze download relationships between publishers on aggregate over 3.9M machines over a 19 month time period, focusing on PUP distribution through PPI services and affiliate programs.

12 Conclusion

We have performed the first systematic study of PUP prevalence and its distribution through PPI services. By using AV telemetry comprising of 8 billion events on 3.9 million hosts over 19 months, we have found that over half (54%) of the examined hosts have PUP installed. The top PUP publishers are highly popular; the top PUP publisher ranks 15 amongst all software publishers (benign or not). We have built the publisher graph that captures the who-installs-who relationships between PUP publishers. We have identified that 65% of the PUP is installed by other PUP and that 24 PPI services distribute over 25% of the PUP and advertiser affiliate programs an additional 19%. We have examined the PUP-malware relationships finding 11K events where popular malware families install PUP for monetization and 5,586 events where PUP distributes malware. PUP-malware interactions are not prevalent and seem to occasionally affect most top PPI services. We conclude that PUP distribution is largely disjoint from malware distribution.

13 Acknowledgments

We thank Richard Rivera for his help with the clustering. Abstract

Although the concept of ransomware is not new (i.e., such attacks date back at least as far as the 1980s), this type of malware has recently experienced a resurgence in popularity. In fact, in the last few years, a number of high-profile ransomware attacks were reported, such as the large-scale attack against Sony that prompted the company to delay the release of the film “The Interview.” Ransomware typically operates by locking the desktop of the victim to render the system inaccessible to the user, or by encrypting, overwriting, or deleting the user’s files. However, while many generic malware detection systems have been proposed, none of these systems have attempted to specifically address the ransomware detection problem.

In this paper, we present a novel dynamic analysis system called UNVEIL that is specifically designed to detect ransomware. The key insight of the analysis is that in order to mount a successful attack, ransomware must tamper with a user’s files or desktop. UNVEIL automatically generates an artificial user environment, and detects when ransomware interacts with user data. In parallel, the approach tracks changes to the system’s desktop that indicate ransomware-like behavior. Our evaluation shows that UNVEIL significantly improves the state of the art, and is able to identify previously unknown evasive ransomware that was not detected by the anti-malware industry.

1 Introduction

Malware continues to remain one of the most important security threats on the Internet today. Recently, a specific form of malware called ransomware has become very popular with cybercriminals. Although the concept of ransomware is not new – such attacks were registered as far back as the end of the 1980s – the recent success of ransomware has resulted in an increasing number of new

families in the last few years [7, 20, 21, 44, 46]. For example, CryptoWall 3.0 made headlines around the world as a highly profitable ransomware family, causing an estimated \$325M in damages [45]. As another example, the Sony ransomware attack [27] received large media attention, and the U.S. government even took the official position that North Korea was behind the attack.

Ransomware operates in many different ways, from simply locking the desktop of the infected computer to encrypting all of its files. Compared to traditional malware, ransomware exhibits behavioral differences. For example, traditional malware typically aims to achieve stealth so it can collect banking credentials or keystrokes without raising suspicion. In contrast, ransomware behavior is in direct opposition to stealth, since the entire point of the attack is to openly notify the user that she is infected.

Today, an important enabler for behavior-based malware detection is dynamic analysis. These systems execute a captured malware sample in a controlled environment, and record its behavior (e.g., system calls, API calls, and network traffic). Unfortunately, malware detection systems that focus on stealthy malware behavior (e.g., suspicious operating system functionality for keylogging) might fail to detect ransomware because this class of malicious code engages in activity that appears similar to benign applications that use encryption or compression. Furthermore, these systems are currently not well-suited for detecting the specific behaviors that ransomware engages in, as evidenced by misclassifications of ransomware families by AV scanners [10, 39].

In this paper, we present a novel dynamic analysis system that is designed to analyze and detect ransomware attacks and model their behaviors. In our approach, the system automatically creates an artificial, realistic execution environment and monitors how ransomware interacts with that environment. Closely monitoring process interactions with the filesystem allows the system to precisely characterize cryptographic ransomware behavior.

In parallel, the system tracks changes to the computer’s desktop that indicates ransomware-like behavior. The key insight is that in order to be successful, ransomware will need to access and tamper with a victim’s files or desktop. Our automated approach, called UNVEIL, allows the system to analyze many malware samples at a large scale, and to reliably detect and flag those that exhibit ransomware-like behavior. In addition, the system is able to provide insights into how the ransomware operates, and how to automatically differentiate between different classes of ransomware.

We implemented a prototype of UNVEIL in Windows on top of the popular open source malware analysis framework Cuckoo Sandbox [13]. Our system is implemented through custom Windows kernel drivers that provide monitoring capabilities for the filesystem. Furthermore, we added components that run outside the sandbox to monitor the user interface of the target computer system.

We performed a long-term study analyzing 148,223 recent general malware samples in the wild. Our large-scale experiments show that UNVEIL was able to correctly detect 13,637 ransomware samples from multiple families in live, real-world data feeds with no false positives. Our evaluation also suggests that current malware analysis systems may not yet have accurate behavioral models to detect different classes of ransomware attacks. For example, the system was able to correctly detect 7,572 ransomware samples that were previously unknown and undetected by traditional AVs, but belonged to modern file locker ransomware families. UNVEIL was also able to detect a new type of ransomware that had not previously been reported by any security company. This ransomware also did not show any malicious activity in a modern sandboxing technology provided by a well-known anti-malware company, while showing heavy file encryption activity when analyzed by UNVEIL.

The high detection rate of our approach suggests that UNVEIL can complement current malware analysis systems to quickly identify new ransomware samples in the wild. UNVEIL can be easily deployed on any malware analysis system by simply attaching to the filesystem driver in the analysis environment.

In summary, this paper makes the following contributions:

- We present a novel technique to detect ransomware known as *file lockers* that targets files stored on a victim’s computer. Our technique is based on monitoring system-wide filesystem accesses in combination with the deployment of automatically-generated artificial user environments for triggering ransomware.
- We present a novel technique to detect ransomware

known as *screen lockers*. Such ransomware prevents access to the computer system itself. Our technique is based on detecting locked desktops using dissimilarity scores of screenshots taken from the analysis system’s desktop before, during, and after executing the malware sample.

- We performed a large-scale evaluation to show that our approach can effectively detect ransomware. We automatically detected and verified 13,637 ransomware samples from a dataset of 148,223 recent general malware. In addition, we found one previously unknown ransomware sample that does not belong to any previously reported family. Our evaluation demonstrates that our technique works well in practice (achieving a true positive [TP] rate 96.3% at zero false positives [FPs]), and is useful in automatically identifying ransomware samples submitted to analysis and detection systems.

The rest of the paper is structured as follows. In Section 2, we briefly present background information and explain different classes of ransomware attacks. In Section 3, we describe the architecture of UNVEIL and explain our detection approaches for multiple types of ransomware attacks. In Section 4, we provide more details about our dynamic analysis environment. In Section 5, we present the evaluation results. Limitations of the approach are discussed in Section 6, while Section 7 presents related work. Finally, Section 8 concludes the paper.

2 Background

Ransomware, like other classes of malware, uses a number of strategies to evade detection, propagate, and attack users. For example, it can perform multi-infection or process injection, exfiltrate the user’s information to a third party, encrypt files, and establish secure communication with C&C servers. Our detection approach assumes that ransomware samples can and will use all of the techniques that other malware samples may use. In addition, our system assumes that successful ransomware attacks perform one or more of the following activities.

Persistent desktop message. After successfully performing a ransomware infection, the malicious program typically displays a message to the victim. This “ransom note” informs the users that their computer has been “locked” and provides instructions on how to make a ransom payment to restore access. This ransom message can be generated in different ways. A popular technique is to call dedicated API functions (e.g., `CreateDesktop()`) to create a new desktop and make it the default config-

uration to lock the victim out of the compromised system. Malware writers can also use HTML or create other forms of persistent windows to display this message. Displaying a persistent desktop message is a classic action in many ransomware attacks.

Indiscriminate encryption and deletion of the user’s private files. A crypto-style ransomware attack lists the victim’s files and aggressively encrypts any private files it discovers. Access is restricted by withholding the decryption key. Encryption keys can be generated locally by the malware on the victim’s computer, or remotely on C&C servers, and then delivered to the compromised computer. An attacker can use customized destructive functions, or Windows API functions to delete the original user’s files. The attacker can also overwrite files with the encrypted version, or use secure deletion via the Windows Secure Deletion API.

Selective encryption and deletion of the user’s private files based on certain attributes (e.g., size, date accessed, extension). In order to avoid detection, a significant number of ransomware samples encrypt a user’s private files selectively. In the simplest form, the ransomware sample can list the files based on the access date. In more sophisticated scenarios, the malware could also open an application (e.g., `word.exe`) and list recently accessed files. The sample can also inject malicious code into any Windows application to obtain this type of information (e.g., directly reading process memory).

In this work, we address all of these scenarios where an adversary has already compromised a system, and is able to launch arbitrary ransomware-related operations on the user’s files or desktop.

3 UNVEIL Design

In this section, we describe our techniques for detecting multiple classes of ransomware attacks. We refer the reader to Section 4 for details on the implementation details of the prototype.

3.1 Detecting File Lockers

We first describe why our system creates a unique, artificial user environment in each malware run. We then present the design of the filesystem activity monitor and describe how UNVEIL uses the output of the filesystem monitor to detect ransomware.

3.1.1 Generating Artificial User Environments

Protecting malware analysis environments against fingerprinting techniques is non-trivial in a real-world deployment. Sophisticated malware authors exploit static fea-

tures inside analysis systems (e.g., name of a computer) and launch reconnaissance-based attacks [31] to fingerprint both public and private malware analysis systems.

The static features of analysis environments can be viewed as the Achilles’ heel of malware analysis systems. One static feature that can have a significant impact on the effectiveness of the malware analysis systems is the user data that can be effectively used to fingerprint the analysis environment. That is, even on bare-metal environments where classic tricks such as virtualization checks are not possible, an unrealistic looking user environment can be a telltale sign that the code is running in a malware analysis system.

Intuitively, a possible approach to address such reconnaissance attacks is to build the user environment in such a way that the user data is valid, real, and non-deterministic in each malware run. These automatically-generated user environments serve as an “enticing target” to encourage ransomware to attack the user’s data while at the same time preventing the possibility of being recognized by adversaries.

In practice, generating a user environment is a non-trivial problem, especially if this is to be done automatically. This is because the content generator should not allow the malware author to fingerprint the automatically-generated user content located in the analysis environment, and also determine that it does not belong to a real user. We elaborate on how we automatically generate an artificial – yet realistic – user environment for ransomware in each malware run in Section 4.1.

3.1.2 Filesystem Activity Monitor

The filesystem monitor in UNVEIL has direct access to data buffers involved in I/O requests, giving the system full visibility into all filesystem modifications. Each I/O operation contains the process name, timestamp, operation type, filesystem path and the pointers to the data buffers with the corresponding entropy information in read/write requests. The generation of I/O requests happens at the lowest possible layer to the filesystem. For example, there are multiple ways to read, write, or list files in user-/kernel-mode, but all of these functions are ultimately converted to a sequence of I/O requests. Whenever a user thread invokes an I/O API, an I/O request is generated and is passed to the filesystem driver. Figure 1 shows a high-level design of UNVEIL in the Windows environment.

UNVEIL’s monitor sets callbacks on all I/O requests to the filesystem generated on behalf of any user-mode processes. We note that for UNVEIL operations, it is desirable to only set one callback per I/O request for performance reasons, and that this also maintains full visibility into I/O operations. In UNVEIL, user-mode process in-

teractions with the filesystem are formalized as access patterns. We consider access patterns in terms of I/O traces, where a trace T is a sequence of t_i such that

$$t_i = \langle P, F, O, E \rangle,$$

P is the set of user-mode processes,

F is the set of available files,

O is the set of I/O operations, and

E is the entropy of read or write data buffers.

For all of the file locker ransomware samples that we studied, we empirically observed that these samples issue I/O traces that exhibit distinctive, repetitive patterns. This is due to the fact that these samples each use a single, specific strategy to deny access to the user’s files. This attack strategy is accurately reflected in the form of I/O access patterns that are repeated for each file when performing the attack. Consequently, these I/O access patterns can be extracted as a distinctive I/O fingerprint for a particular family. We note that our approach mainly considers write or delete requests. We elaborate on extracting I/O access patterns per file in Section 3.1.2.

I/O Data Buffer Entropy. For every read and write request to a file captured in an I/O trace, UNVEIL computes the entropy of the corresponding data buffer. Comparing the entropy of read and write requests to and from the same file offset serves as an excellent indicator of crypto-ransomware behavior. This is due to the common strategy to read in the original file data, encrypt it, and overwrite the original data with the encrypted version. The system uses Shannon entropy [30] for this computation. In particular, assuming a uniform random distribution of bytes in a data block d , we have

$$H(d) = - \sum_{i=1}^n \frac{\log_2 n}{n}.$$

Constructing Access Patterns. For each execution, after UNVEIL generates I/O access traces for the sample, it sorts the I/O access requests based on file names and request timestamps. This allows the system to extract the I/O access sequence for each file in a given run, and check which processes accessed each file. The key idea is that after sorting the I/O access requests per file, repetition can be observed in the way I/O requests are generated on behalf of the malicious process.

The particular detection criterion used by the system to detect ransomware samples is to identify write and delete operations in I/O sequences in each malware run. In a successful ransomware attack, the malicious process typically aims to encrypt, overwrite, or delete user files at some point during the attack. In UNVEIL, these I/O

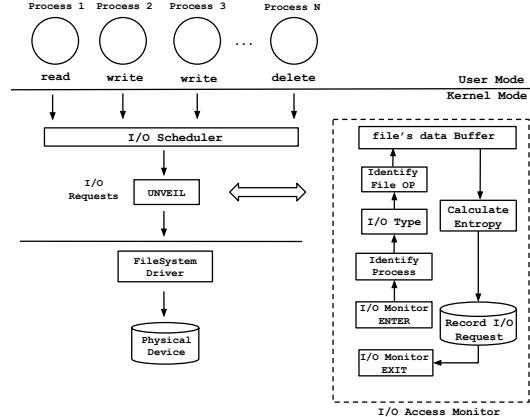

Figure 1: Overview of the design of I/O access monitor in UNVEIL. The module monitors system-wide filesystem accesses of user-mode processes. This allows UNVEIL to have full visibility into interactions with user files.

request patterns raise an alarm, and are detected as suspicious filesystem activity. We studied different file locker ransomware samples across different ransomware families. Our analysis shows that although these attacks can be very different in their attack strategies (e.g., evasion techniques, key generation, key management, connecting to C&C servers), they can be categorized into three main classes of attacks based on their access requests.

Figure 2 shows the high-level access patterns for multiple ransomware families we studied during our experiments. For example, the access pattern shown to the left is indicative of Cryptolocker variants that have varying key lengths and desktop locking techniques. However, its access pattern remains constant with respect to family variants. We observed the same I/O activity for samples in the CryptoWall family as well. While these families are identified as two different ransomware families, since they use the same encryption functions to encrypt files (i.e., the Microsoft CryptoAPI), they have similar I/O patterns when they attack user files.

As another example, in FileCoder family, the ransomware first creates a new file, reads data from a victim’s file, generates an encrypted version of the original data, writes the encrypted data buffer to the newly generated file, and simply unlinks the original user’s file (See Figure 2.2). In this class of file locker ransomware, the malware does not wipe the original file’s data from the disk. For attack approaches like this, victims have a high chance of recovering their data without paying the ransom. In the third approach (Figure 2.3), however, the ransomware creates a new encrypted file based on the original file’s data and then securely deletes the original file’s data using either standard Windows APIs or custom overwriting implementations (e.g., such as Cryp-

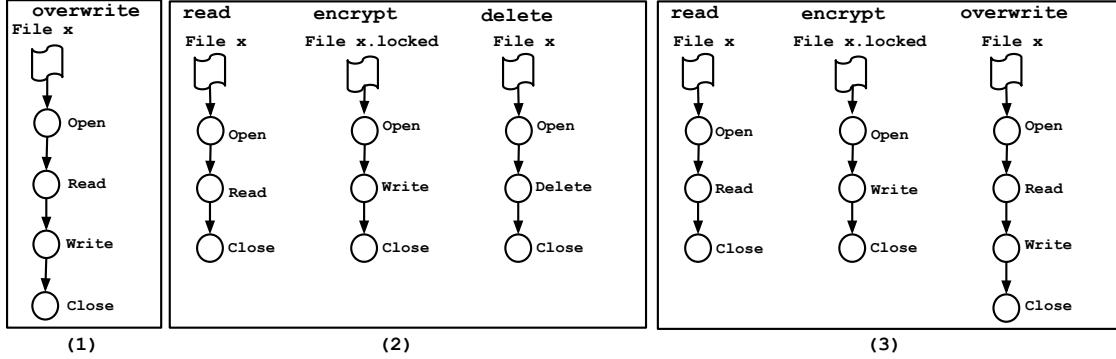

Figure 2: Strategies differ across ransomware families with respect to I/O access patterns. (1) Attacker overwrites the users’ file with an encrypted version; (2) Attacker reads, encrypts and deletes files without wiping them from storage; (3) Attacker reads, creates a new encrypted version, and securely deletes the original files by overwriting the content.

Vault family).

3.2 Detecting Screen Lockers

The second core component of UNVEIL is aimed at detecting screen locker ransomware. The key insight behind this component is that the attacker must display a ransom note to the victim in order to receive a payment. In most cases, the message is prominently displayed, covering a significant part, or all, of the display. As this ransom note is a virtual invariant of ransomware attacks, UNVEIL aims to automatically detect the display of such notes.

The approach adopted by UNVEIL to detect screen locking ransomware is to monitor the desktop of the victim machine, and to attempt to detect the display of a ransom note. Similar to Grier et al. [15], we take automatic screenshots of the analysis desktop before and after the sample is executed. The screenshots are captured from outside of the dynamic analysis environment to prevent potential tampering by the malware. This series of screenshots is analyzed and compared using image analysis methods to determine if a large part of the screen has suddenly changed between captures. However, smaller changes in the image such as the location of the mouse pointer, current date and time, new desktop icons, windows, and visual changes in the task bar should be rejected as inconsequential.

In UNVEIL, we measure the *structural similarity* (SSIM) [49] of two screenshots – before and after sample execution – by comparing local patterns of pixel intensities in terms of both luminance and contrast as well as the structure of the two images. Extracting structural information is based on the observation that pixels have strong inter-dependencies – especially when they are spatially close. These dependencies carry information about the structure of the objects in the image. After a successful ransomware attack, the display of the ransom note often

results in automatically identifiable changes in the structural information of the screenshot (e.g., a large rectangular object covers a large part of the desktop). Therefore, the similarity of the pre- and post-attack images decreases significantly, and can be used as an indication of ransomware.

In order to avoid false positives, UNVEIL only takes screenshots resulting from persistent changes (i.e., changes that cannot be easily dismissed through user interaction). The system first removes such transient changes (e.g., by automatically closing open windows) before taking screenshots of the desktop. Using this pre-processing step, ransomware-like applications that are developed for other purposes such as fake AV are safely categorized as non-ransomware samples.

UNVEIL also extracts the text within the area where changes in the structure of the image has occurred. The system extracts the text inside the selected area and searches for specific keywords that are highly correlated with ransom notes (e.g., <lock, encrypt, desktop, decryption, key>).

Given two screenshots X and Y , we define the structural similarity index of the image contents of local windows x_j and y_j as

$$\text{LocalSim}(x_j, y_j) = \frac{(2\mu_x\mu_y + c_1)(2\sigma_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)(\sigma_x^2 + \sigma_y^2 + c_2)}$$

where μ_x and μ_y are the mean intensity of x_j and y_j , and σ_x and σ_y are the standard deviation as an estimate of x_j and y_j contrast and σ_{xy} is the covariance of x_j and y_j . The local window size to compare the content of two images was set 8×8 . c_1 and c_2 are division stabilizer in the SSIM index formula [49]. We define the overall similarity between the two screenshots X and Y as the arithmetic mean of the similarity of the image contents x_j and y_j at the j^{th} local window where M is the number

of local windows of X and Y :

$$\text{ImgSim}(X, Y) = \frac{1}{M} \sum_{j=1}^M \text{LocalSim}(x_j, y_j).$$

Since the overall similarity is always on $[0, 1]$, the distance between X and Y is simply defined as

$$\text{Dist}(X, Y) = 1 - \text{ImgSim}(X, Y).$$

Finally, we define a similarity threshold τ_{sim} such that UNVEIL considers the sample a potential screen locking ransomware if

$$\text{Dist}(X, Y) > \tau_{\text{sim}}.$$

UNVEIL then extracts the text within the image and searches for ransomware-related words within the modified area. Applying the image similarity test with the best similarity threshold (see Section 5.2.2) gives us the highest recall with 100% precision for the entire dataset.

4 UNVEIL Implementation

In this section, we describe the implementation details of a prototype of UNVEIL for the Windows platform. We chose Windows for a proof-of-concept implementation because it is currently the main target of ransomware attacks. We elaborate on how UNVEIL automatically generates artificial, but realistic user environments for each analysis run, how the system-wide monitoring was implemented, and how we deployed the prototype of our system.

4.1 Generating User Environments

In each run, the user environment is made up of several forms of content such as digital images, videos, audio files, and documents that can be accessed during a user *Windows Session*. The user content is automatically-generated according to the following process:

For each file extension from a space of possible extensions, a set of files are generated where the number of files for each extension is sampled from a uniform random distribution for each sample execution. Each set of files collectively forms a *document space* for the sample execution environment. From a statistical perspective, document spaces generated for each sample execution should be indistinguishable from real user data. As an approximation to this ideal, randomly-selected numbers of files are generated per extension for each run according to the process described above.

In the following, we describe the additional properties that a document space should have in order to complicate programmatic approaches that ransomware samples can

potentially use to identify the automatically-generated user environment.

Valid Content. The user content generator creates real files with valid headers and content using standard libraries (e.g., `python-docx`, `python-pptx`, `OpenSSL`). Based on empirical observation, we created four file categories that a typical ransomware sample tries to find and encrypt: documents, keys and licenses, file archives, and media. Document extensions include `txt`, `doc(x)`, `ppt(x)`, `tex`, `xls(x)`, `c`, `pdf` and `py`. Keys and license extensions include `key`, `pem`, `crt`, and `cer`. Archive extensions include `zip` and `rar` files. Finally, media extensions include `jp(e)g`, `mp3`, and `avi`. For each sample execution, a subset of extensions are randomly selected and are used to generate user content across the system.

In order to generate content that appears meaningful, we collected approximately 100,000 sentences by querying 500 English words in Google. For each query, we collected the text from the first 30 search results to create a sentence list. We use the collected sentences to generate the content for the user files. We used the same technique to create a word list to give a name to the user files. The word list allows us to create files with variable name lengths that do not appear random. Clearly, the problem with random content and name generation (e.g., `xteyshfqb.docx`) is that the attacker could programmatically calculate the entropy of the file names and contents to detect content that has been generated automatically. Hence, by generating content that appears meaningful, we make it difficult for the attacker to fingerprint the system and detect our generated files.

File Paths. Note that the system is also careful to randomly generate the supposed victim’s directory structure. For example, directory names are also generated based on meaningful words. Furthermore, the system also associates files of certain types with standard locations in the Windows directory structure for those file types (e.g., the system does not create document files in a directory with image files, but rather under `My Documents`). The path length of user files is also non-deterministic and is generated randomly. In addition, each folder may have a set of sub-folders. Consequently, the generated paths to user files have variable depths relative to the root folder.

Time Attributes. Another non-determinism strategy used by our approach is to generate files with different *creation*, *modification*, and *access* times. The file time attributes are sampled from a distribution of likely timestamps when creating the file. When the system creates files with different time attributes, the time attributes of the containing folders are also updated automatically. In this case, the creation time of the folder is the minimum of all creation times of files and folders inside the folder, while the modification and access times are the maxi-

mum of the corresponding timestamps.

While we have not observed ransomware samples that have attempted to use fingerprinting heuristics of the content of the analysis environment, the nondeterminism strategies used by UNVEIL serve as a basis for making the analysis resilient to fingerprinting by design.

4.2 Filesystem Activity Monitor

Several techniques have been used to monitor sample filesystem activity in malware analysis environments. For example, filesystem activity can be monitored by hooking a list of relevant filesystem API functions or relevant system calls using the System Service Descriptor Table (SSDT). Unfortunately, these approaches are not suitable for UNVEIL’s detection approach for several reasons. First, API hooking can be bypassed by simply copying a DLL containing the desired code and dynamically loading it into the process’ address space under a different name. Stolen code [17, 19] and sliding calls [19] are other examples of API hooking evasion that are common in the wild. Furthermore, ransomware can use customized cryptosystems instead of the standard APIs to bypass API hooking while encrypting user files. Hooking system calls via the SSDT also has other technical limitations. For example, it is prevented on 64-bit systems due to Kernel Patch Protection (KPP). Furthermore, most SSDT functions are undocumented and subject to change across different versions of Windows.

Therefore, instead of API or system call hooking, UNVEIL monitors filesystem I/O activity using the Windows Filesystem Minifilter Driver framework [34], which is a standard kernel-based approach to achieving system-wide filesystem monitoring in multiple versions of Windows. The prototype consists of two main components for I/O monitoring and retrieving logs of the entire system with approximately 2,800 SLOC in C++. In Windows, I/O requests are represented by I/O Request Packets (IRPs). UNVEIL’s monitor sets callbacks on all I/O requests to the filesystem generated on behalf of user-mode processes. Basing UNVEIL’s filesystem monitor on a minifilter driver allows it to be located at the closest possible layer to the filesystem with access to nearly all objects of the operating system.

4.3 Desktop Lock Monitor

To identify desktop locking ransomware, screenshots are captured from outside of the dynamic analysis environment to prevent potential tampering by the malware. For dissimilarity testing, a python script implements the Structural Similarity Image Metric (SSIM) as described in Section 3.2. UNVEIL first converts the images to floating point data, and then calculates parameters such as

mean intensity μ using Gaussian filtering of the images’ contents. We also used default values ($k_1 = 0.01$ and $k_2 = 0.03$) to obtain the values of c_1 and c_2 to calculate the structural similarity score in local windows presented in Section 3.2.

The system also employs Tesseract-OCR [38], an open source OCR engine, to extract text from the selected areas of the screenshots. To perform the analysis on the extracted text within images, we collected more than 10,000 unique ransom notes from different ransomware families. We first clustered ransom notes based on the family type and the visual appearance of the ransom notes. For each cluster, we then extracted the ransom texts in the corresponding ransom notes and performed pre-filtering to remove unnecessary words within the text (e.g., articles, pronouns) to avoid obvious false positive cases. The result is a word list for each family cluster that can be used to identify ransom notes and furthermore label notes belonging to a known ransomware family.

5 Evaluation

We evaluated UNVEIL with two experiments. The goal of the first experiment is to demonstrate that the system can detect known ransomware samples, while the goal of the second experiment is to demonstrate that UNVEIL can detect previously unknown ransomware samples.

5.1 Experimental Setup

The UNVEIL prototype is built on top of Cuckoo Sandbox [13]. Cuckoo provides basic services such as sample submission, managing multiple VMs, and performing simple human interaction tasks such as simulating user input during an analysis. However, in principle, UNVEIL could be implemented using any dynamic analysis system (e.g., BitBlaze [5], VxStream Sandbox [37]).

We evaluated UNVEIL using 56 VMs running Windows XP SP3 on a Ganeti cluster based on Ubuntu 14.04 LTS. While Windows XP is not required by UNVEIL, it was chosen because it is well-supported by Cuckoo sandbox. Each VM had multiple NTFS drives. We took anti-evasion measures against popular tricks such as changing the IP address range and the MAC addresses of the VMs to prevent the VMs from being fingerprinted by malware authors. Furthermore, we permitted controlled access to the Internet via a filtered host-only adapter. In particular, the filtering allowed limited IRC, DNS, and HTTP traffic so samples could communicate with C&C servers. SMTP traffic was redirected to a local honeypot to prevent spam, and network bandwidth was limited to mitigate potential DoS attacks.

Family	Type	Samples
Cryptolocker	crypto	33 (1.5%)
CryptoWall	crypto	42 (2.0%)
CTB-Locker	crypto	77 (3.6%)
CrypVault	crypto	21 (1.0%)
CoinVault	crypto	17 (0.8%)
Filecoder	crypto	19 (0.9%)
TeslaCrypt	crypto	39 (1.8%)
Tox	crypto	71 (3.3%)
VirLock	locker	67 (3.2%)
Reveton	locker	501 (23.6%)
Tobfy	locker	357 (16.8%)
Urausy	locker	877 (41.3%)
Total Samples	-	2,121

Table 1: The list of ransomware families used in the first experiment.

The operating system image inside the malware analysis system included typical user data such as saved social networking credentials and a valid browsing history. For each operating system image, multiple users were defined to run the experiments. We also ran a script that emulated basic user activity while the malware sample was running on the system, such as launching a browser and navigating to multiple websites, or clicking on the desktop. This interaction was randomly-generated, but was constant across runs. Each sample was executed in the analysis environment for 20 minutes. As described in Sections 3.1 and 3.2, user environments were generated for each run, filesystem I/O traces were recorded, and pre- and post-execution screenshots were captured. After each execution, the VM was rolled back to a clean state to prevent any interference across executions. All experiments were performed according to well-established experimental guidelines [40] for malware experiments.

5.2 Ground Truth (Labeled) Dataset

In this experiment, we evaluated the effectiveness of UNVEIL on a labeled dataset, and ran different screen locker samples to determine the best threshold value τ_{sim} for the large-scale experiment.

We collected ransomware samples from public repositories [1, 3] and online forums that share malware samples [2, 32]. We also received labeled ransomware samples from two well-known anti-malware companies. In total, we collected 3,156 recent samples. In order to make sure that those samples were indeed active ransomware, we ran them in our test environment. We confirmed 2,121 samples to be active ransomware instances. After each run, we checked the filesystem activity of each sample for any signs of attacks on user data. If we did not see any malicious filesystem activity, we checked whether running the sample displayed a ransom note.

Table 1 describes the ransomware families we used in this experiment. We note that the dataset covers the majority of the current ransomware families in the wild. In

Run	OP	Proc	FName	Offset	Entropy
CryptoWall 3	read write ...	explorer.exe explorer.exe	document.cad document.cad	[0,4096) [0,4096)	5.21 7.04
CryptoWall 4	read write ... rename	explorer.exe explorer.exe explorer.exe	project.cad project.cad t67djkje.elkd8	[0,4096) [0,4096)	5.21 7.11

Table 2: An example of I/O access in UNVEIL for CryptoWall 3.0 and CryptoWall 4.0.

Application	OP	Description
CrypVault	read write ...	read low entropy buffer from original file write high entropy buffer to a new file
	write delete	overwrite the buffer of the original file read attributes, delete the original file
CryptoWall4	read write ... rename	read low entropy buffer overwrite with high entropy buffer read attributes, rename the files
SDelete	write ... delete	overwrite data buffer read attributes, delete the file
7-zip	read write ...	read data buffer from original file write data buffer to a new file

Table 3: I/O accesses for deletion and compression mechanisms in benign/malicious applications. Benign programs can generate I/O access requests similar to ransomware attacks, but since they are not designed to deny access to the original files, their I/O sequence patterns are different from ransomware attacks.

addition to the labeled ransomware dataset, we also created a dataset that consisted of non-ransomware samples. These samples were submitted to the Anubis analysis platform [16], and consisted of a collection of benign as well as malicious samples. We selected 149 benign executables including applications that have ransomware-like behavior such as secure deletion, encryption, and compression. A short list of these applications are provided in Table 5. We also tested 384 non-ransomware malware samples from 36 malware families to evaluate the false positive rate of UNVEIL. Table 2 shows an example of I/O traces for CryptoWall 3.0 and CryptoWall 4.0 where the victim’s file is first read and then overwritten with an encrypted version. The I/O access patterns of CryptoWall 4.0 samples to overwrite the content of the files are identical since they use the same cryptosystem. The main difference is that the filenames and extensions are modified with random characters, probably to minimize the chance of recovering the files based on their names in the Master File Table (MFT) in the NTFS filesystem.

5.2.1 Filesystem Activity of Benign Applications with Potential Ransomware-like Behavior

One question that arises is whether benign applications such as encryption or compression programs might generate similar I/O request sequences, resulting in false positives. Note that with benign applications, the original file content is treated carefully since the ultimate goal is to generate an encrypted version of the original file, and not to restrict access to the file. Therefore, the default mechanism in these applications is that the original files remain intact even after encryption or compression. If automatic deletion is deliberately activated by the user after the encryption, it can potentially result in a false positive (see Figure 2.2). However, in our approach, we assume that the usual default behavior is exhibited and the original data is preserved. We believe that this is a reasonable assumption, considering that we are building an analysis system that will mainly analyze potentially suspicious samples captured and submitted for analysis. Nevertheless, we investigated the I/O access patterns of benign programs, shown in Table 3. The I/O traces indicate that these programs exhibit distinguishable I/O access patterns as a result of their default behavior.

Benign applications might not necessarily perform encryption or deletion on user files, but can change the content of the files. For example, updating the content of a Microsoft PowerPoint file (e.g., embedding images and media) generates I/O requests similar to ransomware (see Figure 2.1). However, the key difference here is that such applications usually generate I/O requests for a single file at a time and repetition of I/O requests does not occur over multiple user files. Also, note that benign applications typically do not arbitrarily encrypt, compress or modify user files, but rather need sophisticated input from users (e.g., file names, keys, options, etc.). Hence, most applications would simply exit, or expect some input when executed in UNVEIL.

5.2.2 Similarity Threshold

We performed a precision-recall analysis to find the best similarity threshold τ_{sim} for desktop locking detection. The best threshold value to discriminate between similar and dissimilar screenshots should be defined in such a way that UNVEIL is able to detect screen locker ransomware while maintaining an optimal precision-recall rate. Figure 3 shows empirical precision-recall results when varying τ_{sim} . As the figure shows, with $\tau_{\text{sim}} = 0.32$, more than 97% of the ransomware samples across both screen and file locker samples are detected with 100% precision. In the second experiment, we used this similarity threshold to detect screen locker ransomware in a malware feed unknown to UNVEIL.

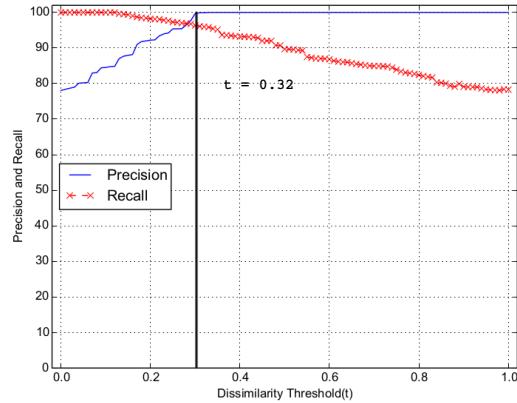

Figure 3: Precision-recall analysis of the tool. The threshold value $\tau_{\text{sim}} = 0.32$ gives the highest recall with 100% precision.

Evaluation	Results
Total Samples	148,223
Detected Ransomware	13,637 (9.2%)
Detection Rate	96.3%
False Positives	0.0%
New Detection	9,872 (72.2%)

Table 4: UNVEIL detection results. 72.2% of the ransomware samples detected by UNVEIL were not detected by any of AV scanners in VirusTotal at the time of the first submission. 7,572 (76.7%) of the newly detected samples were destructive file locker ransomware samples.

5.3 Detecting Zero-Day Ransomware

The main goal of the second experiment is to evaluate the accuracy of UNVEIL when applied to a large dataset of recent real-world malware samples. We then compared our detection results with those reported by AV scanners in VirusTotal.

This dataset was acquired from the daily malware feed provided by Anubis [16] to security researchers. The samples were collected from May 18th 2015 until February 12th 2016. The feed is generated from the Anubis submission queue, which is fed in turn by Internet users and security companies. Hence, before performing the experiment, we filtered the incoming Anubis samples by removing those that were not obviously executable (e.g., PDFs, images). After this filtering step, the dataset contained 148,223 distinct samples. Each sample was then submitted to UNVEIL to obtain I/O access traces and pre-/post-execution desktop image dissimilarity scores.

5.3.1 Detection Results

Table 4 shows the evaluation results of the second experiment. With the similarity threshold $\tau_{\text{sim}} = 0.32$, UNVEIL labeled 13,637 (9.2% of the dataset) samples in the Anu-

bis malware feed as being ransomware; these included both file locker and desktop locker samples.

Evaluation of False Positives. As we did not have a labeled ground truth in the second experiment, we cannot provide an accurate precision-recall analysis, and verifying the detection results is clearly challenging. For example, re-running samples while checking for false positives is not feasible in all cases since samples may have become inactive at the time of re-analysis (e.g., the C&C server might have been taken down).

Hence, we used manual verification of the detection results. That is, for the samples that were detected as screen locker ransomware, we manually checked the post-attack screenshots that were reported taken by UNVEIL. The combination of structural similarity test and the OCR technique to extract the text provides a reliable automatic detection for this class of ransomware. We confirmed that UNVEIL correctly reported 4,936 samples that delivered a ransom note during the analysis.

Recall that UNVEIL reports a sample as a file locker ransomware if the I/O access pattern follows one of the three classes of ransomware attacks described in Figure 2. For file locker ransomware samples, we used the I/O reports for each sample. We listed all the I/O activities on the first five user files during that run and looked for suspicious I/O activity such as requesting *write* and/or *delete* operations. Note that the detection approach used in UNVEIL is only based on the I/O access pattern. We do not check for changes in entropy in the detection phase and it is only used for our evaluation.

If we find multiple write or delete I/O requests to the first five generated user files and also a significant increase in the entropy between read and write data buffers at a given file offset, or the creation of new high entropy files, we confirmed the detection as a true positive. The creation of multiple new high entropy files based on user files is a reliable sign of ransomware in our tests. For example, the malware sample that uses secure deletion techniques may overwrite files with low entropy data. However, the malicious program first needs to generate an encrypted version of the original files. In any case, generating high entropy data raises an alarm in our evaluation.

By employing these two approaches and analyzing the results, we did not find any false positives. There were a few cases that had significant change in the structure of the images. Our closer investigation revealed that the installed program generated a large installation page, showed some unreadable characters in the window, and did not close even if the button was clicked (i.e., non-functional buttons). In another case, the program generated a large setup window, but it did not proceed due to a crash. These cases produce a higher dissimilarity

score than the threshold value. However, since the extracted text within those particular windows did not contain any ransomware-related contents, UNVEIL safely categorized them as being non-ransomware samples.

Evaluation of False Negatives. Determining false negative rates is a challenge since manually checking 148,223 samples is not feasible. In the following, we provide an *approximation* of false negatives for UNVEIL.

In our tests on the labeled dataset, false negatives mainly occurred in samples that make persistent changes on the desktop, but since the dissimilarity score of pre-/post-attack is less than $\tau_{\text{sim}} = 0.32$, it is not detected as ransomware by UNVEIL. Our analysis of labeled samples from multiple ransomware families (see Section 5.2) shows that these cases were mainly observed in samples with a similarity score between the interval [0.18, 0.32]. This is because for lower similarity scores, changes in the screenshots are negligible or small (e.g., Windows warning/error messages). Consequently, in order to increase the chance of catching false negative cases, we selected all the samples where their dissimilarity score was between [0.18, 0.32]. This decreases the size of potential desktop locker ransomware that were not detected by UNVEIL to 4,642 samples. We manually checked the post-attack screenshots of these samples, and found 377 desktop locker ransomware that UNVEIL was not able to detect. Our analysis shows that the false negatives in desktop locker ransomware resulted from samples in one ransomware family that generated a very transparent ransom note with a dissimilarity score between [0.27, 0.31] that was difficult to read.

For file locker ransomware, we first removed the samples that were not detected as malware by any of the AV scanners in VirusTotal after multiple resubmissions in consecutive days (see Section 5.3.2). By applying this approach, we were able to reduce the number of samples to check by 47%. Then, we applied a similar approach we used as described above. We listed the first five user files generated for that sample run and checked whether any process requested write access to those files. We also checked the entropy of multiple data buffers. If we identified write access with a significant increase in the entropy of data buffers compared to the entropy of data buffer in the read access for those files, we report it as a false negative.

Our test shows that UNVEIL does not have any false negatives in file locker ransomware samples. Consequently, we conclude that UNVEIL is able to detect multiple classes of ransomware attacks with a low false positive rate (FPs = 0.0% at a TP = 96.3%).

5.3.2 Early Warning

One of the design goals of UNVEIL is to be able to automatically detect previously unknown (i.e., zero-day) ransomware. In order to run this experiment, we did the following. Once per day over the course of the experiment, we built a malware dataset that was concurrently submitted to UNVEIL and VirusTotal. If a sample was detected as ransomware by UNVEIL, we checked the VirusTotal (VT) detection results. In cases where a ransomware sample was not detected by any VT scanner, we reported it as a new detection.

In addition, we also measured the lag between a new detection by UNVEIL and a VT detection. To that end, we created a dataset from the newly detected samples submitted on days $\{1, 2, \dots, n-1, n\}$ and re-submitted these samples to see whether the detection results changed. We considered the result of all 55 VT scanners in this experiment. Since the number of scanners is relatively high, we defined a VT detection ratio ρ as the ratio of the total number of scanners that identified the sample as ransomware or malware to the total number of scanners checked by VT. ρ is therefore a value on the interval $[0, 1]$ where zero means that the sample was not detected by any of the 55 VT scanners, and 1 means that all scanners reported the sample as malware or ransomware. Since there is no standard labeling scheme for malware in the AV industry, a scanner can label a sample using a completely different name from another scanner. Consequently, to avoid biased results, we consider the labeling of a sample using *any* name as a successful detection.

In our experiment, we submitted the detected samples every day to see how the VT detection ratio ρ changes over time. The distribution of ρ for each submission is shown in Figure 4. Our analysis shows that ρ does not significantly change after a small number of subsequent submissions. For the first submission, 72.2% of the ransomware samples detected by UNVEIL were not detected by any of the 55 VT scanners. After a few submissions, ρ does not change significantly, but generally was concentrated either towards small or very large ratios. This means that after a few re-submissions, either only a few scanners detected a sample, or almost all the scanners detected the sample.

5.4 Case Study: Automated Detection of a New Ransomware Family

In this section, we describe a new ransomware family, called SilentCrypt, that was detected by UNVEIL during the experiments. After our system detected these samples and submitted them to VirusTotal, several AV vendors picked up on them and also started detecting them a

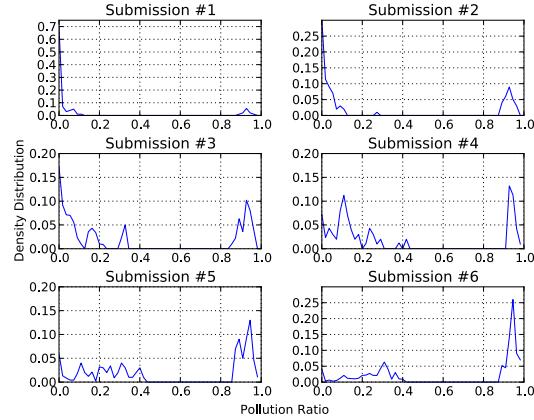

Figure 4: Evolution of VT scanner reports after six submissions. 72.2% of the samples detected by UNVEIL were not detected by any of AV scanners in the first submission. After a few re-submissions, the detection results do not change significantly. The detection results tend to be concentrated either towards small or very large detection ratios. This means that a sample is either detected by a relatively small number of scanners, or almost all of the scanners.

couple of days later, confirming the malice of the sample that we automatically detected.

This family uses a unique and effective method to fingerprint the runtime environment of the analysis system. Unlike other malware samples that check for specific artifacts such as registry keys, background processes, or platform-specific characteristics, this family checks the private files of a user to determine if the code is running in an analysis environment. When the sample is executed, it first checks the number of files in the user's directories, and sends this list to the C&C server before starting the attack.

Multiple online malware analysis systems such as malwr.com, Anubis, and a modern sandboxing technology provided by a well-known, anti-malware company did not register any malicious activity for this sample. However, the sample showed heavy encryption activity when analyzed by UNVEIL.

An analysis of the I/O activity of this sample revealed that this family first waited for several minutes before attacking the victim's files. Figure 5 shows the three main I/O activities of one of the samples in this family. The sample traverses the current user's main directories, and creates a list of files and folders. If the sample receives permission to attack from the C&C server, it begins encrypting the targeted files. To confirm UNVEIL's alerts, we conducted a manual investigation over several days. Our analysis concluded that the malicious activity is started only if user activity is detected. Unlike other ransomware samples that imme-

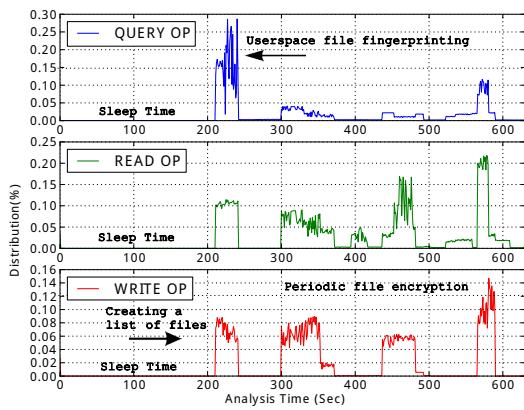

Figure 5: I/O activities of a previously unknown ransomware family detected by UNVEIL. The sample first performs victim file fingerprinting to ensure that the running environment is not a bare user environment.

diate attack a victim’s files when they are executed, this family only encrypt files that have recently been opened by the user while the malicious process is monitoring the environment. That is, the malicious process reads the file’s data and overwrites it with encrypted data if the file is used. The file name is then updated to “filename.extension.locked_forever” after it has been encrypted.

UNVEIL was able to detect this family of ransomware automatically because it was triggered after the system accessed some of the generated user files as a part of the user activity emulation scripts. Once we submitted the sample to VirusTotal, the sample was picked up by other AV vendors (5/55) after five days with different labels. A well-known, sandboxing-based security company confirmed our findings that the malware sample was a new threat that they had not detected before. We provide an anonymous video of a sample from this ransomware family in [6].

6 Discussion and Limitations

The evaluation in Section 5 demonstrates that UNVEIL achieves good, practical, and useful detection results on a large, real-world dataset. Unfortunately, malware authors continuously observe defensive advances and adapt their attacks accordingly. In the following, we discuss limitations of UNVEIL and potential evasion strategies.

There is always the possibility that attackers will find ways to fingerprint the automatically generated user environment and avoid it. However, this comes at a high cost, and increases the difficulty bar for the attacker. For example, in desktop-locking ransomware, malware can

use heuristics to look for specific user interaction before locking the desktop (e.g., waiting for multiple login events or counting the number of user clicks). However, implementing these approaches can potentially make detection easier since these approaches require hooking specific functions in the operating system. The presence of these hooking behaviors are themselves suspicious and are used by current malware analysis systems to detect different classes of malware. Furthermore, these approaches delay launching the attack which increases the risk of being detected by AV scanners on clients before a successful attack occurs.

Another possibility is that a malware might only encrypt a specific part of a file instead of aggressively encrypting the entire file, or simply shuffle the file content using a specific pattern that makes the files unreadable. Although we have not seen any sample with these behaviors, developing such ransomware is quite possible. The key idea is that in order to perform such activities, the malicious program should open the file with write permission and manipulate at least some data buffers of the file content. In any case, if the malicious program accesses the files, UNVEIL will still see this activity. There is no real reason for benign software to touch automatically generated files with write permission and modify the content. Consequently, such activities will still be logged. Malware authors might use other techniques to notify the victim and also evade the desktop lock monitor. As an example, the ransomware may display the ransom note via video or audio files rather than locking the desktop. As we partially discussed, these approaches only make sense if the malware is able to successfully encrypt user files first. In this case, UNVEIL can identify those malicious filesystem access as discussed in Section 3.1.2.

We also believe that the current implementation of text extraction to detect desktop locker ransomware can be improved. We observed that the change in the structure of the desktop screen-shots is enough to detect a large number of current ransomware attacks since UNVEIL exploits the attacker’s goal which is to ensure that the victims see the ransom note. However, we believe that the text extraction module can be improved to detect possible evasion techniques an attacker could use to generate the ransom note (e.g., using uncommon words in the ransom text).

Clearly, there is always the possibility that an attacker will be able to fingerprint the dynamic analysis environment. For example, stalling code [26] has become increasingly popular to prevent the dynamic analysis of a sample. Such code takes longer to execute in a virtual environment, preventing execution from completing during an analysis. Also, attackers can actively look for signs of dynamic analysis (e.g., signs of execution in a VM

such as well-known hard disk names). Note that UNVEIL is agnostic as to the underlying dynamic analysis environment. Hence, as a mitigation, UNVEIL can use a sandbox that is more resistant to these evasion techniques(e.g., [26, 48]). The main contribution of UNVEIL is not the dynamic analysis of malware, but rather the introduction of new techniques for the automated, specific detection of ransomware during dynamic analysis.

UNVEIL runs within the kernel, and aims to detect user-level ransomware. As a result, there is the risk that ransomware may run at the kernel level and thwart some of the hooks UNVEIL uses to monitor the filesystem. However, this would require the ransomware to run with administrator privileges to load kernel code or exploit a kernel vulnerability. Currently, most ransomware runs as user-level programs because this is sufficient to carry out ransomware attacks. Kernel-level attacks would require more sophistication, and would increase the difficulty bar for the attackers. Also, if additional resilience is required, the kernel component of UNVEIL could be moved outside of the analysis sandbox.

7 Related Work

Many approaches have been proposed to date that have aimed to improve the analysis and detection of malware. A number of approaches have been proposed to describe program behavior from analyzing byte patterns [29, 43, 41, 50] to transparently running programs in malware analysis systems [4, 23, 22, 47]. Early steps to analyze and capture the main intent of a program focused on analysis of control flow. For example, Kruegel et al. [28] and Bruschi et al. [9] showed that by modeling programs based on their instruction-level control flow, it is possible to bypass some forms of obfuscation. Similarly, Christodorescu et al. [12] used instruction-level control flow to design obfuscation-resilient detection systems. Later work focused on analyzing and detecting malware using higher-level semantic characterizations of their runtime behavior derived from sequences of system call invocations and OS resource accesses [24, 25, 11, 33, 42, 51].

Similar to our use of automatically-generated user content, decoys have been used in the past to detect security breaches. For instance, the use of decoy resources has been proposed to detect insider attacks [8, 52]. Recently, Juels et al. [18] used *honeywords* to improve the security of hashed passwords. The authors show that decoys can improve the security of hashed passwords since the attempt to use the decoy password for logins results in an alarm. In other work, Nikiforakis et al. [35] used decoy files to detect illegally obtained data from file hosting services.

There have also been some recent reports on the ransomware threat. For example, security vendors have reported on the threat of potential of ransomware attacks based on the number of infections that they have observed [46, 7, 44, 36]. A first report on specific ransomware families was made by Gazer where the author analyzed three ransomware families including Krotten and Gpcode [14]. The author concluded that while these early families were designed for massive propagation, they did not fulfill the basic requirements for mass extortion (e.g., sufficiently long encryption keys). Recently, Kharraz et al. [21] analyzed 15 ransomware families and provided an evolution-based study of ransomware attacks. They performed an analysis of charging methods and the use of Bitcoin for monetization. They proposed several high-level mitigation strategies such as the use of decoy resources to detect suspicious file access. Their assumption is that every filesystem access to delete or encrypt decoy resources is malicious and should be reported. However, they did not implement any concrete solution to detect or defend against these attacks.

We are not aware of any systems that have been proposed in the literature that specifically aim to detect ransomware in the wild. In particular, in contrast to existing work on generic malware detection, UNVEIL detects behavior specific to ransomware (e.g., desktop locking, patterns of filesystem accesses).

8 Conclusions

In this paper we presented UNVEIL, a novel approach to detecting and analyzing ransomware. Our system is the first in the literature to specifically identify typical behavior of ransomware such as malicious encryption of files and locking of user desktops. These are behaviors that are difficult for ransomware to hide or change.

The evaluation of UNVEIL shows that our approach was able to correctly detect 13,637 ransomware samples from multiple families in a real-world data feed with zero false positives. In fact, UNVEIL outperformed all existing AV scanners and a modern industrial sandboxing technology in detecting both superficial and technically sophisticated ransomware attacks. Among our findings was also a new ransomware family that no security company had previously detected before we submitted it to VirusTotal.

Abstract

Most modern malware infections happen through the browser, typically as the result of a drive-by or social engineering attack. While there have been numerous studies on measuring and defending against drive-by downloads, little attention has been dedicated to studying social engineering attacks.

In this paper, we present the first systematic study of web-based social engineering (SE) attacks that successfully lure users into downloading malicious and unwanted software. To conduct this study, we collect and reconstruct more than two thousand examples of in-the-wild SE download attacks from live network traffic. Via a detailed analysis of these attacks, we attain the following results: (i) we develop a categorization system to identify and organize the tactics typically employed by attackers to gain the user’s attention and deceive or persuade them into downloading malicious and unwanted applications; (ii) we reconstruct the web path followed by the victims and observe that a large fraction of SE download attacks are delivered via online advertisement, typically served from “low tier” ad networks; (iii) we measure the characteristics of the network infrastructure used to deliver such attacks and uncover a number of features that can be leveraged to distinguish between SE and benign (or non-SE) software downloads.

1 Introduction

Most modern malware infections happen via the browser, typically triggered by social engineering [9] or drive-by download attacks [33]. While numerous studies have focused on measuring and defending against drive-by downloads [14, 17, 28, 38], malware infections enabled by social engineering attacks remain notably understudied [31].

Moreover, as recent defenses against drive-by downloads and other browser-based attacks are becoming harder to circumvent [18, 24, 32, 36, 40], cyber-criminals increasingly aim their attacks against the weakest link,

namely the user, by leveraging sophisticated social engineering tactics [27]. Because social engineering (SE) attacks target users, rather than systems, current defense solutions are often unable to accurately detect them. Thus, there is a pressing need for a comprehensive study of social engineering downloads that can shed light on the tactics used in modern attacks. This is important not only to inform better technical defenses, but may also allow us to gather precious information that may be used to better train users against future SE attacks.

In this paper, we present a study of real-world SE download attacks. Specifically, we focus on studying *web-based SE attacks* that unfold *exclusively via the web* and that do not require “external” triggers such as email spam/phishing, etc. An example of such attacks is described in [9]: a user is simply browsing the web, visiting an apparently innocuous blog, when his attention is drawn to an online ad that is subtly crafted to mimic a warning about a missing browser plugin. Clicking on the ad takes him to a page that reports a missing codec, which is required to watch a video. The user clicks on the related codec link, which results in the download of malicious software.

To conduct our study, we collect and analyze hundreds of *successful* in-the-wild SE download attacks, namely SE attacks that actually result in a victim downloading malicious or unwanted software. We harvest these attacks by monitoring *live* web traffic on a large academic network. Via a detailed analysis of our SE attack dataset, we attain the following main results: (i) we develop a categorization system to identify and organize the tactics typically employed by attackers to gain a user’s attention and deceive or persuade them into downloading malicious and unwanted applications; (ii) we reconstruct the *web path* (i.e., sequence of pages/URLs) followed by SE victims and observe that a large fraction of SE attacks are delivered via online advertisement (e.g., served via “low tier” ad networks); (iii) we measure the characteristics of the network infrastructure (e.g., domain names) used to

deliver such attacks, and uncover a number of features that can be leveraged to distinguish between SE and benign (i.e., “non-SE”) software downloads.

Our findings show that a large fraction of SE attacks (almost 50%) are accomplished by *repackaging* existing benign applications. For instance, users often download free software that comes as a bundle including the software actually desired by the user plus some Adware or other Potentially Unwanted Programs (PUPs). This confirms that websites serving free software are often involved (willingly or not) in distributing malicious or unwanted software [4, 7].

The second most popular category of attacks is related to alerting or urging the user to install an application that is supposedly needed to complete a task. For instance, the user may be *warned* that they are running an outdated or insecure version of Adobe Flash or Java, and are offered to download a software update. Unfortunately, by downloading these supposed updates, users are infected. Similarly, users may stumble upon a page that supposedly hosts a video of interest. This page may then inform the user that a specific video codec is needed to play the desired video. The user *complies* by downloading the suggested software, thus causing an infection (see Section 3 for details).

Another example of an SE download attack is represented by fake anti-viruses (FakeAVs) [35]. In this case, a web page alerts the user that their machine is infected and that AV software is needed to clean up the machine. In a way similar to the SE attack examples reported above, the user may be persuaded to download (in some cases after a payment) the promoted software, which will infect the user’s machine. However, while FakeAVs have been highly popular among attackers in the recent past, our study of in-the-wild SE malware downloads finds that they represent less than 1% of modern SE attacks. This sharp decline in the number of FakeAV attacks within the last few years is consistent with the recent development of technical countermeasures against this class of attacks [5] and increased user awareness [6].

As mentioned earlier, a large fraction of SE download attacks (more than 80%) are initiated via advertisements, and that the “entry point” to these attacks is represented by only a few low-tier advertisement networks. For instance, we found that a large fraction of the web-based SE attacks described above are served primarily via two ad networks: `oncickads.net` and `adcash.com`.

By studying the details of SE download attacks, we also discover a number of features that aid in the detection of SE download attacks on live web traffic. We train a classifier using these features and measure its effectiveness at detecting SE downloads.

Summary of Contributions:

- We present the first systematic study of modern web-based SE download attacks. For instance, our analysis of hundreds of SE download attack instances reveals that most such attacks are enabled by online advertisements served through a handful of “low tier” ad networks.
- To assist the process of understanding the origin of SE download attacks, we develop a categorization system that expresses how attackers typically gain a user’s attention, and what are the most common types of deception and persuasion tactics used to trick victims into downloading malicious or unwanted applications. This makes it easier to track what type of attacks are most prevalent and may help to focus user training programs on specific user weaknesses and particularly successful deception and persuasion tactics currently used in the wild.
- Via extensive measurements, we find that the most common types of SE download attacks include *fake updates* for Adobe Flash and Java, and that fake anti-viruses (FakeAVs), which have been a popular and effective infection vector in the recent past, represent less than 1% of all SE downloads we observed in the wild. Furthermore, we find that existing defenses, such as traditional anti-virus (AV) scanners, are largely ineffective against SE downloads.
- Based on our measurements, we then identify a set of features that allow for building a statistical classifier that is able to accurately detect ad-driven SE download attacks with 91% true positives and only 0.5% false positives.

2 Study Overview

Our study of SE download attacks is divided in multiple parts. To better follow the results discussed in the following sections, we now present a brief summary of their content.

In Section 3, we analyze the range of deception and persuasion tactics employed by the attackers to victimize users, and propose a categorization system to systematize the in-the-wild SE tactics we observed.

In Section 4, we discuss how we collect software downloads (including malicious ones) from live network traffic and reconstruct their *download path*. Namely, we trace back the sequence of pages/URLs visited by a user before arriving to a URL that triggers the download of an executable file (we focus on Windows portable executable files). We then analyze the collected software download events, and label those downloads that result

from SE attacks. This labeled dataset is used in the following sections to enable a detailed analysis of the characteristics of the SE download attacks.

We analyze our dataset of in-the-wild SE download attacks in Section 5. Specifically, we measure how the SE attack tactics are distributed, according to the categorization system proposed in Section 3, and highlight the most popular *successful* SE malware attacks. According to our dataset, the majority of SE attacks are promoted via online advertisement. Therefore, in Section 5 we also present an analysis of the network-level properties of ad-based SE malware attacks, and contrast them with properties of ad-driven benign software downloads.

In Section 6, we focus on detecting ad-based SE download attacks. We first show that anti-virus products detect only a small fraction of all SE attacks, leaving most “fresh” SE download events undetected. We then devise a number of statistical features that can be extracted from the network properties of ad-driven software download events, and show that they allow us to build an accurate SE attack classifier, which could be used to detect and stop SE download attacks before they infect their victims.

Finally, we discuss possible limitations of our SE attacks study and detection approach in Sections 7, and contrast our work to previously published research in Section 8.

3 SE Download Attacks

In this section, we analyze the range of deception and persuasion tactics employed by the attackers to victimize users (Section 3.1). We also provide some concrete examples of SE download attacks, to highlight how real users may fall victim to such attacks (Section 3.2).

SE Attacks Dataset. Our analysis is based on a dataset consisting of 2,004 real-world SE download attacks. We collected these attacks by monitoring the network traffic of a large academic network (authorized by our organization’s IRB), passively reconstructing the download of executable binary files and tracing back the browsing path followed by the users to reach the file download event. We then analyzed the observed file download events to identify possible malware, adware or PUP downloads. Finally, we performed an extensive manual analysis of the suspicious downloads to identify and label those downloads that were triggered by SE attacks, and to precisely reconstruct the attack scenarios. A detailed description of our dataset collection and labeling approach is provided in Section 4. Furthermore, in Section 5 we measure properties of the collected attacks, such as what types of SE attacks are the most prevalent, and provide information on the network-level characteristics of SE download distribution operations.

In the following, we will focus on analyzing our SE download attack dataset with the goal of categorizing the different types of deception and persuasion tactics used by attackers to lure victims into downloading malicious and unwanted software.

3.1 Categorizing SE Download Tactics

The dataset of 2,004 SE download attacks that we reconstructed and labeled via extensive manual analysis efforts (detailed in Section 4) gives us an excellent opportunity to study the wide range of depiction and persuasion tactics employed by the attackers. To better understand how SE attacks work, we develop a categorization system that aims to provide a systematization of the techniques used by successful SE download attacks. Specifically, we categorize different SE attacks according to; (1) the ways the adversaries get the user’s attention and (2) the type of deception and persuasion tactics employed. Our categorization of SE attacks is summarized in Figure 1.

Gaining the user’s attention. The first step in a SE attack is to get the user’s attention. This is accomplished for example by leveraging online advertisement (ad), search engine optimization (SEO) techniques or by posting messages (and clickable links) on social networks, forums, and other sites that publish user-generated content.

As we will show in Section 5, the most popular of these methods is *ads*. On-line advertisement allows the attacker to easily “publish” their deception/persuasion ad on a site that is likely already popular among the targeted victims. In addition, ads help hide the deception/persuasion campaign and attack infrastructure (i.e., hide it from users as well as security researchers), simply because SE ads are exposed only to targeted users via search keywords, the user’s cookies, etc.

Another method employed to attract the user’s attention is *search*. For instance, search engines can be abused via black hat SEO attacks to pollute the search results with harmful links. In addition, in our categorization of SE attacks we use a generic definition of “search” that does not only include search engines; anytime a user perform a query to locate specific content on a website, we classify it as a search event. For instance, we have observed users that become victims of SE attacks while simply searching for content within a website that hosts video streaming (e.g., movies, video clips, etc.).

Attackers also use *web posts* to attract the user’s attention. We define a web post as content that has been added to a website by a visitor and is now available for display to others. For instance, many of the web posts used in the SE download attacks we observed were located within groups of legitimate posts about a topic of interest. The majority of such web posts were related to content (e.g.,

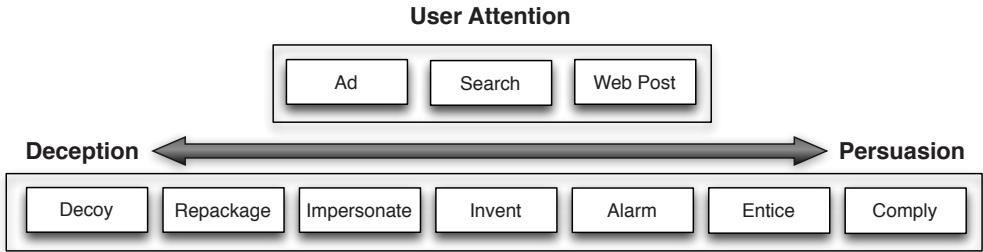

Figure 1: Categorization of SE downloads on the web.

clickable links) such as free software, books, music and movies.

It is not uncommon for these three techniques (ads, search, and web posts) to be combined. For instance, attackers will use search and ads in combination to get the user’s attention. Targeted search engine ads related to the search terms entered by users are often displayed before the real search results, thus increasing the likelihood of a click. This common search engine feature is often abused by attackers. Also, users may search for certain specific terms on web forums, social network sites, etc., and may fall victim to targeted web posts.

Deception and persuasion tactics. After an attacker gains the user’s attention, they must convince them to download and install their malicious or unwanted software. This typically involves combining a subset of the deception and persuasion techniques summarized in Figure 1. As one scrolls from left to right in the figure, the techniques move from deception towards persuasion. Notice that none of the techniques we list involve only deception or only persuasion; instead, the different techniques vary in their levels of each. We now provide a description of the deception and persuasion classes shown in Figure 1. We will then present examples of real-world SE download attacks that make use of a combination of these techniques.

- (1) **Decoy:** Attackers will purposely place decoy “clickable” objects, such as a hyperlink, at a location on a web page that will attract users to it and away from the actual object desired (or searched) by the user. An image of a “flashy” download button (e.g., delivered as an ad banner) on a free download site located prior to the actual download link desired by the user is an example of this technique.
- (2) **Repackage:** To distribute malicious and unwanted software, attackers may group benign and PUP (or malware) executables together, and present them to the user as a single application. An example technique from this class is adware bundled with a benign application and served as a single software download on a free software distribution website.
- (3) **Impersonate:** Using specific images, words and colors can make an executable appear as if it was a

known popular benign application. Also, claiming that a software provides desirable features or services (though it does not supply them) is a way to convince the user to download and install the application. Malicious executables pretending to be an Adobe Flash Player update, e.g., by using logos or icons similar to the original Adobe products and keywords such as “adobe” and “flash,” is an example of impersonation techniques from this class.

- (4) **Invent:** Creating a false reality for the user may compel them to download a malicious or unwanted executable. For example, alerting the user stating that their machine is infected with malware and instructing them to download (malicious) clean-up software (e.g., a fake AV) is an example of the *invent* tactic.
- (5) **Alarm:** Using fear and trepidation aims to scare the user into downloading (malicious) software that promises to safeguard them. For instance, an online ad claiming that the user’s browser is out-of-date and vulnerable to exploitation is an example of *alarm* techniques.
- (6) **Entice:** Attackers often attempt to attract users to download a malicious or unwanted executable by offering features, content or advantages. As an example, a user may be shown an ad for a system optimization utility stating that it will “speedup” their PC, but hides malicious software.
- (7) **Comply:** A user may be (apparently) required to install an (malicious) application before she can continue. For instance, a user visiting a video streaming website may be prompted to install a necessary “codec” before she can watch a free movie. As the user is motivated to watch the movie, she complies with the codec installation request, thus getting infected with malware.

It is important to note that none of the SE attacks in our study fall into a single class. Instead the in-the-wild SE attacks we collected often use techniques across two or more of the above classes to trick the user into infecting their machine. Labeling a download using these classes involves understanding the motivations employed to convince a user to install the malicious software. These are

typically easy to identify by examining the words and images used in an attack. For instance, an attack that *impersonates* will claim to be software that it is not, such as Adobe Flash Player. On the other hand, an attack that *enticing* a user will often use words like “free” and describe all the benefits of installing the software. Entice and impersonate are not mutually exclusive and are used together in some SE attacks. Allowing an SE attack to be assigned to more than one class simplifies the labeling process because all perception/deception tactics can be included, not just the one believed to be the primary tactic.

3.2 Examples of In-The-Wild SE Attacks

In this section, we present two examples from our dataset of reconstructed SE download attacks, and classify their SE tactics using our categorization system (see Figure 1). To aid in our discussion we define the notation “*attention:deception/persuasion*,” where the *attention* string refers to how attackers attempt to attract users’ attention, and the *deception/persuasion* string refers to the combination of the deception/persuasion techniques used to trigger the malware download. For example, if an SE attack relies on an *ad* and uses *alarm* and *impersonate* deception/persuasion tactics, then we label the attack using our notation as “*ad:alarm+impersonate*.”

Attack 1. A user searches for “Gary Roberts free pics” using a popular search engine. A page hosted on a compromised website is returned as a top result. The page contains various content referring to “Gary Roberts”, but this content is incoherent and likely only present for blackhat search engine optimization (SEO). However, the user never sees the content because the javascript code located at the top of the served page immediately closes the document, and then reopens it to inject a script that redirects the user to a page that says “gary-roberts-free-pics is ready for download. Your file download should automatically start within seconds. If it doesn’t, click to restart the download.” But the downloaded file does not contain any pictures, and instead carries malicious code that is later flagged as malware by some AV vendors.

Using our categorization system we classify this attack as “*search:entice+decoy+impersonate*.” *Search* is the method of gaining the users attention. In this example this is obvious because the SE page appeared in the results page provided by a search engine. The *entice* part of the attack is the offering of “free” pics of the subject of interest. *Decoy* is due to the fact that blackhat SEO was used to elevate the SE page in the search results above other legitimate pages. Lastly, what the user downloads is not pics of Gary Roberts; instead, it is a malicious executable *impersonating* what the user wants (e.g., Gary

Figure 2: SE ad for Ebola early warning system.

Roberts free pictures).

Attack 2. A user is watching an episode of “Agents of Shield” on a free video website when they are presented with an *ad*. The ad, similar to the one shown in Figure 2, presents the user with the option of downloading an early warning system for Ebola. However, the downloaded file does not provide information about an Ebola outbreak; instead, it infects the user’s system with malicious software.

We classify this attack as “*ad:alarm+impersonate*” using our categorization system. The user’s attention is gained through an *ad*, in which their fear of Ebola is used to *alarm* the user into downloading a tracking system. Unfortunately, what the user downloads only *impersonates* a tracking systems, and instead contains malicious code.

4 Collecting and Labeling SE Attacks

In this section we discuss in detail how we collected and labeled our dataset of 2,004 SE download attacks. We will then present an analysis of the prevalence and characteristics of the collected attacks in Section 5.

4.1 Data Collection Approach

To collect and reconstruct SE download attacks, we monitor all web traffic at the edge of a large network (this study was authorized by our organization’s Institutional Review Board). Using deep packet inspection, we process the network traffic in real-time, reconstructing TCP connections, analyzing the content of HTTP responses and recording all traffic related to the download of executable files (Windows executables).

While monitoring the traffic, we maintain a buffer of all recent HTTP transactions (i.e., request-response pairs) that occurred in the past few minutes. When an HTTP transaction that carries the download of an executable file is found, we passively reconstruct and store a copy of the file itself. In addition, we trigger a dump of the traffic buffer, recording all the web traffic generated

by the same client that initiated the file download during the past few minutes before the download started. In other words, we store all HTTP traffic a client generated up to (and including) the executable file download.

We then process these HTTP transaction captures using the trace-back algorithm presented in [30]. The trace-back algorithm builds a graph where each node is an HTTP transaction. Given two nodes T_1 and T_2 , they are connected by an edge if T_2 was “likely referred to” by T_1 . For instance, a directed edge is drawn from T_1 to T_2 if the user clicked on a link in T_1 ’s page and as a consequence the browser loaded T_2 . Then, starting from the download node, the algorithm walks backwards along this graph to trace back the most likely path (i.e., sequence of HTTP transactions) that brought the user to initiate the download event. For more details, we refer the reader to [30].

These reconstructed download paths are later analyzed to identify and categorize SE download attacks. It is important to note that we do not claim automatic download path traceback as a contribution of this paper. Instead, our focus is on the collection, analysis, and categorization of SE download attacks, and on the detection and mitigation of ad-based SE infections. Automatic download traceback is just one of the tools we use to aid in our analysis.

We deployed the data collection process described above on a large academic network serving tens of thousands users for a period of two months. To avoid unnecessarily storing the download traces related to frequent software updates for popular benign software, we compiled a conservative whitelist consisting of 128 domain names owned by major software vendors (e.g., Microsoft, Adobe, Google, etc.). Therefore, executable files downloaded from these domains were excluded from our dataset.

Overall, during our two month deployment, we collected a total of 35,638 executable downloads. The process we used to identify the downloads due to SE attacks is described in the following sections.

4.2 Automatic Data Filtering

Even though we filter out popular benign software updates up front, we found that the majority of executable downloads observed on a network are updates to (more or less popular) software already installed on systems. As we are interested in new infections caused by web-based SE attacks, we aim to automatically identify and filter out such software updates.

To this end, we developed a set of conservative heuristics that allow us to identify and filter out most software update events based on an analysis of their respective *download path*. First, we examine the *length* of the download path. The intuition is that software updates

tend to come from very short download paths, which often consist of a single HTTP request to directly fetch a new executable file from a software vendor’s website (or one of its mirrors). Conversely, the download path related to SE download attacks usually consists of a number of navigation steps (e.g., the user may navigate through different pages before stumbling upon a malicious SE advertisement).

For the next step in the analysis, we review the *user-agent* string observed in the HTTP requests on the download path. The user-agent string appearing in software update requests is typically not the one used by the client’s browser (similar observations were made by the authors of [30]), because the user-agent found in these requests often contains the name of the software that is being updated (e.g., Java or Acrobat reader). Since web-based SE attacks happen to users browsing the web, HTTP requests on the download path typically carry the user-agent string of the victim’s browser.

Therefore, to automatically identify and filter out update downloads we use the following heuristics. If the download path contains a single HTTP transaction (the update request itself), and the user-agent string does not indicate that the request has been made by a browser, we filter out the event from our dataset.

Overall, the conservative filtering approach outlined above allowed us to reduce the number of download paths to be further analyzed. Specifically, we were able to reduce our download traces dataset by 61%, leaving us with a total of 13,762 that required further analysis and labeling.

4.3 Analysis of Software Download Events

After filtering, our dataset consists of 13,762 software download events (i.e., the downloaded executable files and related download paths) that required further detailed analysis and labeling. As our primary goal is to create a high quality dataset of labeled SE download attacks, we aim to manually analyze and perform a detailed reconstruction of the attacks captured by our archive of software download events.

To aid in the manual analysis process and reduce the cost of this time-consuming effort, we leveraged unsupervised learning techniques. Specifically, we identify a number of statistical features that allow us to discover clusters of download events that are similar to each other. For instance, we aim to group different downloads of the same benign software by different clients. At the same time, we also aim to group together similar download events triggered by the same SE attack campaign.

To identify and automatically cluster similar download events, we developed a set of statistical features. We would like to emphasize that none of the features we describe below is able to independently yield high-quality

clustering results. Rather, it is the combination of these features that allows us to obtain high quality clusters of related software download events.

Notice also that the purpose of this clustering process is simply to reduce the time needed to manually analyze the software download events we collected. By using a conservative clustering threshold (discussed below) and by manually reviewing all obtained clusters, we minimize the impact of possible noise in the results.

To perform the clustering, we leverage a number of simple statistical features, some of which (e.g., URL similarity, domain name similarity, etc.) are commonly used to find the similarity between network-level events. Notice, however, that our main goal in this clustering process is not to design novel features; rather, we simply aim to reduce the manual analysis and labeling efforts needed to produce a high-quality dataset of in-the-wild SE download attacks.

We now describe our clustering features:

- (1) **Filename Similarity:** Benign executable files distributed by the same organization (e.g., an application distributed by a given vendor or software distribution site) tend to have similar filenames. Notice that often this also holds for SE attack campaigns, because the files distributed by the same campaign often follow a consistent “theme” to aid in the *deception* of the end users. For instance, the malware files distributed by a fake Flash Player upgrade attack campaign (see Section 3) may all include the word “Adobe” in the filename to convince the user that the downloaded file is legitimate.
- (2) **File Size Similarity:** Benign files that are identical or variants (i.e., different versions) of the same software are usually very close in size. Similarly, SE campaigns typically infect victims with a variant of the same malware family. While the malware file’s size may vary due to polymorphism, the size difference is typically small, compared to the total file size.
- (3) **URL Structure Similarity:** A benign website that serves software downloads will often host all of its executable files at the same or very similar structured URLs. In a similar way, SE campaigns often use malware distribution “kits” and go weeks or even months before a noticeable change in the structure of their URL paths is observed. This is unlike malicious URLs, which frequently change to avoid blacklisting.
- (4) **Domain Name Similarity:** While the domain names used to distributed malware files belonging to the same SE attack campaign may change, some campaigns will reuse some keywords in their domains that are meant to deceive the user. For instance, the domains used in a Fake AV malware campaign

may contain the keyword “security” to convince the user of its legitimacy. Also, download events related to (different versions of) the same benign software are often distributed via a handful of stable domain names.

- (5) **Shared Domain Predecessor:** SE attacks that share a common node (or predecessor) in the download path are often related. For instance, an SE malware campaign may exploit an ad network with weak anti-abuse practices. Therefore, while the final domain in the download path from which the malware is actually downloaded may change (e.g., to avoid blacklisting), the malware download *paths* of different users that fall victim to the same SE campaign may share a node related to the abused ad network, for example. On the other hand, in case of benign downloads both the download and “attention grabbing” domain tend to be stable, as the main goal is quality of service towards the end user.
- (6) **Shared Hosting:** While domains involved in malware distribution tend to change frequently, SE malware campaigns often reuse (parts of) the same hosting infrastructure (e.g., some IPs). The intuition is that hosting networks that tolerate abuse (knowingly or otherwise) are a rare and costly resource. On the other hand, domain names are significantly easier to obtain and can be used as crash-and-burn resource from the adversary. On the benign downloads side, legitimate software distribution websites are usually stable and do not change hosting very frequently, for quality of service reasons.
- (7) **HTTP Response Header Similarity:** The headers in an HTTP response are the result of the installed server-side software and configuration of the web server. The set of response headers and their associated values offer a lot of variation. However, most of the web servers for a benign site tend to have common configurations so they respond with similar headers. Also, some SE campaigns use the same platform for their attacks and do not change their server-side configurations even when they move to new domains.

For each of the 13,762 downloads we compute a feature vector based on the features listed above, and calculate the pairwise distance between these feature vectors. We then apply an agglomerative hierarchical clustering algorithm to the obtained distance matrix. Finally, we cut the dendrogram output by the hierarchical clustering algorithm to obtain the final clusters of download events. To cut the dendrogram we chose a conservative cut height to error on the side of not grouping related downloads and significantly reduce the possibility of grouping unrelated ones. This process produced 1,205 clusters, thus resulting in an order of magnitude reduc-

tion in the number of items that require manual inspection. In the following section we explain how we analyzed and labeled these clusters.

4.4 Labeling SE Download Attacks

After clustering similar software download events, we manually examine each cluster to distinguish between those that are related SE download attack campaigns, and clusters related to other types of software download events, including benign downloads, malware downloads triggered by drive-by downloads, and (benign or malicious) software updates. This labeling process allows us to focus our attention on studying SE download attacks, and to exclude other types of benign and malicious downloads (notice that because in this paper we are primarily interested on SE attacks, we exclude non-SE malware attacks from our study).

To perform the cluster labeling, each cluster was manually reviewed by randomly sampling 10% of the download events grouped in the cluster, and then performing a detailed manual analysis of the events in this sample set. For small clusters (e.g. clusters with < 50 events) we sampled a minimum of 5 download events. For clusters containing less than 5 download traces, we reviewed all of the events. As discussed earlier, our clustering process uses a conservative cut height. The net effect is that the clusters tend to be “pure,” thus greatly reducing the possibility of errors during the cluster labeling process. At the same time, some groups of download events that are similar to each other may be split into smaller clusters. However, this does not represent a significant problem for our labeling process. The only effect of having a larger number of highly compact clusters is to create additional manual work, since a random sample of events from each cluster is manually analyzed.

In addition to manually reviewing the download paths contained in the clusters, to assist our labeling we also make use of antivirus (AV) labels for the downloaded executable files. To increase AV detections we “aged” the downloads in our dataset for a period of two months, before scanning them with more than 40 AV engines using virustotal.com. Notice that AV labels are mainly used for confirmation purposes. The actual labeling of SE attacks is performed via an extensive review of each download path (i.e., sequence of pages/URLs visited to arrive to the executable file download). If we suspect a cluster is malicious (based on our manual analysis), having one or more AV hits offers additional confirmation, but is not required if we have strong evidence that the download was triggered by an SE attack.

Updates: Even though the heuristics we described in Section 4.2 filter out the vast majority of software updates, our heuristics are quite conservative and therefore some update events may still remain. To determine if

a download event is related to a (malware or benign) update, we examine the length of the download path and the time between requests. If the length of the total download path is < 4 or the time between requests is < 1 second, we consider the download event for detailed manual review. In this case, we analyze the HTTP transactions that precede the download by examining the content for artifacts, such as text and clickable buttons, that are indicators of human interaction. If none are found we label the download as an *update*.

Drive-by: Next we look for drive-by download indicators. To assist our labeling, we borrow some of the features proposed in [30]. Notice that the labeling of drive-by downloads is *not* a contribution of our paper. This is only a means to an end. The novel contributions of this paper are related to studying the characteristics of SE download attacks.

To label drive-by attacks, we look for “exploitable content,” such as pdf, flash, or java code on the path to a malware download. Browser plugins and extensions that process this type of content often expose vulnerabilities that are exploited by attackers. If we suspect the download event under analysis is a drive-by, we reverse engineer the content of the HTTP transactions that precede the suspected attack. This typically requires deobfuscating javascript and analyzing potentially malicious javascript code. For instance, if we identify code that checks for vulnerable versions of browser software and plugins (an indication of “drive-by kits”), we label the download as *drive-by*. We identify and label 26 drive-by downloads.

Social Engineering: If the cluster is not labeled as *update* or *drive-by*, we further examine the download events to determine if they are due to SE attacks. For this analysis, we inspect the content of all HTTP transactions on the download path. This content was saved at the time of the download and does not require revisiting of the URLs on the download path. Because SE downloads are attacks on the user, they are initiated by a user-browser interaction (e.g., clicking a link). Therefore, our goal is to identify the page on the download path containing the link likely clicked by the user that ultimately initiated the executable file download. By manually reviewing the web content included in the download path, we attempt to determine if *deception* or *questionable persuasion* tactics were used to trick the user into downloading the executable file (see Section 3). In case of positive identification of such tactics, we label the cluster as *social engineering*; otherwise, we label it as “likely” benign.

Notice that the analysis and labeling of SE download attacks is mainly based on the identification of deception tactics to trick a user to download an executable file. However, we also use AV scanning for confirmation pur-

poses. By doing so, we found that the majority of the clusters we label as social engineering contained one or more of downloaded files that were labeled as malicious by some AVs. This provides additional confirmation of our labeling of SE download attacks.

Overall, among 1,205 clusters in our dataset, we labeled 136 clusters as *social engineering*. In aggregate, these clusters included a total of 2,004 SE download attacks. In Section 3 we analyzed these SE download attacks and developed a categorization system that allows us to organize these attacks based on the deception and persuasion tactics used to attack the user. In the next section, we measure the popularity of these tactics based on the data we collected.

5 Measuring SE Download Attacks

In this section we measure the popularity of the tactics attackers employ to gain the user’s attention and of the deception and persuasion techniques that convince users to (unknowingly) download malicious and unwanted software. In addition, we measure properties of ad-based SE download attacks, which can be used to inform the development of effective defenses against SE attacks that leverage ad campaigns.

5.1 Popularity of SE Download Attacks

Table 1 shows the number and percentage of SE download attacks for each tactic employed by the attackers to gain the user’s attention. Over 80% of the SE attacks we observed used *ads* displayed on websites visited by the user. An additional 7% employed both *search* and *ad*, whereby the user first queries a search engine and is then presented with targeted ads based on the search terms. The popularity of ads in SE download attacks is likely due to the fact that they are a very efficient way for attackers to reach a large audience, thus maximizing the number of potential victims. Furthermore, well-crafted targeted ads are naturally highly effective at attracting a user’s attention.

Table 1: Popularity of SE techniques for gaining attention.

User’s Attention	Total	Percentage
Ad	1,616	80.64%
Search+Ad	146	7.29%
Search	127	6.34%
Web Post	115	5.74%

Gaining the user’s attention is not sufficient for an SE download attack to succeed. A user must also be tricked into actually “following the lead” and downloading the malicious or unwanted software. Table 2 shows the popularity of the deception and persuasion techniques we observed in our dataset of SE download attacks. The most

popular combination of deception and persuasion techniques is *repackage+entice*, making up over 48% of the observations. In most of these cases, the user is offered some type of “free” software of interest (e.g., a game or utility). Unfortunately, while the free software itself may not be malicious, it is often bundled with malicious applications such as *adware* or PUPs.

Table 2: Popularity of SE techniques for tricking the user.

Trick	Total	Percentage
Repackage+Entice	972	48.50%
Invent+Impersonate+Alarm	434	21.66%
Invent+Impersonate+Comply	384	19.16%
Repackage+Decoy	155	7.74%
Impersonate+Decoy	46	2.30%
Impersonate+Entice+Decoy	12	0.60%
Invent+Comply	4	0.20%
Impersonate+Alarm	1	0.05%

The next two most popular combinations of deception and persuasion tactics are *invent+impersonate+alarm* and *invent+impersonate+comply*, comprising 22% and 19% of the SE downloads we observed. An example of *invent+impersonate+alarm* is a Fake Java update attack, whereby the user is shown an ad that states “WARNING!!! Your Java Version is Outdated and has Security Risks, Please Update Now!” and uses images (e.g., logos or icons) related to Java (notice that this and all other examples we use throughout the paper represent real-world cases of successful SE attacks from our dataset). Ads like this are typically presented to users while they are visiting legitimate websites. In this example, the attacker is *inventing* the scenario that the user’s Java VM is out-of-date, *alarming* them with “WARNING!!!” displayed in a pop-up ad, and then *impersonating* a Java update that must be installed to resolve the issue. Notice that this is different from *repackage+entice*, in that the real Java software update is never delivered (only the malware is). Furthermore, the attacker leverages alarming messages about a well-known software to more aggressively “push” the user to download and install malicious software.

The difference between *invent+impersonate+alarm* and *invent+impersonate+comply* is in the persuasion component; i.e., *alarm* vs. *comply*. *Alarm* leverages fear (e.g., the computer may be compromised) to compel the user to download and install malicious software. On the other hand, *comply* leverages a pretend requirement necessary to complete a desired user task. For instance, a user may be presented with an ad on a video streaming website that says “Please Install Flash Player Pro To Continue. Top Video Sites Require The Latest Adobe Flash Player Update.” In this example, the attacker is *inventing* the need to install “Flash Player Pro” and tells the user they must *comply* before they can continue with watching the desired video. Unfortunately, this results

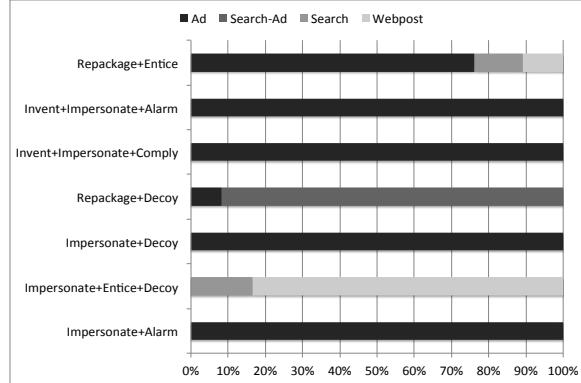

Figure 3: How attackers gain the user’s attention per deception/persuasion technique.

in the user downloading malicious software that simply *impersonates* a popular benign application and offers no actual utility to the user.

Table 3: Popularity of different “scam” tactics in the Ad:Invent+Impersonate subclasses.

	Alarm	Comply
Fake Flash	68%	20%
Fake Java	30%	0%
Fake AV	1%	0%
Fake Browser	1%	0%
Fake Player	0%	80%

Table 3 shows the popularity of different “scam” tactics in the invent+impersonate subclasses *alarm* and *comply*. Fake Flash and Java updates are the two most popular in the *alarm* class. In this same class we also observe Fake Browser updates and Fake AV alerts, but they are much less common, each comprising only about 1% of our observations. Fake Flash updates are also common in the *comply* class; however, the most popular scam tactic is telling the user they must update or install a new video player before they can continue. In these Fake Player attacks, images that resemble Adobe Flash Player are often used, but the terms “Adobe” or “Flash” are not directly mentioned. Therefore in Table 3 we distinguish between explicit Fake Flash and Fake Player.

Figure 3 shows how attackers gain the user’s attention for each of the observed deception and persuasion techniques. For instance, ads are the most common way used to attract users’ attention for repackage+entice, comprising 75% of our observations. *Search* and *web posts* contribute the remaining 25%. All observations for invent+impersonate+alarm, invent+impersonate+comply, impersonate+alarm and impersonate+decoy rely exclusively on ads to gain the user’s attention. At the other extreme, none of our observations for impersonate+entice+decoy use ads. This is likely due to the fact that this combination of deception and persuasion

techniques is more effective when the user’s attention is gained through *search* and *web posts*. However, notice that this comprises less than 1% of all SE downloads in our dataset (see Table 2).

5.2 Ad-based SE Download Delivery Paths

As shown in Table 1, the majority of SE attacks we observed use online ads to attract users’ attention. To better understand these attacks, we examine the characteristics of their *ad delivery path*. We begin by reconstructing the web path (i.e., the sequence of URLs) followed by the victims to arrive to the download URL (see Section 4). Then, we identify the first ad-related node on the web path using a set of regular expressions derived from the Adblock Plus rules [1]. We define the set of nodes (i.e., HTTP transactions) on the web path beginning at the first ad node and ending at the download node as the *ad delivery path*.

Table 4: Top five ad entry point domains.

Comply	Alarm	Entice
26% onclickads.net	16% adcash.com	20% doubleclick.net
10% adcash.com	7% onclickads.net	16% google.com
10% popads.net	7% msn.com	12% googleadservices.com
7% putlocker.is	6% yesadsrv.com	11% msn.com
3% allmyvideos.net	4% yu0123456.com	8% coupons.com

Table 4 shows the top 5 “entry point” domain names on the ad delivery paths (i.e., the first domain on the ad paths) for the *comply*, *alarm* and *entice* attack classes. Almost 50% of the ad entry points for the *comply* class begin with one of the following domains: `onclickads.net`, `adcash.com` or `popads.net`. By investigating these domains, we found that they have also been abused by adware in the past. Specifically, these domains are the source of pop-up ads injected into the user’s browsing experience by several well known adware programs and ad-injecting extensions [43].

Table 4 also shows that the top two ad entry points for the *alarm* class are the same as the *comply* class, though in reverse ranking. The third domain is `msn.com`, which has a good reputation. However, this domain is appearing at the top of the ranking probably because it sometimes redirects (via syndication) to less reputable ad networks, which in turn direct the user to an SE download. Notice also that the top entry domains in the *entice* class all have very good reputations (`doubleclick.net` is owned by Google). This is likely due to the fact that the majority of downloads in this class are for legitimate software that is simply bundled with “less aggressive” PUPs.

Besides performing an analysis of the “entry point” to the ad delivery path, we also analyze the last node on the path, namely the HTTP transaction that delivers the download. Table 5 shows the most popular SE download domains for the *comply*, *alarm* and *entice* classes. We

Table 5: Top five ad-driven SE download domains.

Comply	Alarm	Entice
17% softwaare.net	7% downloaddabs.com	41% imgfarm.com
5% newthplugin.com	4% downloaddado.com	17% coupons.com
5% greatsoftfree.com	4% whensoftisupdated.net	11% shopathome.com
4% soft-dld.com	3% safesystemupgrade.org	5% crusharcade.com
3% younplugin.com	3% onlinelivevideo.org	3% ilivid.com

found that the domains listed for the *comply* and *entice* classes serve mostly adware and PUPs.

To better understand the network-level properties of SE downloads, we also measure the “age” of these domains by leveraging a large passive DNS database (pDNS-DB) that stores historic domain name resolutions. Specifically, we define the domain age as the difference in days from the time the domain was first queried (i.e., first recorded in the pDNS-DB) to the day of the download. All the domains in Table 5 that are part of the *comply* and *alarm* classes are less than 200 days old, with the majority being less than 90 days. On the other hand, the domains in Table 5 for the *entice* class are all at least several years old. This is because most of the downloads in this class are for legitimate software that is simply bundled with adware or PUPs. For instance, we find a large variety of “free” software ads that direct users to the domain `imgfarm.com` for download. This is the reason that over 40% of the downloads in the *entice* class are from that domain.

The “middle of path” domains, namely the ones between the ad entry point and the download domain itself, tend to be a mix of recent and old domains. In fact, the most popular *comply* and *alarm* class “middle of path” domains are a 50/50 split of recent and old. However, this is not the case for the *entice* class, for which most domains are several years old. At the same time, the majority of ad delivery paths for all three classes include at least one middle domain name with an age that is less than 200 days.

5.3 Ad-Driven Benign Downloads

As mentioned earlier, more than 80% of the SE download attacks we observed use ads to gain the user’s attention (see Table 1). Based on common experience, it may seem unlikely that many benign software downloads would result from clicking on an ad. As a result, one may think that if software is downloaded after clicking on an ad, that software is unlikely to be benign. Somewhat surprisingly, we found that this may not necessarily be the case, as we explain below.

First, to automatically identify ad-driven benign software downloads, we first derive a set of ad detection regular expressions from the rules used by the popular AdBlock Plus browser extension [1]. We match these regular expressions against the nodes on the reconstructed download path for each benign download (the down-

load labeling process is described in Section 4.4). If an AdBlock rule matches the download path, we label that benign software download as *ad-driven*. We find that around 7% of all benign software downloads are ad-driven. Even though the percentage is low compared to SE downloads, in absolute terms this number is significant because the vast majority of software downloads observed in a network are benign. In fact, by considering the overall number of confirmed malware and benign software downloads and how many of these downloads are ad-driven, we find that if a software download is reached by clicking on an ad there is a 40% chance that that software is benign.

Table 6: Ad-based benign download popularity.

Category	Percentage
Games	32%
Utilities	30%
Music	15%
Business	11%
Video	8%
Graphics	2%
Social	2%

To further understand what type of benign software downloads are ad-driven, we investigate through manual analysis 100 randomly selected samples of benign software download events. Table 6 shows the type of software that is represented in our sample and their relative popularity. Games and utilities are the most popular categories, comprising 62% of all downloads. For example, the game “Trion Worlds” is the most popular with 17 downloads, followed by “Spotify” with 10 downloads.

6 Detecting SE Download Attacks

In this section, we measure the antivirus (AV) detection rate for SE downloads and group them into broad malware classes using AV labels. Also, we show that it is possible to accurately detect SE download attacks by constructing a statistical classifier that uses features derived from the SE attack measurements we presented in Section 5.

6.1 Antivirus Detection

To assess how AV products cope with SE downloads, we scan each SE download sample in our dataset with more than 40 AV engines (using VirusTotal.com). We scanned each of the samples on the day we collected them. Then, we also “aged” the samples for a period of one month, and rescanned them with the same set of AV engines. If at least one of the top five AV vendors (w.r.t. market share) and a minimum of two others detect it, we label the executable as malicious.

We first group malicious downloads into three broad classes, namely *malware*, *adware* and *PUP*. These

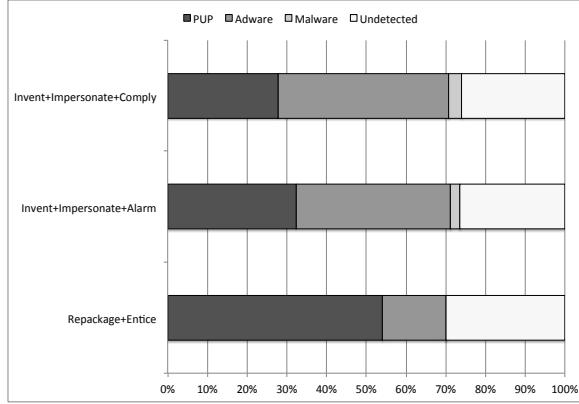

Figure 4: AV detections one month after download.

classes are meant to roughly indicate the potential “aggressiveness” of the malicious software. We assign these class labels based on a conservative set of heuristics that consist of matching keywords on the labels provided by the AVs. For instance, to identify adware we look for the string “adware” as well as the names of several popular adware applications (e.g., “amonetize,” etc.). Similarly, for the PUP class we look for the strings such as “PUP”, “PUA” and popular PUP application names. If both PUP and adware match, we label the sample based on a majority voting rule (across the different AV vendor labels). In the case of a tie, we conservatively label the sample as PUP. The remaining samples are labeled as malware, and manually reviewed for verification purposes.

Figure 4 shows the percentage of attacks that result in the download of malware, adware, and PUP, respectively. We show a breakdown for the top three deception/persuasion categories, which in aggregate represent more than 95% of all ad-driven SE attacks. The majority of malicious downloads in the invent+impersonate+comply and invent+impersonate+alarm deception/persuasion tactics belong to the *adware* class. A smaller percentage of downloads in these categories, 3.2% and 2.4% respectively, are labeled as *malware*. For repackage+entice the majority of downloads are labeled as *PUP*; no malware is found in this deception/persuasion category.

Notice that the relatively small percentage of *malware* is likely due to the fact that our heuristics for grouping malicious downloads into broad classes is very conservative, because it requires only a single AV label to contain an “adware” or “PUP” string to label the sample as belonging to the adware or PUP classes (see Section 4.4). In addition, adware is simply much more prevalent than malware, making the malware set size look relatively small compared to the rest of the dataset. Lastly, notice that only 70% – 75% of all malicious executables were labeled by the AVs, even after “aging” and rescanning the

samples. The remaining 25% – 30% is therefore labeled as *undetected* in Figure 4.

Table 7 shows the AV detection rate on the day of download for malware, adware and PUPs. Namely, we consider all SE download samples that were detected by AVs after aging and rescanning (i.e., after one month), and show the percentage of these samples that were also detected on the day we first observed them being downloaded. As can be seen, the detection rate in this case is quite small, thus confirming the reactive nature of AV detection.

Table 7: Zero day AV detections.

	Malware	Adware	PUP
Invent+Impersonate+Comply	0%	0%	6.9%
Invent+Impersonate+Alarm	5.9%	11.6%	26.9%
Repackage+Entice	NA	28.7%	34.4%

6.2 SE Detection Classifier

Guided by our measurements around SE attacks that we presented in Section 5, we devise a set of statistical features that can be used to accurately detect ad-driven SE downloads. We focus on ad-driven attacks because they are responsible for more than 80% of all SE downloads we observed (see Table 1).

Problem Definition. Given an executable file download event observed on the network, we first automatically reconstruct its *download path*, i.e., the sequence of pages/URLs the user visited to arrive to the HTTP transaction carrying the file, as explained in Section 4. Then, given a set of labeled ad-driven SE download events (Section 4.4) and also ad-driven benign software downloads (Section 5.3), we first translate the *download path* of each event into a vector of statistical features. Finally, we use the obtained labeled dataset of feature vectors to train a statistical classifier using the Random Forest [10] algorithm that can detect future ad-driven SE download attacks and distinguish them from benign ad-driven software downloads.

Statistical Features. We now present the set of detection features we derived and the intuitions behind their utility. In the following, we assume to be given as input the download path related to a software download event observed on the network, which we translate into a feature vector. Notice that no single feature by itself enables accurate detection; it’s their combination that allows us to reach high accuracy.

- **Ad-Driven** (binary feature). We check whether the download path contains an ad-related URL. This feature is computed by matching AdBlock [1] rules against the sequence of URLs on the download path.
Intuition: while the majority of SE downloads are

promoted via advertisement (Section 5), only 7% of benign downloads result from clicking on an ad (Section 5.3).

- **Minimum Ad Domain Age.** We measure the age of each domain on the *ad path*, namely the subsequence of the download path consisting of ad-related domains, and use the minimum age across these domains. *Intuition:* ad-serving domains that consistently direct users to malicious ads are often blacklisted, so they move to new domains. In essence, this feature is a way of (approximately) measuring the reputation of the *ad path*. Our measurements show that the majority of ad paths for the *comply*, *alarm* and *entice* attack classes all have domains less than one year in age. For benign download paths, this is true in only less than 5% of the cases.
- **Maximum Ad Domain Popularity.** Using our dataset (Section 4), we first consider all ad-related domains involved in the download paths observed in the past (i.e., in the training set). Then, for each domain, we count the number of distinct download paths on which the domain appeared, for both ad-driven SE attacks and the benign download paths. If the domain is found in more than 1% of the benign download paths, it is discarded. Otherwise, we compute the number of distinct SE attack paths in which the domain appeared. Finally, given all ad-related domains in the download path we are currently considering, we take maximum number of times a domain along this path appeared in an SE attack path. *Intuition:* some ad networks, and the domains from which they serve ads, are more abused than others, e.g., due to scarce policing of ad-related fraud and abuse in lower-tier ad networks. Therefore, they tend to appear more frequently in the download path of SE downloads. For instance, Table 4 in Section 5.2 shows the popularity of *ad entry points* for SE downloads.
- **Download Domain Age.** We measure the number of days between the download event and the first time we observed a DNS query to the effective second level domain for the download URL (final node of the web path) using a large historic passive DNS database. *Intuition:* the vast majority of benign downloads are delivered from domains that have been active for a long time because it takes time for a website to establish itself and attract visitors. On the other hand, SE domains are often “young” as they change frequently to avoid blacklisting. Our data shows that the download domain of over 80% of the invent+impersonate SE subcategories *comply*

and *alarm* are less than one year in age, whereas for benign download this only holds in 5% of the cases.

- **Download Domain Alexa Rank.** We measure the Alexa rank of the domain that served the software download. We compute this features using the effective second level domain for the download URL and the Alexa top 1 million list. *Intuition:* malicious executables are more likely to be hosted on unpopular domains because of their need of avoiding blacklisting. Conversely, benign software downloads are often hosted on popular domains. For instance, measurements on our data show that over 60% of the benign downloads are from domains with an Alexa rank in the top 100,000. On the other hand, the more “aggressive” SE downloads, such as those from the *alarm* class, are primarily delivered from very unpopular domains (very few are in the top 1 million). At the same time, the domains involved in SE attacks that trigger the download of PUP fall somewhere between, in terms of domain popularity.

6.3 Evaluating the SE Detection Classifier

In this section, we present the results of the evaluation of our SE detection classifier. We start by describing the composition of the training and test dataset, and then present an analysis of the false and true positives.

Datasets. To measure the effectiveness of the SE classifier, we use two separate datasets. The first dataset, \mathcal{D}_1 , which we use to train the classifier, consists of the software downloads described and measured in Sections 4 and 5. Specifically, this dataset includes 1,556 SE download paths (we consider all ad-driven SE attacks from the dataset described in Section 4), and 11,655 benign download paths.

The second dataset, \mathcal{D}_2 , consists of new executable downloads (and their reconstructed download paths) that we collected from the same deployment network in the *three months following* the completion of the measurements we presented in Section 5. Notice also that, \mathcal{D}_2 was collected *after* the feature engineering phase and after building our detection classifier. Namely, both the feature engineering and the training of the classifier were completed with *no access* to the data in \mathcal{D}_2 . Overall, \mathcal{D}_2 contains 1,338 ad-driven SE downloads, and 9,760 benign download paths. We label \mathcal{D}_2 following the steps outlined in Section 4.4.

Classification Results. After training our SE detection classifier using dataset \mathcal{D}_1 and the Random Forest learning algorithm, we test the classifier on dataset \mathcal{D}_2 .

Table 8 reports the confusion matrix for the classification results. The classifier correctly identified over 91% of the ad-driven SE downloads. Furthermore, it has a very low false positive rate of 0.5%.

Table 8: Confusion matrix for the SE detection classifier.

	Predicted Class	
	Benign	Ad-Based SE
Benign	99.5%	0.5%
Ad-Based SE	8.8%	91.2%

Table 9: SE Subclass Performance.

	True Positives
Repackage+Entice	65%
Invent+Impersonate+Alarm	98%
Invent+Impersonate+Comply	90%

Figure 9 shows a breakdown of the classification results for the subclasses of ad-based SE downloads. The invent+impersonate+alarm and invent+impersonate+comply categories have 98% and 90% true positive rates, respectfully. The lower performance for repackage+entice is due to downloads of legitimate software bundled with PUPs from well established domains. Because these domains are “mixed use,” and have high popularity or Alexa ranking, they make the detection task more difficult.

Feature Importance. We estimate feature importance by performing forward feature selection [20]. The single feature that provides the largest information gain is *download domain age*. Using only that feature we have a 69% true positive rate and a 6% false positive rate. By adding *maximum ad domain popularity*, we obtain a true positive rate above 80% with less than 3% false positives. As we add other features (using the forward search), both the true positives and false positives continue to improve. Thus, all the features help achieve high accuracy.

7 Discussion

In this paper, we focus exclusively on *successful* web-based SE download attacks (we consider the attacks we collected and study successful because they actually trigger the delivery of malicious software to the victim’s machine). Social engineering attacks carried over different channels (e.g., email) and that have different objectives (e.g., phishing attacks to steal personal information, rather than malware infections) are not part of our measurements, and are therefore also not reflected in the categories of SE tactics we described in Section 3. However, we believe ours is an important contribution. In fact, as defenses for drive-by downloads continue to improve (e.g., through the hardening of browser software and operating system defenses) we expect the attackers to increasingly make use of web-based SE attacks for malware propagation. Therefore, the reconstruction and analysis of SE download attacks is important because in-the-wild SE attack samples could be used to better train users and mitigate the impact of future attacks; thus, complementing automatic attack detection solutions.

Our study relies on visibility over HTTP traffic and

deep packet inspection. One might think that the inability to analyze HTTPS traffic represents a significant limitation. However, it is important to take into account the following considerations. When a user browses from an HTTPS to an HTTP site, they are often redirected through an unsecured intermediate URL, so that the `Referer` field can be populated with the domain and other information related to the origin site [3]. Alternatively, the origin site can set its referrer policies [2] to achieve the same result without need of intermediate redirections. As an example, even though many of the searches performed using search engines such as Google, Yahoo and Bing occurred over HTTPS, we were able to identify the search engines as the origin of web paths because the related domain names appeared in the `Referer` field of the subsequent HTTP transactions. Furthermore, modern enterprise networks commonly employ SSL man-in-the-middle (MITM) proxies that decrypt traffic for inspection. Therefore, our SE attack detection system could be deployed alongside SSL MITM proxies.

Throughout the study, we use the term *malicious* to describe the software downloaded as the result of an SE attack. However, there exist many shades of maliciousness and some malicious software (e.g., ransomware, botnets, etc.) are more “aggressive” than others (e.g., adware and PUPs). Therefore, in several parts of the analysis we broke down our results by distinguishing between *malware*, *adware* and *PUPs*. As shown in Section 6.1, only a relatively small percentage of the SE downloads collected for our measurements were categorized by our AV-label-based heuristics as *malware*. The majority were labeled as adware or PUP. However, we should notice that AV labels are known to be noisy and that our labeling heuristics are very conservative (see Section 4.4). Furthermore, over 25% of the malicious downloads remained unlabeled due to lack of AV detection (Section 6.1). Therefore, it is possible that the number of malware is somewhat higher than reflected in Section 6.1. However, the categorization system, network-level properties and detection results for SE attacks that deliver adware apply to attacks that result in malware downloads as well.

While the software downloads and traffic we collected for our study were collected from a single academic network, we should consider that the deployment network was very large, serving tens of thousands diverse users, consisting of users from different ages, cultures and backgrounds.

Because our SE detection classifier is designed to detect ad-based SE download attacks, an attacker could evade the system by using tactics other than online ads to attract the user’s attention (e.g., *search* or *web post*, as discussed in Section 3). However, advertisements are the

predominant tactic used by attackers because they allow them to “publish” their SE attacks on sites that already popular with the targeted victims. In addition, ads are only shown to the users that “match” their delivery criteria, thus reducing exposure to others (including security researchers) that could result in the discovery and mitigation of these attack vectors.

Another way an attacker may try to evade detection, is to specifically attempt to evade our statistical features (see Section 6.2). For instance, to evade the *download domain age* and *domain Alexa rank* features, the attacker could host the malicious files on a free file sharing site. This could result in a download domain with an age > 1 year and a high Alexa ranking. However, the *ad-driven*, *minimum ad domain age* and *maximum ad domain popularity* features, which are harder for the attacker to control, could still allow to identify most attacks. For example, simply knowing that a software download resulted from an online ad puts its probability of being malicious at more than 50%, according to the real-world data we collected (see Section 5.3). Furthermore, if hosting malicious downloads on free hosting sites became popular, then a *Free File Hosting* feature could be added to our feature set, as it is unlikely that many ad-driven benign software downloads are served from free file hosting sites.

8 Related Work

Social engineering is primarily an attack on users, not systems. The fundamental concepts that are employed to exploit the user are rooted in modern psychology, specifically in the study of persuasion [13] and deception [41]. SE attacks have been studied in [21, 27]. While these works study SE tactics in general, they do not focus on SE download attacks. To the best of our knowledge, the only systematic study on SE malware is [8], which discusses the psychological and technical ploys adopted by SE attacks and some trends in SE malware. However, [8] focuses on malware that spreads via e-mail and on SE tactics used by malware to lure the user to activate (i.e., run) the malicious code. In addition, the data analyzed in [8] is limited to malware attack case studies and statistics published by others in the *VirusBulletin* journal until 2010. In contrast, we focus on web-based SE downloads, and on reconstructing and analyzing how users are tricked into downloading malicious software in the first place. Also, our analysis is based on recent real-world instances of successful SE attacks collected from a live network.

Malware downloads have been studied in a number of works [11, 22, 34, 39]. For instance, [34, 39] use a content-agnostic detection approach that relies on computing a reputation score for the domains/IPs from which malware downloads are served. However, [34, 39] are

generic malware download detection systems that offer no understanding of what caused a malware download in the first place. In other words, they cannot identify the origin of the attack, but only its side effects (i.e., only the malware download even itself), and therefore offer no clue on whether an infection was caused by a SE attack. Other works focus on the properties of malware droppers [11, 22], whereby already infected machines download malware updates or new malware strains. In contrast, we study how users fall victim to web-based SE download attacks, and design a detection system that can accurately detect ad-driven SE downloads.

Researchers have also separately examined specific types of SE malware attacks, such FakeAVs [15, 16, 19, 25, 37]. Our work is different because we propose a general approach to studying, measuring and classifying SE download attacks on the web. We do not limit ourselves to specific attack types such as Fake AVs. Therefore, our work has broader applications, and also provides mitigation against generic ad-based SE download attacks, which represent a large percentage of all SE download attacks we observed in the wild.

Other works have focused on traffic redirection chains to understand and detect malicious websites and attack delivery [23, 26, 38]. Among these systems, Mad-Tracer [23] studies malicious advertisement, including ad chains that deliver malware downloads. This is done by crawling popular websites, and using a supervised classifier trained on data labeled by leveraging domain name blacklists (e.g., Google SafeBrowsing). While part of our work, namely our ad-driven SE download detection system, also leverages some properties of advertisement chains to detect ad-driven malicious downloads, it is important to notice that we focus specifically on *in-the-wild SE download attacks* and are able to identify a large variety of SE download attacks. For instance, [23] only reports fake anti-viruses (AVs) as malware delivered via ad-based *scams*. Instead, in our study we find many other types of SE-driven downloads that leverage a variety of deception and persuasion tactics. In fact, our measurements show that fake AVs represent only a small fraction (less than 1%) of all SE attacks. In addition, rather than actively looking (or crawling) for possible malware downloads on popular websites, we collect *live SE attacks* by directly witnessing successful attacks against users in a large academic network. This allows us to collect *successful SE attacks*, rather than *possible attacks* as done in [23].

In our work, we use a combination of web traffic reconstruction and analysis to trace back the origin of the attacks, namely the SE tactic that tricked the user into downloading malicious software. Researchers have studied web traffic reconstruction in [12, 29, 30, 42]. Among these, the closest to our work is WebWitness [30], a re-

cently proposed incident investigation system that aims to provide context to malicious downloads by reconstructing the path taken by the user to download executable files. WebWitness is able to classify the cause of a malicious download as *drive-by*, *social engineering* or *update*. In [30], the main focus is on studying drive-by downloads and developing a new defense against drive-by download attacks. However, social engineering attacks are not studied. WebWitness is able to separate drive-by downloads from social engineering downloads once an *oracle* identifies a download as malicious, and is not able to independently detect SE attack. Although we utilize WebWitness' trace-back algorithm, our contributions are very different from [30], because we study SE download attacks in depth, focusing on their collection, analysis and categorization, as well as the detection and mitigation of ad-based SE-driven infections.

9 Conclusion

In this paper, we presented the first systematic study of social engineering (SE) attacks that trigger software downloads. To this end, we collected and reconstructed more than two thousand examples of in-the-wild SE download attacks captured at a large academic network. We performed a detailed analysis and measurements on the collected data, and developed a categorization system to identify and organize the tactics typically employed by attackers to make SE download attacks successful. Furthermore, by measuring the characteristics of the network infrastructure used to deliver such SE attacks, we were able to engineer a number of features that can be leveraged to distinguish between SE and benign (or non-SE) software downloads with a true positive rate of 91% at a false positive rate of only 0.5%.

Abstract

This paper discusses a novel approach to specification-based intrusion detection in the field of networked control systems. Our approach reduces the substantial human effort required to deploy a specification-based intrusion detection system by automating the development of its specification rules. We observe that networked control systems often include comprehensive documentation used by operators to manage their infrastructures. Our approach leverages the same documentation to automatically derive the specification rules and continuously monitor network traffic. In this paper, we implement this approach for BACnet-based building automation systems and test its effectiveness against two real infrastructures deployed at the University of Twente and the Lawrence Berkeley National Laboratory (LBNL). Our implementation successfully identifies process control mistakes and potentially dangerous misconfigurations. This confirms the need for an improved monitoring of networked control system infrastructures.

1 Introduction

Starting from Denning’s seminal work in 1986 [9], *intrusion detection* has evolved into a number of different approaches. Among them, *anomaly-based intrusion detection* and, most recently, *specification-based intrusion detection* have gained attention for their potential to detect previously unknown attacks (e.g., zero-day attacks).

A specification-based intrusion detection system (IDS) leverages functional specifications of a system to model its properties, or *features*, creating a reference of correct behavior. Differently from anomaly-based IDSs, behavior of features is not derived by a learning phase (prone to false positives) but directly extracted from documentation. This ensures the quality of the generated models and improves detection. Several research efforts in the literature confirm the accuracy of

specification-based intrusion detection [62]. However, these approaches assume manual (human) analyses, often focused just on network protocol documentations.

Scaling a specification-based approach to an entire infrastructure faces three key challenges. First, targeted systems do not always have consistent features, and thus *constraints*, that allow to describe functional rules (e.g., common networks do not usually guarantee stable communication patterns or message timing). Second, even when such constraints are present, bridging the semantic gap between infrastructure properties and the low-level features actually observable by an IDS remains hard [22]. Third, deploying a specification-based intrusion detection requires an explicit and unambiguous description of the features’ behaviors, as well as substantial human effort in crafting the related specification rules.

This work aims to fill this last challenge by automating specification-based intrusion detection to a fairly high degree. We propose an approach to automatically mine IDSs’ specification rules from available documentation. Our approach works under the following assumptions:

- Documentation about monitored systems must be *available*. No specification-based intrusion detection would be possible without relying on correct information that describes an infrastructure’s components, mechanisms and constraints. Documentation should be provided in an electronic form to allow automated knowledge extraction.
- Information retrieved from the documentation must be *linkable* to what an IDS can observe. On a network, information about components, mechanisms and constraints need to map to features monitored by the IDS (e.g., information on a whitelist of network services should link to the correct IP address).

We do not claim that these principles can be generically applied to any system. However, we observe that environments such as Networked Control Systems

(NCSs) [20] suit this approach. NCSs are “systems whose constituents such as sensors, actuators, and controllers are distributed over a network, and their corresponding control-loops are formed through a network layer” [30]. Examples of NCSs include: industrial control systems [65], building automation systems [42] and in-vehicle networks [31]. NCSs generally have the properties discussed above. Communications over these networks are quite stable [22] (e.g., neither the number of devices nor the way data is shared change regularly). Moreover, automation guarantees the presence of control algorithms and consequently the existence of consistent features that will eventually become the core of the specification rules. These features and their constraints also represent the most attractive target for an attacker who wants to manipulate the controlled processes [14].

The two assumptions defined above hold for NCSs. Information related to system features are often documented in configuration files, reference books and manuals (e.g., “Substation Configuration Language” files for industrial control systems, “Protocol Implementation Conformance Statement” for building automation systems, CAN matrixes and corresponding documentation for in-vehicle networks). Linkability is generally guaranteed by the absence of encryption and by the verbosity of the adopted protocols.

In this paper, we design and discuss a specification-based network intrusion detection system (NIDS) for BACnet-based building automation systems to demonstrate and investigate our concept. First, we present specification-based intrusion detection in §2. Then, we introduce building automation and BACnet in §3. We outline our approach in §4. Details of the approach in the context of building automation systems are discussed in §5 to §7. Finally, we examine the general applicability of our work in §8.

2 State of the Art

Ko et al. introduce specification-based intrusion detection in [34]. The authors describe their approach towards automated detection of Unix privileged program misuses and suggest to “specify programs’ intended behavior” by modeling their normal execution beforehand. The proposed solution works through the definition of a Program Policy Specification Language aiming to formally define programs’ operations by simple predicate logic and regular expressions. Later works such as [13] resume and improve the proposed ideas. Ko et al. improve their introductory research in [35] by defining a formal framework used to define and detail security-relevant behavior of Unix programs. In [33], the framework gets integrated into a comprehensive specification-based IDS, called SHIM. SHIM merges several different detection

approaches that apply to both network communications and operating system activities. Its use, together with machine learning techniques, was shown to be an effective solution towards the development of automated intrusion response strategies [3]. From the previous works, Sekar et al. continue developing the research field by proposing complementary approaches in [52] (based on the use of the Auditing Specification Language) and [54] (based on a custom language called “Regular Expressions for Events” or REE). The same authors, present in [53] a hybrid approach aiming to increase the information of a specification-based IDS with the use of anomaly-based intrusion detection techniques. The authors use Extended Finite State Automata (EFSA) to model and detail network protocol behavior. Then they refine the set of monitored features via a learning phase exploiting statistical analyses on the traffic traces.

Over the years, researchers customized specification-based intrusion detection to fit different infrastructures such as mobile ad hoc networks [60, 44, 23, 56, 61, 19] and WLANs [16]. Furthermore, specification-based IDSs were developed for specific use cases both for network-based (e.g., VoIP technologies [59], carrier Ethernet [26]) and host-based security (e.g., kernel dynamic data structures [48], mobile operating systems [7]).

Specification-based intrusion detection has gained a main role in NCSs. Works such as [8], [27], and [37] present specification-based IDSs for Modbus, Zigbee and DNP3 respectively. Hadeli et al. notably apply a semi-automated specification approach to substation automation systems employing MMS and GOOSE [21]. The authors leverage operator input to parse infrastructure-related documentation and derive security checks. Ultimately, Berthier et al. take this approach a step forward by modeling not just employed protocols (in this case C12.22) but smart-meter security constraints and policies as well [4]. This research shows the feasibility and effectiveness of modeling high-level infrastructure properties.

State-of-the-art research on specification-based intrusion detection assumes that protocol and system documentation is readily available when designing and configuring the IDS. Few thoughts are spent on where and how to retrieve this information, especially not in an automated way. Moreover, all the aforementioned works do not explore *the possibility of autonomously extracting the information needed to build the related IDSs from documentation*, instead relying on human evaluation and translation to rules. This possibility would allow to efficiently apply specification-based approaches to entire infrastructures. As discussed in the introduction, our research focuses on this key aspect of specification-based intrusion detection with the aim of making its development more time-effective and accurate.

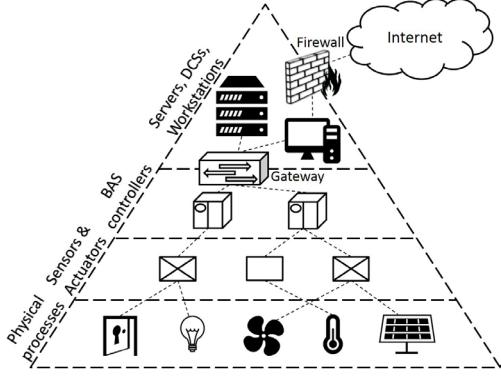

Figure 1: Building automation network layout

3 Case Study: Building Automation

Building automation systems (BASs) or building management systems (BMSs) are networked infrastructures controlling operations and services within a building (or a group of buildings). Among other uses, building automation systems can monitor and control HVAC (heating, ventilation, and air conditioning), lighting, energy consumption, and physical security and safety [42].

A building automation network usually follows a hierarchical layout [28] (Figure 1). At the bottom, sensors and actuators directly connect to the monitored physical processes and send information back and forth to building automation controllers. Controllers communicate with servers and distributed control systems (DCSs) to coordinate high-level control procedures and policies. Finally, operators can access and manage building automation components connecting through their workstations and human-machine interfaces (HMIs).

In the last decade, the employment of building automation solutions has constantly increased (both for commercial and residential buildings) and its market share is expected to grow in the following years [39]. Despite numerous benefits (e.g., energy efficiency, “smart homes”, etc.) building automation makes several new threat scenarios not just feasible but realistic [24, 17, 18, 47]. Nevertheless, only few solutions have been proposed to improve building automation system security [18, 6, 45].

3.1 BACnet

The “Building Automation and Control Network” (BACnet) protocol [1] facilitates building automation system communication for a wide array of different devices and different settings. While exact statistics of the proliferation of BACnet are difficult to come by, already back in 2003 there were more than 28,000 BACnet installations in 82 countries [28].

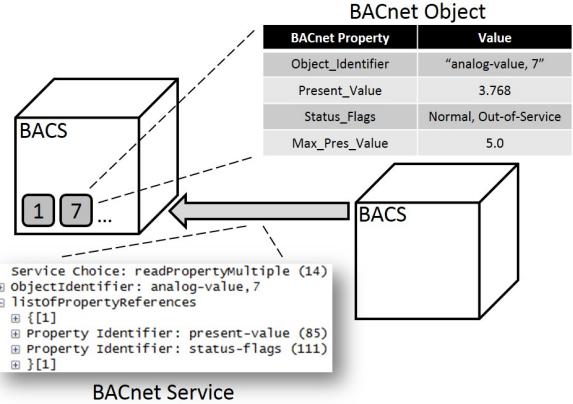

Figure 2: BACnet interaction example

BACnet has a layered protocol architecture, similar to the ISO/OSI model. The BACnet protocol has an application layer, containing the actual application data payload as well as a network layer that abstracts the differences of the network architectures supported by BACnet and implements its own routing protocol. Underneath the network layer, BACnet also specifies how it can be used with different types of data links.

The BACnet application layer rests on two important core concepts: *objects* and *services* (Figure 2). A Building Automation and Control System (BACS)¹ includes one or more BACnet objects that are used to represent its functions. Objects are of a specific type, like Analog Input or Analog Output. BACnet supports a wide range of high-level object types like Calendars, Date Value objects, or Credential Data Input objects. BACnet users and vendors can define “proprietary” objects as well to serve specific functionalities. Object types have different attributes that are called properties, which are extensible for specific purposes. The second core concept of the BACnet application layer are services. While objects describe the different functions that are implemented by a BACS, services define how to communicate with the BACS, offering functionality such as reading object information from a device. Their names reflect the semantics of the operation (e.g., ReadProperty).

Individual BACSS typically only support a small selection of possible objects and services. Manufacturers use a “Protocol Implementation Conformance Statement” (PICS) to describe which objects and services are implemented by a specific device. The BACnet standard implies that all BACSS shall have a PICS identifying “all of the portions of BACnet that are implemented” [1]. Information in PICS includes: a brief description of the de-

¹In the remainder of this paper, we will refer to any controller implementing BACnet as BACS.

vice; a list of supported BACnet Interoperability Building Blocks (BIBBs) that define classes of BACnet services supported by a device; and a list of supported standard and proprietary BACnet objects and properties with their characteristics.

To complete device descriptions, operators may take advantage of configuration files such as “Engineering Data Exchange” (EDE) files [2]. Generally, operators compile these documents to represent internal characteristics of a deployed BACS. EDE files include detail information on devices’ BACnet implementations (e.g., which BACnet objects a device is currently using) and value constraints (e.g., in Figure 2, Present_Value of Analog Value 7 must be less than 5.0).

3.2 Attacks on BACnet

BACnet defines a limited security architecture providing peer and operator authentication along with data confidentiality and integrity (“Clause 24 — Network Security” [1]). However, none of this is implemented in available products [43]. This leaves BACnet infrastructures vulnerable to numerous cyber-threats [24, 63, 58, 29].

We categorize attacks on BACnet into three main groups: snooping, denial of service (DoS), and process control subverting. This categorization derives from the list of BACnet protocol threats described in [24].

Snooping attacks concern stealing information about a specific building automation system. To achieve this goal, these attacks require access to the building automation system network. Once inside, attackers can take advantage of BACnet services such as `ReadProperty` and `ReadPropertyMultiple` to gain knowledge of the BACS. This includes device models, locations, status, and information on their BACnet support (e.g., which BACnet services and objects they implement). Attackers may need this information to understand the infrastructure and pave the way to further intrusions. However, snooping attacks do not disrupt any process of the building automation system.

Differently, DoS attacks try to interfere with control processes by making controllers unreachable for operators. This category only considers DoS attacks that are performed through the use of BACnet routing features (e.g., malicious modifications to the BACnet routing tables) and leaves other kinds of DoS out of its scope. As for the snooping attacks, DoS attacks need malicious users to have access to the network. Moreover, this kind of attacks requires information about the network layout. Attackers can achieve their goal by sending BACnet messages, such as `Initialize-Routing-Table`, to modify a BACS’ routing tables. In this way, operators lose visibility on single devices or even entire sections of the building automation system.

Finally, process control subverting includes those attacks that directly modify control processes and, consequently, interfere with physical operation. This kind of attacks requires more skilled attackers with sufficient knowledge about the building automation system functioning. In this scenario, attackers exploit specific controllers by using several different BACnet services, such as `WriteProperty` or `DeleteObject`, to change the BACSs’ structures and operations. This leads to a loss of control by the operators and, consequently, leads to risks for components and people.

3.3 Evaluation Environments

For this work, we analyzed two different building automation installations over more than two months of constant operation. The first building automation system belongs to the University of Twente in the Netherlands and is in charge of supervising utilities and services provided to the university campus. Its duties encompass energy consumption control, HVAC, and room monitoring and management (e.g., pressure and temperature control, shading, etc.). The second building automation system belongs to the Lawrence Berkeley National Laboratory (LBNL) and supervises several services on its premises. The LBNL process control focuses mostly on room monitoring and energy consumption for the Lab facilities. Both infrastructures deal with hundreds of BACSs from several different vendors.

The IDS we deployed at the University of Twente linked to a SPAN port on a switch directly connected with the SCADA servers monitoring the whole building automation system. The same switch is responsible for routing most of the traffic of the building automation network. This allowed us to capture and analyze most of the BACnet messages exchanged by BACSs. Differently, at LBNL we could monitor only a subset of the building automation system by linking to a switch in charge of connecting BACSs inside one building. However, this was sufficient to automatically gather the information needed for our approach to craft the specification rules.

The two infrastructures generally showed similar traffic patterns. Several BACSs shared the same sets of objects and used the same kind of messages to exchange information. Furthermore, both UT’s and LBNL’s traffic samples included numerous BACnet routing messages (e.g., `Who-Is`, `I-Am`, `Who-Has`, and `I-Have`) organizing communication paths within the two networks. However, the two infrastructures presented some differences related to communication and control strategies (e.g., all BACSs deployed at UT used confirmed services thus requiring acknowledgments from message recipients while some devices at LBNL used just unconfirmed ones). Particularly, the employment of

BACSSs from different vendors led operators to employ individual procedures implemented through the use of `ConfirmedPrivateTransfer` BACnet services. Such services are used to invoke proprietary or non-standard routines in remote BACSSs.

3.4 Setting and Threat Model

The reason to develop a network-based IDS is twofold. First, a network-based solution is easier to deploy than host-based ones. Secondly, this setup allows us to have minimum impact on NCS processes. Once deployed, we assume that our system is able to capture real-time traffic of the monitored building automation system in a completely passive fashion and to retrieve documentation publicly available on the Internet. This allows to gather the information we need to build specification rules and implement effective detection.

On the other side, we assume attackers can gain full access to the network as well. We consider this happening in a way that is similar to standard IT environments (e.g., phishing, software vulnerability exploitation). Tools such as Shodan [40] show how easy it is to find building automation networks exposing their devices to the Internet. Once inside, attackers can obtain a convenient viewpoint on the building automation control processes. Two key factors support this assumption. First, most building automation protocols take advantage of broadcast communications to exchange information among devices (e.g., routing notifications). This already allows attackers to easily observe a large part of the traffic. Secondly, the hierarchical structure of common building automation networks steers valuable information messages towards servers and DCSs. By gaining access to one of these servers, attackers can observe most of the traffic within the building automation system.

Within a building automation network, attackers may use attacks outlined in §3.2 to gain knowledge on, or subvert, the correct functioning of the building automation system. In this last scenario, any safety feedback in place can usually be overridden [49]. Therefore, attackers can put infrastructure components under stress, possibly threatening human safety when it comes to devices such as electrical equipment.

4 Specification Mining Approach

Our approach works towards automated development of specification rules for network security monitoring. Setting up and customizing a specification-based IDS for a particular infrastructure requires a large amount of information about the monitored system, implying a substantial manual effort in gathering and refining the specification rules. As details of the infrastructures are often

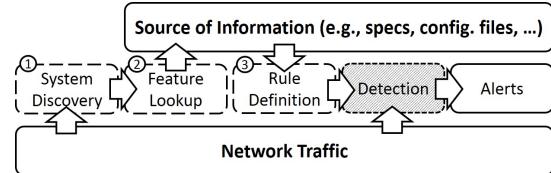

Figure 3: Specification-mining approach

described within specs and configuration files, especially in many NCS environments, the process of collecting this information—and, consequently, the development of the actual IDS—can be automated to a fairly high degree through the following steps (see also Figure 3):

(1) System Discovery gathers information about the monitored NCS. In this step, our system analyzes the network traffic in order to: 1) identify devices communicating on the network (e.g., models, brands); and 2) determine role and purpose of each identified device (e.g., a device is a controller, an HMI, etc.). Every time the system collects enough information about a specific device it proceeds with the next step.

(2) Feature Lookup implements a set of information retrieval techniques to gather knowledge about devices identified during System Discovery. The purpose of this step is to: 1) find verified information (e.g., specs, configuration files) about the infrastructure’s devices; and 2) select features and constraints from the retrieved documents and arrange results in a structured form.

A successful Feature Lookup relies on the assumptions of *availability* and *linkability* outlined in the introduction. The assumption of *availability* implies the existence of documents about infrastructures and components that are automatically retrievable. This requires the information to be provided in electronic form and being suitable for parsing. Also, this assumption includes an assurance on the authenticity of the retrieved information (e.g., by the use of reliable sources, by the employment of secure retrieval techniques). The assumption of *linkability* guarantees that the information derived by the retrieved documentation can be checked by the system against observations within the traffic (e.g., messages, variables, etc.). Particularly, after the identification of network devices and the successful retrieval of their related constraints from the documentation, the assumption of *linkability* enables assigning effective specification rules to the right targets.

(3) Rule Definition uses the knowledge obtained in the Feature Lookup to craft the specification rules. To achieve this goal, the system needs to: 1) select identified information from Feature Lookup; 2) translate this information to specification rules.

We focus our specification-based intrusion detection on *controllers* (e.g., BACSSs for building automation systems, Programmable Logic Controllers or PLCs for ICSs, Electronic Control Units or ECUs for in-vehicular networks). This decision comes from the key role these components have within NCSs: Controllers are involved in any monitoring and control operation of the infrastructure either autonomously or accessed by operators. Furthermore, controllers are likely targets for attackers (as illustrated in §3.2).

We observe that NCS controllers share a number of properties. First, every controller *employs a limited set of variables to fulfill its function*. These variables can go from simple memory addresses to complex objects but *often have predetermined types*. Moreover, all controllers *use a limited set of methods (or services) to access and manipulate variables of other controllers*. Finally, *each variable can assume a limited range of values according to its type or the physical characteristic it represents*. We leverage these shared properties to define a set of general constraints, or *abstract rules*, checking NCS variables' *types*, *values* and access *methods*. These abstract rules are the seeds we use to automatically generate specialized specification rules. To achieve this, we define a mechanism that maps information retrieved in the Feature Lookup step to the abstract rules. This process automatically completes the abstract rules and, as a result, customizes detection for the monitored NCS.

Once a rule is defined, it becomes active and, thus, part of the detection mechanism. During detection, an active rule verifies if its related constraint is fulfilled or not. When this last condition becomes true, the system triggers an alert for the user.

Having presented the phases in a generic way, we now describe our experimental setup and, then, how we have instantiated them to build a specification-based IDS for BACnet-based building automation systems.

Implementation background We implement our approach using the Python programming language [51] and Bro [46]. Bro is a network traffic analyzer employed in different domains such as network security monitoring and performance measurement. The system comes with comprehensive built-in functionality for traffic analysis and supports several network protocols ranging from standard (e.g., HTTP, FTP) to domain-specific (e.g., Modbus [41], DNP3 [10]). Bro provides a Turing-complete scripting language that allows users to select and analyze network events (e.g., connection establishments). We choose to describe specification rules through the “Bro scripting language” because of its efficiency and expressiveness. We developed a BACnet parser for Bro using Spicy [55], a parser generator whose specification language allows users to define a protocol’s

syntax and semantics at a high level. We publish the BACnet parsing code for Spicy, as well as the Python scripts , as open source software.² However, we cannot open-source the Bro code containing the rule checks due to privacy agreements with the two building automation system sites.

5 System Discovery

To identify BACSSs we implement three different techniques that we term: “*BACnet Device Object analysis*”, “*BACnet Address linking*”, “*BACnet Property set fingerprinting*”. The first technique directly follows from the protocol standard and relies on the mandatory presence of a *Device* object in every BACS device. The *Device* object defines “a standardized object whose properties represent the externally visible characteristics of a BACnet device”. Among these properties there are: *Object_Name*, *Vendor_Name*, *Vendor_Identifier*, *Model_Name*, *Firmware_Revision*, *Application_Software_Version*, *Location*, and *Description*. Most of these properties are set by vendors and provide information on a device’s identity (e.g., *Model_Name*) and role (e.g., *Description*). BACnet services such as *ReadProperty* and *ReadPropertyMultiple* can access those properties. As these services are widely employed by user interfaces and logging servers to automatically update data related to infrastructure’s components, information on *Device* objects regularly passes through the network and, thus, is available to System Discovery. As the *Object_Identifier* property of a *Device* object is a parameter that uniquely identifies a device in a BACnet network, a message such as the one in Figure 4 allows us to identify a BACS and understand its purpose. In the Wireshark screenshot example, BACS with identifier “17001” is a “Blue ID S10 Controller”.

For BACnet objects of other types, since no information can be extracted from the IP address (multiple BACnet devices may share the same IP address), a further parameter allows to identify message sources and destinations: the BACnet address. As for the *Device* object’s *Object_Identifier*, the BACnet address (together with the *Network Identifier*) is unique within a BACnet network. In the “*BACnet Address linking*” technique, the BACnet address bridges the gap between a known *Device* object and any BACnet object included in the same BACS. Figure 5 shows an example of this analysis. When “device 4001” is known (as a result of the previous technique), any message carrying both the related *Device* object’s *Object_Identifier* and the

BACnet Address allows us to link the two parameters (Figure 5a). Any later message then carrying the BACnet address along with a further object (e.g., “Analog Value 171”) enables linking to the corresponding device (Figure 5b). This technique works well because I-Am messages pass the network frequently to ensure visibility of all BACnet objects.³

Finally, if no information can be extracted from Device objects or BACnet addresses, System Discovery can benefit from observations of the BACnet properties. As discussed in §3.1, the BACnet property set is

³The technique can also directly use messages carrying Device object information if the source BACnet address is present in the header. However, for this kind of messages, having the BACnet Address fields is not mandatory.

extensible. Every object of a BACS has a set of standard and proprietary properties that form a “fingerprint” of that object and device. The third technique assumes that two objects sharing the same fingerprint are likely to be of the same kind. During System Discovery, it is possible to create a database of identified fingerprints each one pointing to the corresponding BACS (identified with the previous two techniques). Whenever an unknown object presents a property set already in the database, the system infers the most likely related device.

Experiments Previous work by us shows that traditional fingerprinting techniques are usually ineffective on most NCSs [5]. In our tests, tools such as Nmap [38] and PoF [64] were able to identify just a limited number of Windows and Linux workstations. The techniques presented above proved more effective. Thanks to frequent ReadPropertyMultiple, our system was able to gather information on most BACSs. Moreover, BACnet address linking and BACnet property set fingerprinting allowed the system to link most of the observed BACnet objects to identified devices. At the end of System Discovery, we gathered information on ~15k BACnet objects belonging to the 445 devices shown in Tables 1 and 2.

Thanks to the information from the operators, we

know that we correctly identified 98.2% of the BACSSs actually deployed (445 out of 453 devices). Eight devices did not link to any useful BACnet message or identifiable property set. However, these devices convey almost no information over the network (a few hundreds BACnet messages over two months of capturing compared to an average of tens of thousands) and did not involve any notable equipment. Identifying the aforementioned 445 devices took just a few hours of monitoring.

6 Feature Lookup

Searching for documentation on identified BACSSs is possible because the two assumptions of *availability* and *linkability* hold for BACnet-based building automation systems. Verified information about BACSSs is *available* within PICSs and EDE files. This information includes BACSSs' vendors, models and even refers to specific BACnet objects, thus is *linkable* to what we observed over System Discovery.

Feature Lookup targets both online and offline documentation. On the one hand, we use Google APIs to search and retrieve publicly available documents such as PICSs on the Internet. On the other hand, we retrieve EDE files from private repositories in the installations. Both cases allow for document authenticity. In the former case, we narrow the search to a subset of reliable sources such as vendors' websites and reputable third parties (e.g., BACnet International Laboratories⁴). In the latter case, we assume a secure connection to a trusted dataset managed by the operators.

Once a BACS links to one or more of these documents, our system parses the documents looking for useful information. According to BACnet specifications, a PICS has a standard template and we observe that most PICSs are closely modeled to it. Figure 6 shows three extracts from the PICS of the “Blue ID S10 Controller” mentioned in the previous section.

As outlined in §3.1, each PICS provides a description of the related BACS and the BIBBs it implements (Figure 6a). Moreover, PICSs include information about supported BACnet objects and properties, as well as their characteristics (Figures 6b and 6c).

EDE files also follow a standard template but they use a simpler “comma-separated values” (CSV) format. Each EDE file presents details of a specific BACS (Figure 7 shows an extract of Device 4001 EDE file). Data includes all implemented BACnet objects (e.g., “device 4001” owns “Analog Value 171”, “Multi-state Value 15”, etc.) and their descriptions. Furthermore, EDE files include information about Present_Value properties with

value ranges (e.g., “Analog Value 171” can vary from min-present-value 0 to max-present-value 100).

Experiments The program we implemented to search for online documentation uses the outputs of System Discovery (vendors and models) and further keywords such as “PICS” to retrieve information about identified BACSSs. The system ranks Google results coming from public repositories (e.g., www.bacnetinternational.net) and the web by quantifying the presence of the keywords in document titles. For example, the “Blue ID S10 Controller” links to a PDF document titled “BACnet_PICS_Blue_ID_S10_Controller.pdf” (Figure 6). With this technique we identified a PICS for 99.3% of the de-

vices deployed in the two building automation systems (442 out of 445 among the devices identified in the System Discovery step). Two ‘Siemens PXR11’ and one ‘Paragon Controls Inc. EQ’ were the only devices that did not link to any PICS. However, we could not find the related PICSs even by a manual search either.

Offline research targeted specific devices directly. While online documentation always provides general information about BACnests of a certain kind (e.g., all “Blue ID S10 Controller”), offline repositories provide detailed information related only to devices deployed in the monitored building automation system. For this reason, instead of vendors and models we searched through the available documents using device `Object_Instances`. For example, starting from “Device object 4001” from System Discovery, we found an EDE file titled “Controller 4001_EDE.csv”. While LBNL did not provide any configuration file, operators from the University of Twente shared with us 10 files of this kind. While they confirmed that there was indeed an EDE file for every deployed device, they could not grant us unlimited access to all of them due to information sensitivity. For this reason, the operators chose the 10 files based on roles and purposes of the related devices. Each file we obtained described a BACS identified over System Discovery.

The aforementioned privacy concerns refer to the initial manual analysis we had to perform over the EDE files and would not hamper the applicability of our approach. In an ideal deployment, one would have a secure connection between the IDS and the machine storing the EDE files, without any human activity involved for retrieval operations and processing. However, both University of Twente and LBNL operators store infrastructure documentation on computers also used for other purposes than building automation, and direct connections to those resources were infeasible.

Finally, we implemented two programs to parse PICSs and EDE files respectively. In the first case, the program goes from document’s top to bottom guided by the diagram shown in Figure 8. For every available PICS, the program first selects all implemented BIBBs and BACnet objects (Figures 6a and 6b). Each object can be creatable/deletable and this information follows the object as a “yes/no” or equivalent symbols (Figure 6b). Finally, for every object, the script selects a list of properties that can be writable or not (Figure 6c). Figure 9 shows parsing results of the “Blue ID S10 Controller” coming from the PICS showed in Figure 6.

Most of the retrieved PICS did not have any information about property values. Instead, this information was included in the EDE files. A further program went through all EDE files selecting `Present_Value` minimum and maximum values for every listed object. This new information was structured as shown in Figure 10.

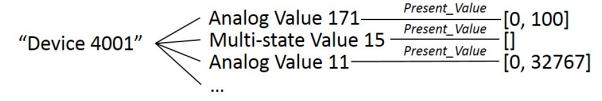

Figure 10: Parsing EDE example results

7 Rule Definition and Detection

Next we describe how the information gathered in previous steps is used to define specification rules. In §4, we motivated our focus on variables’ *types*, *values* and related access *methods* as basis for our specification rules. From this, we derive three *abstract* rules: 1) a “Type” rule checks if a variable of a specific type is allowed; 2) a “Value” rule checks which values a variable may assume; and 3) a “Method” rule checks which methods can be used to access a specific variable. All rules have the same structure: each element (type, value, method) is evaluated against a set of allowed possibilities. For example, in the “Type” rule, a variable’s type is evaluated against all the allowed types of variable a controller may implement (Algorithm 1).

We use a Python program to automate the process of mapping information retrieved over Feature Lookup to the abstract rules. In the following, we discuss how we map these abstract rules into specification rules for monitoring for each type.

Type Rule: The “Type” rule checks which BACnet objects and properties each BACS can use. This information comes from the PICSs (Figures 6b and 6c) and, thus, is included in the results of Feature Lookup (Figure 9). Therefore, a script selects allowed objects and properties of each identified BACS and transforms the “Type” rule into the two specification rules shown in Algorithm 2.

In the case of the “Blue ID S10 Controller”, the

Algorithm 1 Abstract “Type” rule

```
1: if Variabletype  $\notin$  ControllerAllowedVariableTypes then  
2:   Alert(“Variable type not permitted”)  
3: end if
```

Algorithm 2 BACnet “Type” rules

```
1: if BACnet Object  $\notin$  ControllerAllowedObjectTypes then  
2:   Alert(“Forbidden Object”)  
3: end if  
  
1: if BACnet Property  $\notin$  ControllerObjectAllowedPropertyTypes then  
2:   Alert(“Forbidden Property”)  
3: end if
```

Controller_{AllowedObjectTypes} set contains objects Accumulator, Analog Input, etc. In the same way, the Controller_{Accumulator}_{AllowedPropertyTypes} set of a “Blue ID S10 Controller” contains properties Object_Identifier, Object_Name, etc. Whenever the system captures a BACnet message including an object and some property, the two rules check object and property types respectively and alert if these types are not included in the defined sets. This allows the system to detect snooping attacks and any other attack dealing with unexpected objects and properties.

Value Rule: The “Value” rule checks which values BACnet properties may assume. This information comes from the EDE files (Figures 7 and 10) and, thus, is automatically mapped to the concrete rule as shown in Algorithm 3.

Algorithm 3 BACnet “Value” rule

```
1: if BACnet Property value  $\notin$  Controller(Object.Property)AllowedPropertyValues then  
2:   Alert(“Forbidden Value”)  
3: end if
```

For example, when it comes to “Device 4001”, the system alerts if “Analog Value 171” is below 0 or above 100. This rule protects the infrastructure against process control subverting scenarios, and thus attacks attempting to modify parameters of the physical and control processes.

Method Rule: The “Method” rule validates the BACnet services each BACS can use. This information comes from the PICSSs in the form of a list of BIBBs (Figures 6a) and is included in the results of Feature Lookup (Figure 9). BIBBs can be replaced with corresponding services by a simple lookup operation. Therefore, Algorithm 4 checks if a BACnet service belongs to the set of allowed services.

In the case of the “Blue ID S10 Controller”, the Controller_{AllowedServices} includes services from BIBBs DS_RP_A (ReadProperty_Request), DS_RP_B

Algorithm 4 BACnet “Method” rule

```
1: if BACnet Service  $\notin$  ControllerAllowedServices then  
2:   Alert(“Forbidden Service”)  
3: end if
```

(ReadProperty_Response), etc. This rule allows the system to detect attackers misusing BACnet services to fulfill their goals.

Furthermore, we use the “Method” rule to check which BACnet object is creatable/deletable and which BACnet property is writable. Following the standard, we compile three sets of BACnet services with services that create objects, that delete objects, and that write properties respectively. Then, the system uses the information from Feature Lookup to define checks on non-creatable/deletable objects and non-writable properties by using Algorithm 5.

Algorithm 5 BACnet additional “Method” rules

```
1: if BACnet Service  $\in$  CreateObjectServices then  
2:   Alert(“Forbidden object creation”)  
3: end if  
  
1: if BACnet Service  $\in$  DeleteObjectServices then  
2:   Alert(“Forbidden object deletion”)  
3: end if  
  
1: if BACnet Service  $\in$  WritePropertyServices then  
2:   Alert(“Forbidden property writing”)  
3: end if
```

For example, the first two rules alert the presence of services attempting to create or delete Accumulator objects belonging to a “Blue ID S10 Controller”. The third rule reports any service attempting to write to a non-writable property, such as Accumulator’s Object_Identifier.

Experiments Our system filled the abstract rules with the information coming from Feature Lookup crafting hundreds of specification rules. To improve efficiency we arrange the specification rules in an order that avoids meaningless checks (e.g., we do not want to check a BACnet property if we already know that the BACnet object it belongs to is not allowed). For every captured BACnet message, the system checks if the BACnet service is allowed; then, if involved BACnet objects can be used, created or deleted; then, if involved BACnet properties are allowed and writable. Finally, the system examines properties’ actual values. Only a small set of specification rules are of this last type due to the limited number of EDE files that operators provided us with.

As outlined in §3.3, we tested our approach against more than two months of real traffic. Over the two months of capturing, our system triggered 237 unique alerts; 226 at the University of Twente and 11 at LBNL.

Table 3: Detection results

Abstract Rule	Specification Rule	# Alerts
Type Rule	Forbidden object	2
	Forbidden property	234
Value Rule	Forbidden value	0
Method Rule	Forbidden service	0
	Forbidden object creation	0
	Forbidden object deletion	0
	Forbidden property writing	1

```
Service Choice: readPropertyMultiple (14)
④ ObjectIdentifier (214) Vendor Proprietary Value, 121
④ listOfPropertyReferences
④ {[1]}
④ Property Identifier: acked-transition (0)
④ ...
```

Figure 11: Unexpected object ReadProperty_Request

The two results differ because of the different views we achieved over the two infrastructures (as already described, at LBNL we could monitor only a subset of the building automation system and thus a subset of the traffic). Table 3 shows the three abstract rules, the corresponding specification rules and whether or not a rule raised an alert.

We did not find any evidence of malicious activities over the time span of the captures. However, our approach still provided interesting insights. At the University of Twente, the system raised alerts on two BACSs using forbidden objects. Both cases involved a “proprietary” object never described within the PICS. According to the available documentation, the two devices (two Siemens controllers PXC128-U) should not include anything that was not defined within the BACnet standard. Nevertheless, a device probed the two controllers (Figure 11) and received back correct BACnet responses about an unknown object. A meeting with the operators revealed that this object is vendor-defined and gathers information on parameters of the BACSs recognizable and understandable by vendors only. Operators confirmed that vendors have access to the building automation system to monitor their devices, and use of an unknown BACnet object happens even though the documentation does not mention this possibility because of its internal nature. However, operators did not know that involved BACSs provide specific functionalities and attackers can potentially exploit such circumstances.

Detection on BACnet properties provided the highest number of alerts (all alerts at LBNL were of this kind). Our system generated several alerts on ReadProperty and ReadPropertyMultiple messages attempting to retrieve non-existing properties. As a matter of fact, these properties were not defined by the PICSs and, for most cases, we could eventually confirm the

```
Service Choice: readPropertyMultiple (14)

④ ...
```

(b) ReadProperty_Response confirmation of the alert

Figure 12: Unexpected property read operation

non-existence of these properties by observing some BACnet errors carried in the responses to those read requests (Figure 12).

A BACS asking for unimplemented properties is not necessarily a violation of the specs. In fact, all PICSs define what a BACS implements without defining what other BACSs may ask for. A situation in which a BACS sends back a BACnet-error response to warn about a non-existing property (Figure 12b) is in line with the specs and should be of no harm for the system. However, the reason to alert on situations of this kind is twofold. First, this situation may be of interest from a security perspective. Despite being handled by the BACnet protocol, these circumstances may hide a “network discovery” scenario where an attacker tries to gain knowledge of the infrastructure by randomly probing BACSs. As described in §3.2, snooping is one plausible attack in building automation systems. Secondly, the same situation shows a common side-effect of the joint use of different BACnet software solutions. As servers and workstations do not usually know in advance which BACSs they will connect to, predefined BACnet discovery messages exist in order to gather general information of building automation components. These messages do not consider which BACnet properties are defined for each device and simply use large sets of them. This consequently generates several error responses on the network.

To dig deeper into property-related issues, we extended the “unknown property” specification rule to also check if properties enforced by PICSs were always implemented. Therefore, we created a further instance of “Type” rule checking all BACnet error messages to detect missing properties that were supposed to be used by the BACSs. The system revealed several messages reporting “unknown-property” errors about properties declared to be part of devices’ BACnet implementations.

```

Service Choice: writeProperty (15)
⊕ ObjectIdentifier: schedule, 8
⊕ Property Identifier: exception-schedule (38)
⊕ {[3]
⊕ {[0]
⊕ Date: March 15, 2014, (Day of week = Saturday)
⊕ ...

```

Figure 13: Unexpected property write request

All these mismatches between implementation and specification are particularly relevant for what concerns interoperability. In fact, software solutions that define their interactions with a BACS based on its public documentation can incur into inconsistencies caused by incorrect or lacking implementations.

Finally, the system triggered an alert corresponding to an unexpected write operation on a BACnet property supposed to be readable only. A Priva controller received a BACnet WriteProperty request on the `Exception_schedule` of an object `Schedule` (Figure 13). Despite what we knew from the related PICS, the BACS sent back a SimpleACK message, acknowledging the success of the operation (the actual writing was confirmed by later read operations). These kinds of situations are especially dangerous due to the unpredictability of their results. As no indication is provided by the vendor, the write operation can either succeed or fail, and may generate a response or not (even independently from the actual modification of the value within the property). Meeting with the operators revealed that this write operation was due to a human mistake during the configuration of the Priva controller. However, the same situation could fit the “process control subverting” scenario described in §3.2.

8 Discussion

Performed experiments confirm the feasibility of the approach within building automation systems and pave the way for its application to different domains.

8.1 Analysis of the Results

By construction, our IDS is able to detect events that do not match the specifications coming from retrieved documentation. This aspect leads to two considerations:

- On the one hand, an alert raised by the system does not necessarily refer to a security-relevant event as the related mismatches may not directly harm the monitored devices. However, all findings revealed network activities otherwise invisible to operators. Over the two months of analysis, every alert

identified either an actual mismatch between device documentation and implementation (e.g., unimplemented BACnet Properties) or an operator mistake (e.g., the unexpected writing operation). As already discussed, these issues can cause significant gaps in the knowledge operators have about their infrastructures and may potentially lead to dangerous misconfigurations of the involved systems. The meeting with the operators at the University of Twente confirmed that employed HMIs were not able to signal any of the misconfigurations found or even notify the users on generated BACnet errors. As a result, the University of Twente asked to deploy our system into the building automation system continuously and let operators receive notifications of the generated alerts. So while our datasets did not include actual attacks, we were able to reliably detect notable deviations from the specifications at zero false-positives. This result is in line with the work of Uppuluri et al. [62] showing that specification-based intrusion detection works towards optimal detection rate while substantially decreasing the number of false positives compared to anomaly-based detection.

- On the other hand, our approach does not necessarily detect all possible attacks threatening the monitored infrastructure. In fact, any attack operating within the boundaries defined by employed specifications would not be caught by our IDS. However, our solution substantially narrows down what a malicious user can do and covers most of the attack scenarios defined within the categories listed in §3.2. Furthermore, our solution does not exclude the use of other approaches such as pure anomaly-based intrusion detection either improving the obtained rule set or working in parallel.

Each one of the implemented phases effectively achieved the defined goals. Thanks to the numerous read operations, System Discovery took just a few hours of network sniffing to gather all the information needed to describe the whole set of BACSs. With this information, our approach was able to rapidly and automatically identify available sources of information and craft effective specification rules.

Feature Lookup focused just on structured documents such as PICSs and EDE files. In some of the tests, we further extended online research to documents such as BACS user manuals. Our system was able to download 10 manuals related to components deployed in the monitored infrastructures. However, we decided to not further employ manuals because an analysis showed they were fully overlapping with the information found in the PICSs. Nevertheless, one way to improve our

specification-mining approach is to enable handling heterogeneous documentation and, especially, unstructured information. To this regard, we observe that Feature Lookup should abstract from domain-specific parsing scripts and generalize the process of mining and structuring infrastructure features. Correctly selecting information can take advantage of standard data mining and natural language processing. Our work did not present a general approach to this activity. However, works such as [57, 15, 50] may fulfill this goal. With more general techniques capable of extracting knowledge from heterogeneous documentation, the effort of deploying the system completely converges on mapping retrieved information to the abstract rules. According to the monitored infrastructures, operators should identify the related concepts of variable type, value and access method and, eventually, let the system interpret data coming from Feature Lookup and instantiate the specification rules.

Even without such a general approach, our solution drastically reduced the time needed to deploy intrusion detection into a BACnet-based building automation system. Obtaining the same set of specification rules by hand would have required substantial effort, making it infeasible for larger infrastructures. Furthermore, the obtained system comes with the intrinsic capability to update according to the changes of the monitored infrastructure. In fact, whenever new BACSs are deployed, our system transparently reads the new information over the network and goes through the three steps all over again. In the end, this solution makes the implemented system directly applicable to any other BACnet infrastructure with no further effort on configuration or deployment.

The proposed approach works likewise for different building automation technologies. As discussed, this would mostly require a modification of the mapping process linking retrieved information and abstract rules but would leave the core concept unchanged. Other building automation infrastructures such as KNX [32] and LonWorks [11] also meet the requirements of *availability* and *linkability*. These widely used protocols present characteristics similar to the ones observed for BACnet. Moreover, both KNX and LonWorks promote and support the use of documents describing protocol implementation details (although not as formal as BACnet PICS).

To show the generality of our approach beyond building automation systems we outline how the same specification-mining technique applies to two different domains of NCSs, namely ICS and in-vehicle networks.

8.2 Industrial Control Systems

ICS is a term generally used to indicate several types of control systems (e.g., Supervisory Control And Data Acquisition or “SCADA”) used in industrial production

for monitoring and controlling physical processes. ICSs work over several domains such as energy, water treatment, manufacturing, etc. and embrace a wide family of technologies. Among them, Modbus [41], MMS [25], IEC104 [12], and DNP3 [10] are some of the most used protocols and standards deployed for industrial control.

Specification-based intrusion detection for ICSs is not new. Works such as [4] show the effectiveness of this approach applied to electrical grids. However, applying a set of specification rules to a real deployment still requires manually crafting all parameters on specific needs. Again, our research can improve the use of specification-based intrusion detection by leveraging available information of the deployments. For example, in the smart grid scenario, we would focus on Programmable Logic Controllers (PLCs) and Remote Terminal Units (RTUs), as these play a main role in the infrastructure. We would analyze variables handled by these controllers, their types, values and access methods and then use the abstract rules defined in §7.

Regarding the assumption of §6, verified information about the smart grid is *available* within configuration files that use the “Substation Configuration Language” (SCL). SCL files usually provide formal representations of modeled data and communication services. The information included in these files is *linkable* thanks to the included detail descriptions of the involved infrastructures (e.g., “Substation Configuration Description” files). Besides SCL files, operators usually store additional documentation describing physical and control processes as in the building automation use case. An IDS can leverage this documentation to gather further information and derive specification rules.

The three steps of the approach remain unchanged. System discovery will passively gather data about devices communicating over the ICS network. According to the verbosity of the involved protocols, an IDS will eventually collect enough information to identify infrastructure components and start the Feature Lookup step. Once information about PLCs and RTUs functioning is retrieved, Rule Definition will use it to define the actual specification rules.

8.3 In-Vehicle Networks

Similar argumentation can be applied to communication of Electronic Control Units (ECUs) over automotive bus systems like the “Controller Area Network” (CAN) or FlexRay found in all of today’s cars.

CAN is a network where connected ECUs communicate by means of small messages with a payload of only 8 bytes. CAN uses content-based addressing where messages only carry a 11 (or 21) bit message identifier, and receiving ECUs will select messages relevant to them

based on this message identifier. Message identifiers also serve as prioritization, as the employed CSMA/CR medium access scheme will always grant priority to the message with the lowest message identifier avoiding collisions on the bus. Transport layer protocols such as ISO-TP allow for transfer of longer messages fragmented into smaller network packets and more complex forms of addressing crossing gateways connecting multiple CAN segments.

In order to maintain and manage the assignment and semantics of message identifiers, the design phase of an automotive network involves setup of a so-called CAN-Matrix that lists exactly which ECU is supposed to sent which message identifier, which ECUs will receive messages of certain type and also the payload syntax and semantics. This design is done using sophisticated tools like Vector Informatics CANOE.⁵ The data provided by such tools is a perfect data source for specification-based IDS and for our approach, so the criteria of *availability* is met. *linkability* is more of a concern, as messages per se do not contain information on their source or type and a recipient needs to know (part of) the CAN matrix to identify how to decode a certain message ID. However, with the CAN matrix, we do have information on the types of ECUs available and can therefore conduct System discovery. This information can then be used to conduct Feature Lookup. A lot of relevant information (which messages are supposed to be seen on which bus segment) is again contained in the CAN matrix. Unfortunately, documentation in vehicular networks is not as standardized as the PICSs are in BACnet. So feature lookup would probably require more detailed investigations and more complex document parsing. Rule definition is then straightforward. However, having no source or destination addresses in packets, one would have to focus on message IDs, bus segments, and payload for detection.

While specification-based intrusion detection has been proposed many times especially for CAN-based networks [36, 31], a structured approach to rule-mining is missing in this domain so far and we see this as a promising field of application for our approach.

9 Conclusion

As networked control technologies are rapidly emerging, the need for securing these systems faces the key challenge of quickly scaling up to a multitude of heterogeneous devices. Our research aims to automate the deployment of effective security solutions, as well to adapt them in parallel with the monitored systems' lifecycle. More concretely, we present a novel approach to

specification-based intrusion detection for NCSs. While state-of-the-art solutions exploit manually-crafted specification rules, we discuss the feasibility of automatically mining these rules from available documentation. The tests performed on real building automation systems show the effectiveness of the obtained systems and confirm the time improvement in their development and deployment.

10 Acknowledgments

The authors would like to explicitly thank Dina Hadžiosmanović and Andreas Peter for the insightful discussions that gave rise to this research. Furthermore, the authors would like to acknowledge the work of Geert Jan Laanstra, Henk Hobbelink, Vincent Stoffer and Chris Weyandt at the University of Twente and the Lawrence Berkeley National Laboratory.

This research has been partially supported by the European Commission through project FP7-SEC-607093-PREEMPTIVE funded by the 7th Framework Program. This work has also been supported by the U.S. National Science Foundation under Award CNS-1314973. Abstract

New and unseen polymorphic malware, zero-day attacks, or other types of advanced persistent threats are usually not detected by signature-based security devices, firewalls, or anti-viruses. *This represents a challenge to the network security industry as the amount and variability of incidents has been increasing.* Consequently, this complicates the design of learning-based detection systems relying on features extracted from network data. The problem is caused by different joint distribution of observation (features) and labels in the training and testing data sets. This paper proposes a classification system designed to detect both known as well as previously-unseen security threats. The classifiers use statistical feature representation computed from the network traffic and learn to recognize malicious behavior. The representation is designed and optimized to be invariant to the most common changes of malware behaviors. This is achieved in part by a feature histogram constructed for each group of HTTP flows (proxy log records) of a user visiting a particular hostname and in part by a feature self-similarity matrix computed for each group. The parameters of the representation (histogram bins) are optimized and learned based on the training samples along with the classifiers. The proposed classification system was deployed on large corporate networks, where it detected 2,090 new and unseen variants of malware samples with 90% precision (9 of 10 alerts were malicious), which is a considerable improvement when compared to the current flow-based approaches or existing signature-based web security devices.

1 Introduction

Current network security devices classify large amounts of the malicious network traffic and report the results in many individually-identified incidents, some of which are false alerts. On the other hand, a lot of malicious traf-

fic remains undetected due to the increasing variability of malware attacks. As a result, security analysts might miss severe complex attacks because the incidents are not correctly prioritized or reported.

The network traffic can be classified at different levels of detail. Approaches based on packet inspection and signature matching [15] rely on a database of known malware samples. These techniques are able to achieve results with high precision (low number of false alerts), but their detection ability is limited only to the known samples and patterns included in the database (limited recall). Moreover, due to the continuous improvements of network bandwidth, analyzing individual packets is becoming intractable on high-speed network links. It is more efficient to classify network traffic based on *flows* representing groups of packets (e.g. NetFlow [1] or proxy logs [26]). While this approach has typically lower precision, it uses statistical modeling and behavioral analysis [8] to find new and previously unseen malicious threats (higher recall).

Statistical features calculated from flows can be used for unsupervised anomaly detection, or in supervised classification to train data-driven classifiers of malicious traffic. While the former approach is typically used to detect new threats, it suffers from lower precision which limits its practical usefulness due to large amount of false alerts. Data-driven classifiers trained on known malicious samples achieve better efficacy results, but the results are directly dependent on the samples used in the training. Once a malware changes the behavior, the system needs to be retrained. With continuously rising number of malware variants, this becomes a major bottleneck in modern malware detection systems. Therefore, the robustness and invariance of features extracted from raw data plays the key role when classifying new malware.

The problem of changing malware behavior can be formalized by recognizing that a joint distribution of the malware samples (or features) differs for already known training (source) and yet unseen testing (target) data.

This can happen as a result of target evolving after the initial classifier or detector has been trained. In supervised learning, this problem is solved by domain adaptation. Under the assumption that the source and target distributions do not change arbitrarily, the goal of the domain adaptation is to leverage the knowledge in the source domain and transfer it to the target domain. In this work, we focus on the case where the conditional distribution of the observation given labels is different, also called a conditional shift.

The domain adaptation (or knowledge transfer) can be achieved by adapting the detector using importance weighting such that training instances from the source distribution match the target distribution [37]. Another approach is to transform the training instances to the domain of the testing data or to create a new data representation with the same joint distribution of observation and labels [4]. The challenging part is to design a meaningful transformation that transfers the knowledge from the source domain and improves the robustness of the detector on the target domain.

In this paper, we present a new optimized invariant representation of network traffic data that enables domain adaptation under conditional shift. The representation is computed for bags of samples, each of which consists of features computed from network traffic logs. The bags are constructed for each user and contain all network communication with a particular host-name/domain. The representation is designed to be invariant under shifting and scaling of the feature values and under permutation and size changes of the bags. This is achieved by combining bag histograms with an invariant self similarity matrix for each bag. All parameters of the representation are learned automatically for the training data using the proposed optimization approach.

The proposed invariant representation is applied to detect malicious HTTP traffic. We will show that the classifier trained on malware samples from one category can successfully detect new samples from a different category. This way, the knowledge of the malware behavior is correctly transferred to the new domain. Compared to the baseline flow-based representation or widely-used security device, the proposed approach shows considerable improvements and correctly classifies new types of network threats that were not part of the training data.

This paper has the following major contributions:

- **Classifying new malware categories** – we propose a supervised method that is able to detect new types of malware categories from a limited amount of training samples. Unlike classifying each category separately, which limits the robustness, we propose an invariant training from malware samples of multiple categories.

- **Bag representation of samples** – Instead of classifying flows individually, we propose to group flows into bags, where each bag contains flows that are related to each other (e.g. having the same user and target domain). Even though the concept of grouping flows together has been already introduced in the previously published work (e.g. in [32]), these approaches rely on a sequence of flow-based features rather than on more complex representation.
- **Features describing the dynamics of the samples** – To enforce the invariant properties of the representation, we propose to use a novel approach, where the features are derived from the self-similarity of flows within a bag. These features describe the dynamics of each bag and have many invariant properties that are useful when finding new malware variants and categories.
- **Learning the representation from the training data** – To optimize the parameters of the representation, we propose a novel method that combines the process of learning the representation with the process of learning the classifier. The resulting representation ensures easier separation of malicious and legitimate communication and at the same time controls the complexity of the classifier.
- **Large scale evaluation** – We evaluated the proposed representation on real network traffic of multiple companies. Unlike most of the previously published work, we performed the evaluation on highly imbalanced datasets as they appear in practice (considering the number of malicious samples), with most of the traffic being legitimate, to show the potential of the approach in practice. This makes the classification problem much harder. We provided a comparison with state-of-the-art approaches and a widely-used signature-based web security device to show the advantages of the proposed approach.

2 Related Work

Network perimeter can be secured by a large variety of network security devices and mechanisms, such as host-based or network-based Intrusion Detection Systems (IDS) [36]. We briefly review both systems, focusing our discussion on network-based IDS, which are the most relevant to the presented work.

Host-based IDS systems analyze malicious code and processes and system calls related to OS information. Traditional and widely-used anti-virus software or spyware scanners can be easily evaded by simple transformations of malware code. To address this weakness, methods of static analysis [30], [38] were proposed.

Static analysis, relying on semantic signatures, concentrates on pure investigation of code snippets without actually executing them. These methods are more resilient to changes in malware codes, however they can be easily evaded by obfuscation techniques. Methods of dynamic analysis [29], [34], [42] were proposed to deal with the weaknesses of static analysis, focusing on obtaining reliable information on execution of malicious programs. The downside of the dynamic analysis is the necessity to run the codes in a restricted environment which may influence malware behavior or difficulty of the analysis and tracing the problem back to the exact code location. Recently, a combination of static and dynamic analysis was used to analyze malicious browser extensions [20].

Network-based IDS systems are typically deployed on the key points of the network infrastructure and monitor incoming and outgoing network traffic by using static signature matching [15] or dynamic anomaly detection methods [8]. Signature-based IDS systems evaluate each network connection according to the predefined malware signatures regardless of the context. They are capable of detecting well-known attacks, but with limited amount of detected novel intrusions. On the other hand, anomaly-based IDS systems are designed to detect wide range of network anomalies including yet undiscovered attacks, but at the expense of higher false alarm rates [8].

Network-based approaches are designed to detect malicious communication by processing network packets or logs. An overview of the existing state-of-the-art approaches is shown in Table 1. The focus has been on the traffic classification from packet traces [5], [28], [39], [41], as this source provides detailed information about the underlying network communication. Due to the still increasing demands for larger bandwidth, analyzing individual packets is becoming intractable on high-speed network links. Moreover, some environments with highly confidential data transfers such as banks or government organizations do not allow deployment of packet inspection devices due to the legal or privacy reasons. The alternative approach is the classification based on network traffic logs, e.g. NetFlow [1], DNS records, or proxy logs. The logs are extracted at the transport layer and contain information only from packet headers.

Methods introduced in [12] and [23] apply features extracted from NetFlow data to classify network traffic into general classes, such as P2P, IMAP, FTP, POP3, DNS, IRC, etc. A comparison and evaluation of these approaches can be found in a comprehensive survey [24]. A combination of host-based statistics with SNORT rules to detect botnets was introduced in [16]. The authors showed that it is possible to detect malicious traffic using statistical features computed from NetFlow data, which motivated further research in this field. An alternative approach for classification of botnets from NetFlow fea-

tures was proposed in [6]. The authors of [33] have used normalized NetFlow features to cluster flow-based samples of network traffic into four predefined categories. As opposed to our approach, the normalization was performed to be able to compare individual features with each other. In our approach, we extended this idea and use normalization to be able to compare various malware categories. While all these approaches represent relevant state-of-the-art, network threats evolve so rapidly that these methods are becoming less effective due to the choice of features and the way they are used.

One of the largest changes in the network security landscape is the fact that HTTP(S) traffic is being used not only for web browsing, but also for other types of services and applications (TOR, multimedia streaming, remote desktop) including lots of malicious attacks. According to recent analysis [18], majority of malware samples communicate via HTTP. This change has drawn more attention to classifying malware from web traffic. In [25], the authors proposed an anomaly detection system composed of several techniques to detect attacks against web servers. They divide URIs into groups, where each group contains URIs with the same resource path. URIs without a query string or with return code outside of interval [200, 300] are considered as irrelevant. The system showed the ability to detect unseen malware samples and the recall will be compared with our proposed approach in Section 8. In [40], the authors introduced a method for predicting compromised websites using features extracted from page content and Alexa Web Information Service.

Having sufficient amount of labeled malware samples at disposal, numerous approaches proposed supervised learning methods to achieve better efficacy. Classifying DGA malware from DNS records based on connections to non-existent domains (NXDomains) was proposed in [2]. Even though several other data sources were used to detect malware (such as malware executions [3] or JavaScript analysis [22]), the most relevant work to our approach uses proxy logs [9], [17], [27], [44], [32].

In all these methods, proxy log features are extracted from real legitimate and malicious samples to train a data-driven classifier, which is used to find new malicious samples from the testing set. There are five core differences between these approaches and our approach: (1) we do not classify individual flows (in our case proxy log records), but sets of related flows called bags, (2) we propose a novel representation based on features describing the dynamics of each bag, (3) the features are computed from the bags and are invariant against various changes an attacker could implement to evade detection, (4) parameters of the proposed representation are learned automatically from the input data to maximize the detection performance, (5) the proposed classification system

Table 1: Overview of the existing state-of-the-art approaches focusing on classification of malicious traffic (U = unsupervised, S = supervised). In contrast to the existing work, our approach proposes novel and optimized representation of bags, describing the dynamics of each legitimate or malicious sample. The approach is evaluated on latest real datasets with a realistic ratio of malicious and background flows (proxy log records).

was deployed on corporate networks and evaluated on imbalanced datasets (see Table 1) as they appear in practice to show the expected efficacy on these networks.

3 Formalization of the Problem

The paper deals with the problem of creating a robust representation of network communication that would be invariant against modifications an attacker can implement to evade the detection systems. The representation is used to classify network traffic into positive (malicious) or negative (legitimate) category. The labels for positive and negative samples are often very expensive to obtain. Moreover, sample distribution typically evolves in time, so the probability distribution of training data differs from the probability distribution of test data. This complicates the training of classifiers which assume that the distributions are the same. In the following, the problem is described in more detail.

Each sample is represented as an n -dimensional feature vector $x \in \mathbb{R}^n$. Samples are grouped into bags, with every bag represented as a matrix $X = (x_1, \dots, x_m) \in \mathbb{R}^{n \times m}$, where m is the number of samples in the bag and n is the number of features. The bags may have different number of samples. A single category y_i can be assigned to each bag from the set $\mathcal{Y} = \{y_1, \dots, y_N\}$. Only a few categories are included in the training set. The probability distribution on training and testing bags for category y_j will be denoted as $P^L(X|y_j)$ and $P^T(X|y_j)$, respectively. Moreover, the probability distribution of the training data differs from the probability distribution of the testing data, i.e. there is a domain adaptation problem [7] (also called a conditional shift [43]):

$$P^L(X|y_j) \neq P^T(X|y_j), \forall y_j \in \mathcal{Y}. \quad (1)$$

The purpose of the domain adaptation is to apply knowledge acquired from the training (source) domain into test (target) domain. The relation between $P^L(X|y_i)$ and $P^T(X|y_i)$ is not arbitrary, otherwise it would not be possible to transfer any knowledge. Therefore there is a transformation τ , which transforms the feature values of the bags onto a representation, in which $P^L(\tau(X)|y_i) \approx P^T(\tau(X)|y_i)$. The goal is to find this representation, allowing to classify individual bag represented as X into categories $\mathcal{Y} = \{y_1, \dots, y_N\}$ under the above mentioned conditional shift.

Numerous methods for transfer learning have been proposed (since the traditional machine learning methods cannot be used effectively in this case), including kernel mean matching [14], kernel learning approaches [11], maximum mean discrepancy [19], or boosting [10]. These methods try to solve a general data transfer with relaxed conditions on the similarity of the distributions during the transfer. The downside of these methods is the necessity to specify the target loss function and availability of large amount of labeled data.

This paper proposes an effective invariant representation that solves the classification problem with a covariate shift (see Equation 1). Once the data are transformed, the new feature values do not rely on the original distribution and they are not influenced by the shift. The parameters of the representation are learned automatically from the data together with the classifier as a joint optimization process. The advantage of this approach is that the parameters are optimally chosen during training to achieve the best classification efficacy for the given classifier, data, and representation.

4 Invariant Representation

The problem of domain adaptation outlined in the previous section is addressed by the proposed representation of bags. The new representation is calculated with a transformation that consists of three steps to ensure that the new representation will be invariant under scaling and shifting of the feature values and under permutation and size changes of the bags.

4.1 Scale Invariance

As stated in Section 3, the probability distribution of bags from the training set can be different from the test set. In the first step, the representation of bags is transformed to be invariant under scaling of the feature values. The traditional representation X of a bag that consists of a set of m samples $\{x_1, \dots, x_m\}$ can be written in a form of a matrix:

$$X = \begin{pmatrix} x_1 \\ \vdots \\ x_m \end{pmatrix} = \begin{pmatrix} x_{11} & x_{12} & \dots & x_{1n} \\ & \vdots & & \\ x_{m1} & x_{m2} & \dots & x_{mn} \end{pmatrix}, \quad (2)$$

where x_{lk} denotes k -th feature value of l -th sample. This form of representation of samples and bags is widely used in the research community, as it is straightforward to use and easy to compute. It is a reasonable choice in many applications with a negligible shift in the source and target probability distributions. However, in the network security domain, the dynamics of the network environment causes changes in the feature values and the shift becomes more prominent. As a result, the performance of the classification algorithms using the traditional representation is decreased.

In the first step, the representation is improved by making the matrix X to be invariant under scaling of the feature values. **Scale invariance** guarantees that even if some original feature values of all samples in a bag are multiplied by a common factor, the values in the new representation remain unchanged. To guarantee the scale invariance, the matrix X is scaled locally onto the interval $[0, 1]$ as follows:

$$\tilde{X} = \begin{pmatrix} \tilde{x}_{11} & \dots & \tilde{x}_{1n} \\ \vdots & & \\ \tilde{x}_{m1} & \dots & \tilde{x}_{mn} \end{pmatrix} \quad \tilde{x}_{lk} = \frac{x_{lk} - \min_l(x_{lk})}{\max_l(x_{lk}) - \min_l(x_{lk})} \quad (3)$$

4.2 Shift Invariance

In the second step, the representation is transformed to be invariant against shifting. **Shift invariance** guarantees that even if some original feature values of all samples in a bag are increased/decreased by a given amount, the

values in the new representation remain unchanged. Let us define a *translation invariant distance function* $d : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$ for which the following holds: $d(u, v) = d(u + a, v + a)$.

Let x_{pk}, x_{qk} be k -th feature values of p -th and q -th sample from bag matrix X . Then the distance between these two values will be denoted as $d(x_{pk}, x_{qk}) = s_{pq}^k$. The distance $d(x_{pk}, x_{qk})$ is computed for pairs of k -th feature value for all sample pairs, ultimately forming a so called self-similarity matrix S^k . Self-similarity matrix is a symmetric positive semidefinite matrix, where rows and columns represent individual samples and (i, j) -th element corresponds to the distance between i -th and j -th sample. Self-similarity matrix has been already used thanks to its properties in several applications (e.g. in object recognition [21] or music recording [31]). However, only a single self-similarity matrix for each bag has been used in these approaches. This paper proposes to compute a set of similarity matrices, one for every feature. More specifically, a per-feature set of self-similarity matrices $\mathcal{S} = \{S^1, S^2, \dots, S^n\}$ is computed for each bag, where

$$S^k = \begin{pmatrix} s_{11}^k & s_{12}^k & \dots & s_{1m}^k \\ & \vdots & & \\ s_{m1}^k & s_{m2}^k & \dots & s_{mm}^k \end{pmatrix}. \quad (4)$$

The element $s_{pq}^k = d(x_{pk}, x_{qk})$ is a distance between feature values x_{pk} and x_{qk} of k -th feature. This means that the bag matrix X with m samples and n features will be represented with n self-similarity matrices of size $m \times m$. The matrices are further normalized by local feature scaling described in Section 4.1 to produce a set of matrices $\tilde{\mathcal{S}}$.

The shift invariance makes the representation robust to the changes where the feature values are modified by adding or subtracting a fixed value. For example, the length of a malicious URL would change by including an additional subdirectory in the URL path. Or, the number of transferred bytes would increase when an additional data structure is included in the communication exchange.

4.3 Permutation and Size Invariance

Representing bags with scaled matrices $\{\tilde{X}\}$ and sets of locally-scaled self-similarity matrices $\{\tilde{\mathcal{S}}\}$ achieves the scale and shift invariance. **Size invariance** ensures that the representation is invariant against the size of the bag. In highly dynamic environments, the samples may occur in a variable ordering. **Permutation invariance** ensures that the representation should also be invariant against any reordering of rows and columns of the matrices. The final step of the proposed transformation is the transition from the scaled matrices $\tilde{X}, \tilde{\mathcal{S}}$ (introduced in Sec-

tions 4.1 and 4.2 respectively) to normalized histograms. For this purpose, we define for each bag:

$z_k^X :=$ vector of values from k -th column of matrix \tilde{X}

$z_k^S :=$ column-wise representation of upper triangular matrix created from matrix $\tilde{S}^k \in \mathcal{S}$.

This means that $z_k^X \in \mathbb{R}^m$ is a vector created from values of k -th feature of \tilde{X} , while $z_k^S \in \mathbb{R}^r, r = (m-1) \cdot \frac{m}{2}$ is a vector that consists of all values of upper triangular matrix created from matrix \tilde{S}^k . Since \tilde{S}^k is a symmetric matrix with zeros along the main diagonal, z_k^S contains only values from upper triangular matrix of \tilde{S}^k .

A normalized histogram of vector $z = (z_1, \dots, z_d) \in \mathbb{R}^d$ is a function $\phi: \mathbb{R}^d \times \mathbb{R}^{b+1} \rightarrow \mathbb{R}^b$ parametrized by edges of b bins $\theta = (\theta_0, \dots, \theta_b) \in \mathbb{R}^{b+1}$ such that $\phi(z; \theta) = (\phi(z; \theta_0, \theta_1), \dots, \phi(z; \theta_{b-1}, \theta_b))$ where

$$\phi(z, \theta_i, \theta_{i+1}) = \frac{1}{d} \sum_{j=1}^d \llbracket z_j \in [\theta_{i-1}, \theta_i] \rrbracket$$

is the value of the i -th bin corresponding to a portion of components of z falling to the interval $[\theta_{i-1}, \theta_i]$.

Each column k of matrix \tilde{X} (i.e. all bag values of k -th feature) is transformed into a histogram $\phi(z_k^X, \theta_k^X)$ with predefined number of b bins and θ_k^X bin edges. Such histograms created from the columns of matrix \tilde{X} will be denoted as *feature values histograms*, because they carry information about the distribution of bag feature values. On the other hand, histogram $\phi(z_k^S, \theta_k^S)$ created from values of self-similarity matrix $\tilde{S}^k \in \mathcal{S}$ will be called *feature differences histograms*, as they capture inner feature variability within bag samples.

Overall, each bag is represented as a concatenated feature map $\phi(\tilde{X}; \mathcal{S}; \theta): \mathbb{R}^{n \times (m+r)} \rightarrow \mathbb{R}^{2 \cdot n \cdot b}$ as follows:

$$(\phi(z_1^X, \theta_1^X), \dots, \phi(z_n^X, \theta_n^X), \phi(z_1^S, \theta_1^S), \dots, \phi(z_n^S, \theta_n^S)) \quad (5)$$

where n is the number of the original flow-based features, m is the number of flows in the bag, and b is the number of bins. The whole transformation from input network flows to the final feature vector is depicted in Figure 1. As you can see, two types of invariant histograms are created from values of each flow-based feature. At the end, both histograms are concatenated into the final bag representation $\phi(\tilde{X}; \mathcal{S}; \theta)$.

5 Learning Optimal Histogram Representation

The bag representation $\phi(\tilde{X}; \mathcal{S}; \theta)$ proposed in Section 4 has the invariant properties, however it heavily depends on the number of bins b and their edges θ defining the

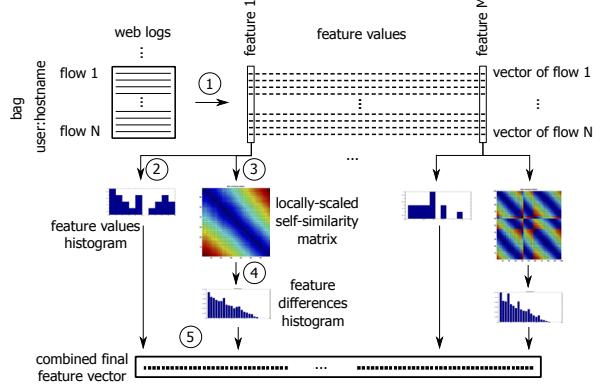

Figure 1: Graphical illustration of the individual steps that are needed to transform the bag (set of flows with the same user and hostname) into the proposed invariant representation. First, the bag is represented with a standard feature vector (1). Then feature values histograms of locally scaled feature values are computed for each feature separately (2). Next, the locally-scaled self-similarity matrix is computed for each feature (3) to capture inner differences. This matrix is then transformed into feature differences histogram (4), which is invariant on the number or the ordering of the samples within the bag. Finally, feature values and feature differences histograms of all features are concatenated into resulting feature vector.

width of the histogram bins. These parameters that were manually predefined in Section 4 C influence the classification performance. Incorrectly chosen parameters b and θ leads to suboptimal efficacy results. To define the parameters optimally, we propose a novel approach of learning these parameters automatically from the training data in such a way to maximize the classification separability between positive and negative samples.

When creating histograms in Section 4 C, the input instances are vectors z_k^X and z_k^S , where $k \in \{1, \dots, n\}$. The algorithm transforms the input instances into a concatenated histogram $\phi(\tilde{X}; \mathcal{S}; \theta)$. To keep the notation simple and concise, we will denote the input instances simply as $z = (z_1, \dots, z_n) \in \mathbb{R}^{n \times m}$ (instead of $z = (z_1^X, \dots, z_n^X, z_1^S, \dots, z_n^S)$), which is a sequence of n vectors each of dimension m .

The input instance z is represented via a feature map $\phi: \mathbb{R}^{n \times m} \rightarrow \mathbb{R}^{n \cdot b}$ defined as a concatenation of the normalized histograms of all vectors in that sequence, that is, $\phi(z; \theta) = (\phi(z_1; \theta_1), \dots, \phi(z_n; \theta_n))$, where $\theta = (\theta_1, \dots, \theta_n)$ denotes bin edges of all normalized histograms stacked to a single vector.

We aim at designing a classifier $h: \mathbb{R}^{n \times m} \times \mathbb{R}^{n+1} \times \mathbb{R}^{n(b+1)} \rightarrow \{-1, +1\}$ working on top of the histogram representation, that is

$$h(z; w, w_0, \theta) = \text{sign}(\langle \phi(z, w) \rangle + w_0) \\ = \text{sign} \left(\sum_{i=1}^n \sum_{j=1}^b \phi(z_i, \theta_{i,j-1}, \theta_{i,j}) w_{i,j} + w_0 \right). \quad (6)$$

The classifier (6) is linear in the parameters (w, w_0) but non-linear in θ and z . We are going to show how to learn parameters (w, w_0) and implicitly also θ via a convex optimization.

Assume we are given a training set of examples $\{(z^1, y^1), \dots, (z^m, y^m)\} \in (\mathbb{R}^{n \times m} \times \{+1, -1\})^m$. We fix the representation ϕ such that the number of bins b is sufficiently large and the bin edges θ are equally spaced. We find the weights (w, w_0) by solving

$$\min_{w \in \mathbb{R}^{b \cdot p}, w_0 \in \mathbb{R}} \left[\gamma \sum_{i=1}^n \sum_{j=1}^{b-1} |w_{i,j} - w_{i,j+1}| \right. \\ \left. + \frac{1}{m} \sum_{i=1}^m \max \{0, 1 - y^i \langle \phi(z^i; \theta), w \rangle\} \right]. \quad (7)$$

The objective is a sum of two convex terms. The second term is the standard hinge-loss surrogate of the training classification error. The first term is a regularization encouraging weights of neighboring bins to be similar. If it happens that j -th and $j+1$ bin of the i -the histogram have the same weight, $w_{i,j} = w_{i,j+1} = w$, then these bins can be effectively merged to a single bin because

$$w_{i,j} \phi(z_i; \theta_{i,j-1}, \theta_{i,j}) + w_{i,j+1} \phi(z_i; \theta_{i,j}, \theta_{i,j+1}) \\ = 2w \phi(z_i; \theta_{i,j-1}, \theta_{i,j+1}). \quad (8)$$

The trade-off constant $\gamma > 0$ can be used to control the number of merged bins. A large value of γ will result in massive merging and consequently in a small number of resulting bins. Hence the objective of the problem (7) is to minimize the training error and to simultaneously control the number of resulting bins. The number of bins influences the expressive power of the classifier and thus also the generalization of the classifier. The optimal setting of λ is found by tuning its value on a validation set.

Once the problem (7) is solved, we use the resulting weights w^* to construct a new set of bin edges θ^* such that we merge the original bins if the neighboring weights have the same sign (i.e. if $w_{i,j}^* w_{i,j+1}^* > 0$). This implies that the new bin edges θ^* are a subset of the original bin edges θ , however, their number can be significantly reduced (depending on γ) and they have different widths unlike the original bins. Having the new bins defined, we learn a new set of weights by the standard SVM algorithm

$$\min_{w \in \mathbb{R}^n, w_0 \in \mathbb{R}} \left[\frac{\lambda}{2} \|w\|^2 + \frac{1}{m} \sum_{i=1}^m \max \{0, 1 - y^i \langle \phi(z^i; \theta^*), w \rangle\} \right].$$

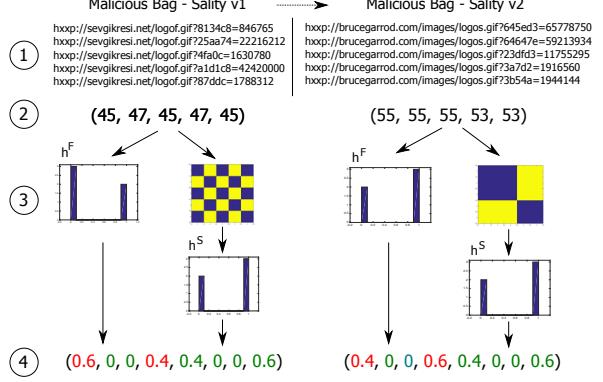

Figure 2: Illustration of the proposed representation applied on two versions of malware Sality. First, two bags of flows are created (1), one bag for each Sality sample. Next, flow-based feature vectors are created for each bag (2). For illustrative purposes, only a single feature is used - URL length. In the third step, histograms of feature values $\phi(z_k^X, \theta_k^X)$ and feature differences $\phi(z_k^S, \theta_k^S)$ are created (3) as described in Section 4.3. Only four bins for each histogram were used. Finally, all histograms are concatenated into the final feature vector (4). Even though the malware samples are from two different versions, they have the same histogram of feature differences $\phi(z_k^S, \theta_k^S)$. Since $\phi(z_k^X, \theta_k^X)$ is not invariant against shift, you can see that half of the values of $\phi(z_k^X, \theta_k^X)$ are different. Still, $\phi(z_k^X, \theta_k^X)$ values may play an important role when separating malware samples from other legitimate traffic.

Note that we could add the quadratic regularizer $\frac{\lambda}{2} \|w\|^2$ to the objective of (7) and learn the weights and the representation in a single stage. However, this would require tuning two regularization parameters (λ and γ) simultaneously which would be order of magnitude more expensive than tuning them separately in the two stage approach.

6 Malware Representation Example

This Section illustrates how the proposed representation (nonoptimized version) is calculated for two real-world examples of malicious behavior. Namely, two versions of a polymorphic malware Sality are compared. Sality [13] is a malware family that has become a dynamic and complex form of malicious infection. It utilizes polymorphic techniques to infect files of Windows machines. Signature-based systems or classifiers trained on a specific malware type often struggle with detecting new variants of this kind of malware. Note that most of the conclusions to the discussion that follows can be drawn for many other malware threats.

Figure 2 shows how the two Sality samples are represented with the proposed approach. First, the input flows are grouped into two bags (one bag for each Sality sample), because all flows of each bag have the same user and the same hostname (1). For the sake of simplicity, only URLs of the corresponding flows are displayed. Next, 88 flow-based feature vectors are computed for each bag (2). To simplify illustration, we use only a single feature – URL length. After this step, each Sality sample is represented with one feature vector of flow-based values. Existing approaches use these vectors as the input for the subsequent detection methods. As we will show in Section 7, these feature values are highly variable for malware categories. Classification models trained with such feature values loose generalization capability.

To enhance the robustness of the flow-based features, the proposed approach computes histograms of feature values $\phi(z_k^X, \theta_k^X)$ and feature differences $\phi(z_k^S, \theta_k^S)$ (3) as described in Section 4.3. To make the illustration simple, only four bins for each histogram were used. Finally, all histograms are concatenated into the final feature vector (4). It can be seen that even though the malware samples are from two different versions, they have the same histogram of feature differences $\phi(z_k^S, \theta_k^S)$. Since the histogram of feature values $\phi(z_k^X, \theta_k^X)$ is not invariant against shift, half of the values of $\phi(z_k^X, \theta_k^X)$ are different.

The number of histogram bins and their sizes are then learned from the data by the proposed algorithm (see Section 5). The proposed representation describes inner dynamics of flows from each bag, which is a robust indicator of malware samples, as we will show in the analysis of various malware families in Section 8. In contrast to the existing methods that use flow-based features or general statistics such as mean or standard deviation, the proposed representation reflects properties that are much more difficult for an attacker to evade detection.

7 Evasion Possibilities

This section discusses evasion options for an attacker when trying to evade a learning-based classification system. According to the recent work [35], the essential components for an evasion are: (1) the set of features used by the classifier, (2) the training dataset used for training, (3) the classification algorithm with its parameters. Without the knowledge of the features, the attacker is faced with major challenges and there is not any known technique for addressing them [35].

Acquire knowledge of classification algorithm with its parameters or the training data is hard if not impossible. Therefore, in the following analysis, we assume that only the features are known to the attacker. When classifying HTTP traffic from proxy logs, it is actually not difficult to create a set of common features widely used

in practice. These features are the baseline flow-based features, such as those described in Table 3. When the attacker performs a mimicry attack, selected features of malicious flows are modified to mimic legitimate traffic (or flows marked as benign by the classifier).

In the following, we will analyze the case when the attacker performs a mimicry attack to evade detection by modifying flow attributes, such as URLs, bytes, and inter-arrival times. Other flow attributes can be altered in a similar way with analogical results. All modifications are divided into two groups, depending on whether the proposed representation is invariant against them.

The proposed representation is invariant to the following changes.

- **Malicious code, payload, or obfuscation** – The advantage of all network-based security approaches is that they extract features from headers of network communication rather than from the content. As a result, any changes to the payload including the usage of pluggable transports designed to bypass Deep Packet Inspection (DPI) devices will have no effect on the features. Some pluggable transports (e.g. ScrambleSuit) are able to change its network fingerprint (packet length distribution, number of bytes, inter-arrival times, etc.). Since the proposed representation mainly relies on the dynamics of URLs of flows in the bag, such changes will not negatively impact the efficacy, which is a great advantage against DPI devices.
- **Server or hostname** – The representation operates at the level of bags, where each bag is a set of flows with the same user and hostname/domain. If an attacker changes an IP address or a hostname of the remote server (because the current one has been blacklisted), the representation will create a new bag with similar feature values as in the previous bag with the original IP address or hostname, which is a great advantage against feeds and blacklists that need to be updated daily and are always behind.
- **URL path or filename** – Straightforward and easy way of evading existing classifiers using flow-based features or URL patterns is the change in path or filename from sample to sample. Since the variability of these features remains constant within each bag, these changes will also have no effect on the proposed representation.
- **Number of URL parameters, their names or values** – This is an alternative to URL path changes.
- **Encoded URL content** – Hiding information in the URL string represents another way to exfiltrate sensitive data. When the URL is encrypted and encoded (e.g. with base64), it changes the URL length

and may globally influence other features as well. As the proposed representation is invariant against shifting, changing the URL length will not change the histograms of feature differences.

- **Number of flows** – Another option for an attacker to hide in the background traffic is increasing or reducing the number of flows related to the attack. Such modification of the attack does not affect the representation, as long as there are enough flows to create the feature vectors.
- **Time intervals between flows** – This feature has been used in many previous approaches for its descriptive properties. It is an alternative way to the proposed representation how to model a relationship between individual flows. Our analysis revealed that current malware samples frequently modify the inter-arrival time to remain hidden in the background traffic – see Figure 3 for details. Therefore, we do not rely on this unstable feature that can be also influenced by network delays or failures.
- **Ordering of flows** – An attacker can easily change the ordering of flows to evade detection based on patterns or predefined sequences of flows. For the proposed representation the ordering of flows does not matter.

The proposed representation is not invariant to the following changes.

- **Static behavior** – The representation does not model malware behaviors, where all flows associated with a malware are identical. Such behavior has no dynamics and can be classified with flow-based approaches with comparable results. In our dataset, only 10% of flows were removed because of this constraint.
- **Multiple behaviors in a bag** – In case more behaviors are associated with a bag, such as when a target hostname is compromised and communicates with a user with legitimate and malicious flows at once, the representation does not guarantee the invariance against the attacker’s changes. Such bags contain a mixture of legitimate and malicious flows and their combination could lead to a different representation. Note that there wasn’t any malware sample in our data that would satisfy this condition, since the legitimate traffic has to be authentic (not artificially injected) to confuse the representation.
- **Encrypted HTTPS traffic** – Most features presented in this paper are computed from URLs or other flow fields, that are not available in encrypted HTTPS traffic. In this case, only a limited set

Table 2: Number of flows and bags of malware categories and legitimate background traffic used for training and testing the proposed representation and classifier. Right-most column shows the amount of bags that were found and blocked by an existing signature-based device. Majority of the malicious bags from the test were missed, as the device, relying on a static database of signatures, was not able to catch evolving versions and new types of the malicious behaviors.

of flow-based features can be used, which reduces the discriminative properties of the representation. However, majority of malware communication is still over HTTP protocol, because switching to HTTPS would harm the cyber-criminals’ revenues due to problems with signed certificates [18].

- **Real-time changes and evolution** – In case a malware sample for a given user and hostname would start changing its behavior dynamically and frequently, the bag representation will vary in time. Such inconsistency would decrease the efficacy results and enlarge the time to detect. However, creating such highly dynamic malware behavior requires a considerable effort, therefore we do not see such samples very often in the real network traffic.

We conclude our analysis with the observation, that attackers change flow features very frequently (see Figure 3). The goal of the proposed representation is to be invariant against most of the changes to successfully detect new, previously unseen malware variants.

8 Experimental Evaluation

The proposed approach was deployed on the top of proxy logs exporters in companies of various types and sizes to detect unseen malware samples. The system architecture is shown in Figure 4. Collector connected to a

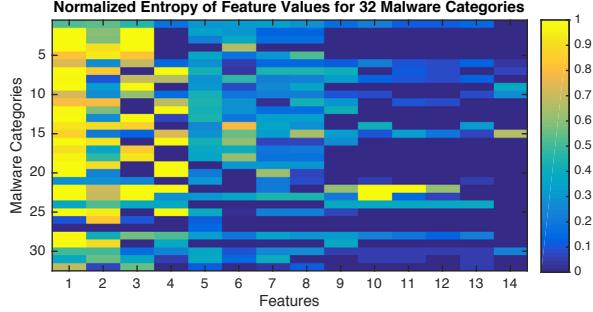

Figure 3: Flow-based features (columns) are changing for most of the malware categories (rows). The figure uses normalized entropy to show the variability of each feature within each malware category. Yellow color denotes that the feature value is changed very often, while blue color means that the feature has the same values for all samples of the given category. **Features:** 1-URL, 2-interarrival time, 3-URL query values, 4-URL path, 5-number of flows, 6-number of downloaded bytes, 7-server IP address, 8-hostname, 9-URL path length, 10-URL query names, 11-filename, 12-filename length, 13-number of URL query parameters, 14-number of uploaded bytes. **Malware categories:** 1-Click-fraud (amz), 2-Asterope family 1, 3-Asterope family 2, 4-Beden, 5-Click-fraud, 6-DGA, 7-Dridex, 8-Exfiltration, 9-InstallCore, 10-Mudrop Trojan Dropper, 11-Monetization, 12-Zeus, 13-Mudrop, 14-MultiPlug, 15-mixture of unknown malware, 16-Click-fraud (tracking), 17-Poweliks family 1, 18-Poweliks family 2, 19-Qakbot Trojan, 20-Rerdom Trojan, 21-Ramnit worm, 22-RVX, 23-Sality, 24-Threats related to a traffic direction system (TDS) 1, 25-TDS 2, 26-TDS 3, 27-Tinba Trojan, 28-C&C tunneling, 29-Uptare, 30-Vawtrak, 31-Vittalia, 32-Zbot. Details about the malware categories are given in Section 8.

proxy server stores incoming and outgoing network traffic in form of proxy log records. The proxy logs represent information about individual HTTP/HTTPS connections or flows. Each 5-minute interval, the proxy logs are sent to the detection engine, where the proposed method detects the malicious behaviors. Report created from the malicious behaviors is then displayed on a console to an operator. The next section provides the specification of datasets and malware categories, followed by the results from the experimental evaluation. Next section provides the specification of datasets and malware categories, followed by the results from the experimental evaluation.

8.1 Specification of the Datasets

The data was obtained from several months (January - July 2015) of real network traffic of 80 international

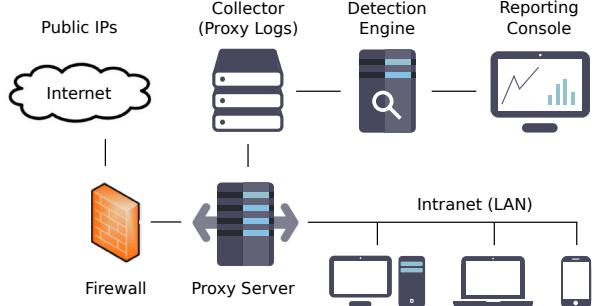

Figure 4: Overview of the system architecture. Collector connected to a proxy server stores incoming and outgoing network traffic in form of proxy log records. Each 5-minute interval, the proxy logs are sent to the detection engine and the results are displayed to an operator on the reporting console.

companies of various sizes in form of proxy logs [26]. The logs contain HTTP/HTTPS flows, where one flow is one connection defined as a group of packets from a single host and source port with a single server IP address, port, and protocol. Summary of the datasets used in the evaluation is described in Table 2.

Malware samples will be referred as **positive bags**, where one positive bag is a set of records (connections) with the same source towards the same destination. The bags not labeled as malicious are considered as legitimate/negative. Each bag should contain at least 5 flows to be able to compute a meaningful histogram representation. Training dataset contains 5k malicious (8 malware families) and 27k legitimate bags, while testing dataset is consist of 2k malicious (\gg 32 malware families) and 241k legitimate bags (more than 15 million flows). Positive samples for training were acquired using many types of publicly available feeds, services, and blacklists, while the results on the testing data were analyzed manually by security experts. Each HTTP flow consists of the following fields: user name, srcIP, dstIP, srcPort, dstPort, protocol, number of bytes, duration, timestamp, user agent, and URL. From these flow fields, we extracted 115 flow-based features typically used in the prior art (Table 3).

This means that training and testing data are composed of completely different malware bags from different malware families, which makes the classification problem much harder. This scenario simulates the fact that new types of threats are created to evade detection. The benchmarking signature-based network security device (widely used in many companies) was able to detect only 2% of the malicious bags from the testing set. Training a classifier for each category separately is an easier task, however such classifiers are typically overfitted to a single category and cannot detect further variations without retraining.

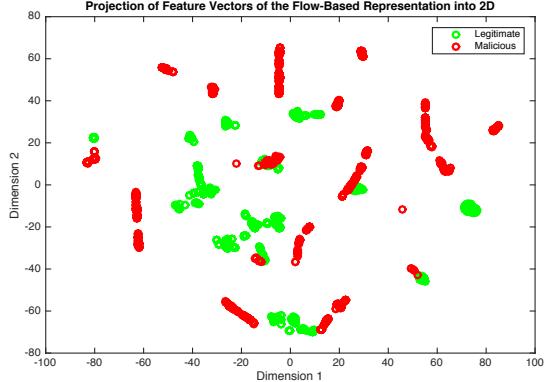

Figure 5: Graphical projection of feature vectors of the baseline flow-based representation into two dimensions using t-SNE transformation. Feature vectors from 32 different malware categories are displayed. Due to high variability of flow-based feature values, legitimate and malicious samples are scattered without any clear separation. The results show that the flow-based representation is suitable for training classifiers specialized on a single malware category, which often leads to classifiers with high precision and low recall.

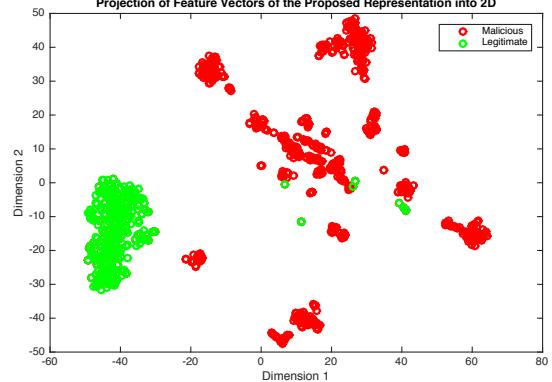

Figure 6: Graphical projection of feature vectors of the proposed representation into two dimensions using t-SNE transformation. Thanks to the invariant properties, malicious bags from various categories are grouped together, as they have similar dynamics modeled by the representation. Most of the legitimate bags are concentrated on the left-hand side, far from the malicious bags. This shows that training a classifier with the proposed representation will achieve higher recall with comparable precision.

number of '/' in path/query/referer

Table 3: List of selected flow-based features extracted from proxy logs. We consider these features as baseline (as some features were used in previously published work), and compare it with the proposed representation.

Table 4 from Appendix A describes an important fact about the URLs from individual malicious bags. As you can see, URLs within each malicious bag are similar to each other (as opposed to most of legitimate bags). This small non-zero variability of flow-based feature values is captured by the proposed representation using both types of histograms. The variability is very general but also

descriptive feature, which increases the robustness of the representation to further malware changes and variants.

8.2 Evaluation on Real Network Traffic

This section shows the benefits of the proposed approach of learning the invariant representation for two-class classification problem in network security. Feature vectors described in Section 8.1 correspond to input feature vectors $\{x_1, \dots, x_m\}$ defined in Section 3. These vectors are transformed into the proposed representation of histograms $\phi(\hat{X}; \mathcal{P}; \theta)$, as described in Section 4. We have evaluated two types of invariant representations. One with predefined number of equidistant bins (e.g. 16, 32, etc.) computed as described in Section 4, and one when the representation is learned together with the classifier to maximize the separability between malicious and legitimate traffic (combination of Section 4 and 5). For the representation learning, we used 256 bins as initial (and most detailed) partitioning of the histograms. During the learning phase, the bins were merged together, creating 12.7 bins per histogram on average.

Both approaches are compared with the baseline flow-based representation used in previously published work, where each sample corresponds to a feature vector computed from one flow. Results of a widely used signature-based security device are also provided (see Table 2) to demonstrate that the positive samples included in the evaluation pose a real security risk, as majority of them

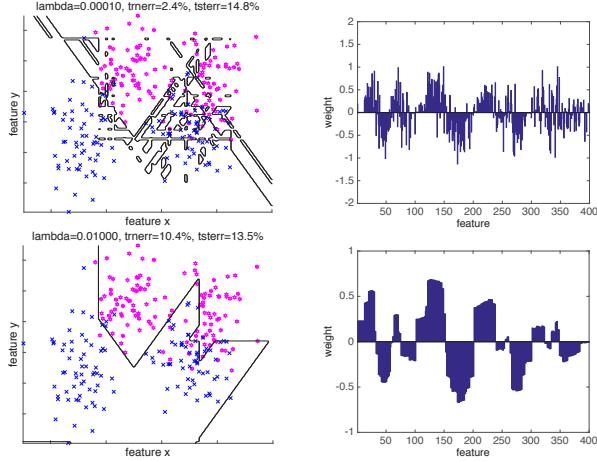

Figure 7: Visualization of the proposed method of learning the invariant representation on 2-dimensional synthetic data. Figures in the left row show the decision boundaries of two class classifier learned from the bins for two different values of parameter λ (0.0001, 0.01) which controls the number of emerging bins (the corresponding weights are shown in the right row). With increasing λ the data are represented with less bins and the boundary becomes smoother and less over-fitted to the training data.

was not detected. Maximum number of flows for each bag was 100, which ensures that the computational cost is controlled and does not exceed predefined limits.

Two-dimensional projection of the feature vectors for the flow-based and the proposed representation is illustrated in Figures 5 and 6 respectively. Bags from 32 malicious categories are displayed with red circles, while the legitimate bags are denoted with green circles. The projections show that the flow-based representation is suitable for training classifiers specialized on a single malware category. In case of the proposed representation, malicious bags from various categories are grouped together and far from the legitimate traffic, which means that the classifiers will have higher recall and comparable precision with the flow-based classifiers.

Next, we will show the properties of the proposed method of learning the representation to maximize the separation between positive and negative samples (see Section 5 for details). Figure 7 visualizes the proposed method on synthetic 2-dimensional input data. The input 2D point $(x, y) \in \mathbb{R}^2$ is represented by 4-dimensional feature vector $(x^2, y^2, x + y, x - y)$. Each of the 4 features is then represented by a histogram with 100 bins (i.e. each feature is represented by 100 dimensional binary vector with all zeros but a single one corresponding to the active bin). Figures in the top row show the decision boundaries of two-class classifiers learned from data. The bot-

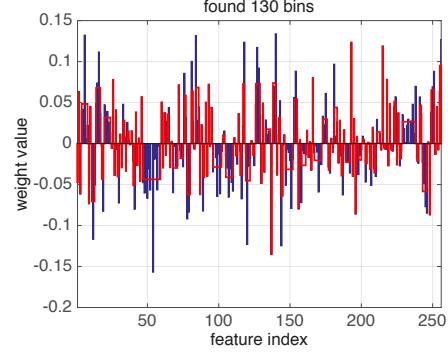

Figure 8: Weights (blue bars) and derived bins of a histogram (red line) for a standard SVM and one of the invariant features. Since the bins are equidistant and pre-defined at the beginning, the resulting histogram (defined by the red line) has complicated structure, leading most probably to complex boundary and over-fitted results (as shown in Figure 7 on the left hand side).

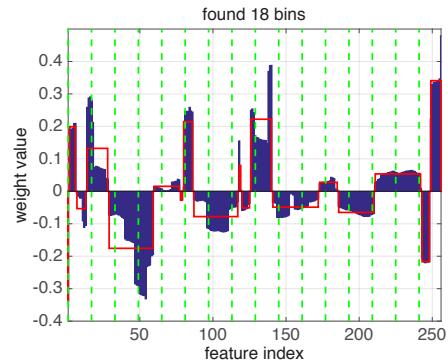

Figure 9: Weights (blue bars) and derived bins of a histogram (red line) for the proposed bin optimization. In this case, the weights show a clear structure and the derived histogram has only 18 bins. The decision boundary is in this case smoother and the classifier trained from this representation will be more robust. Green dashed lines also show how the histogram bins would look like if they are positioned equidistantly (16 bins).

tom row shows the weights of the linear classifier corresponding to the bins (in total 400 weights resulting from 100 bins for each out of 4 features). The columns correspond to the results obtained for different setting of the parameter λ which controls the number of emerging bins and thus also the complexity of the decision boundary. With increasing λ the data are represented with less bins and the boundary becomes smoother. Figure 7 shows the principle of the proposed optimization process. The bins of the representation are learned in such a way that it is much easier for the classifier to separate negative and positive samples and at the same time control the com-

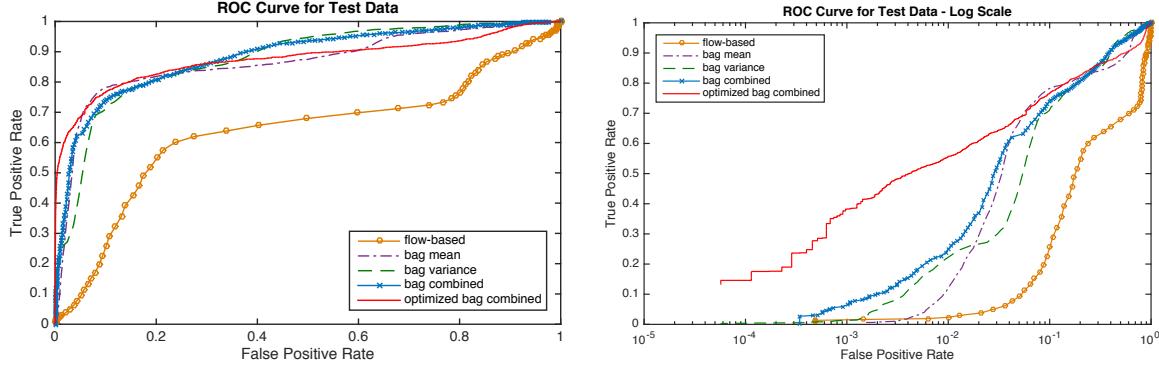

Figure 10: ROC curves of SVM classifier on test data for five types of representations (logarithmic scale on the right). Flow-based representation shows very unsatisfactory results showing that flow-based approach cannot be applied in practice to detect unseen malware variants. The combination of feature values with feature differences histogram (bag combined) led to significantly better efficacy results. These results were further exceeded when the parameters of the invariant representation were learned automatically from the training data (optimized bag combined).

plexity of the classifier.

Figures 8 and 9 show the bins and weights learned from the training set of real network traffic. The blue vertical lines represent learned weights associated with 256 bins of a histogram computed on a single input feature. The red lines show new bins derived from the weights by merging those neighboring bins which have the weights with the same sign. Figure 8 shows the weights and the derived bins for a standard SVM which has no incentive to have similar weights. The histogram derived from the SVM weights reduces the number of bins from 256 to 130. Figure 9 shows the results for the proposed method which enforces the similar weights for neighboring bins. In this case, the weights exhibit a clear structure and the derived histogram has only 18 bins. The decision boundary is in this case smoother and the classifier trained from this representation will be more robust.

Next, a two-class SVM classifier was evaluated on five representations: baseline flow-based, per-feature histograms of values $\phi(z_k^X, \theta_k^X)$ (bag mean), per-feature histograms of feature differences $\phi(z_k^S, \theta_k^S)$ (bag variance), the combination of both (bag combined), and the combination of both with bin optimization (optimized bag combined). The training and testing datasets were composed of bags described in Table 2.

The results on testing data are depicted in Figure 10. Note that positive bags in the testing set are from different malware categories than bags from the training set, which makes the classification problem much harder. The purpose of this evaluation is to compare flow-based representation, which is used in most of previously published work, with the proposed invariant representation. Flow-based representation shows very unsatisfactory results, mainly due to the fact that the classifier was based only on the values of flow-based features that are not

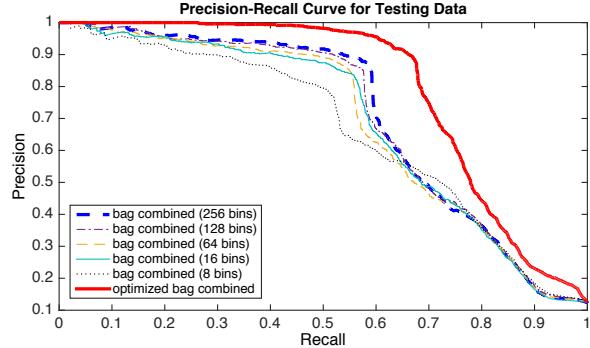

Figure 11: Precision-recall curve of SVM classifier trained on the proposed representation with different number of histogram bins for each feature. All classifiers are outperformed by the classifier, where the parameters of the invariant representation are learned automatically from the data (optimized bag combined). The classifier achieved 90% precision (9 of 10 alerts were malicious) and 67% recall on previously unseen malware families.

robust across different malware categories (as shown in Section 7). The classifier based on combined bag representation performed significantly better. These results were further exceeded when the parameters of the invariant representation were learned automatically from the training data (using bin optimization from Section 5), which is shown in Figure 10 with logarithmic scale.

Precision-recall curve is depicted in Figure 11 to compare the efficacy results of classifiers based on the proposed representation with predefined number of bins per feature (8, 16, 64, 128, and 256 bins) with the same representation, but when the parameters are learned from the training data (using bin optimization from Section 5).

Overall, the results show the importance of combining both types of histograms introduced in Section 4 together, allowing the representation to be more descriptive and precise without sacrificing recall. But most importantly, when the parameters of the representation are trained to maximize the separability between malicious and legitimate samples, the resulting classifier performs in order of a magnitude better than a classifier with manually predefined parameters.

9 Conclusion

This paper proposes a robust representation suitable for classifying evolving malware behaviors. It groups sets of network flows into bags and represents them using a combination of invariant histograms of feature values and feature differences. The representation is designed to be invariant under shifting and scaling of the feature values and under permutation and size changes of the bags. The proposed optimization method learns the parameters of the representation automatically from the training data, allowing the classifiers to create robust models of malicious behaviors capable of detecting previously unseen malware variants and behavior changes.

The proposed representation was deployed on corporate networks and evaluated on real HTTP network traffic with more than 43k malicious samples and more than 15M samples overall. The comparison with a baseline flow-based approach and a widely-used signature-based web security device showed several key advantages of the proposed representation. First, the invariant properties of the representation result in the detection of new types of malware. More specifically, the proposed classifier trained on the optimized representation achieved 90% precision (9 of 10 alerts were malicious) and detected 67% of malware samples of previously unseen types and variants. Second, multiple malware behaviors can be represented in the same feature space while current flow-based approaches necessitate training a separate detector for each malware family. This way, the proposed system considerably increases the capability of detecting new variants of threats.

Table 4: Example URLs of flows from several malicious bags and from two legitimate bags. The URLs within each malicious bag are similar to each other while the URLs within legitimate bags differ. The small non-zero variability of flow-based feature values is captured by the proposed representation using histograms of features and feature self-similarity matrices. Such transformation of the feature values makes the representation robust to malware changes and unseen variants.

Abstract

The Network Time Protocol (NTP) is used by many network-connected devices to synchronize device time with remote servers. Many security features depend on the device knowing the current time, for example in deciding whether a certificate is still valid. Currently, most services implement NTP without authentication, and the authentication mechanisms available in the standard have not been formally analyzed, require a pre-shared key, or are known to have cryptographic weaknesses. In this paper we present an authenticated version of NTP, called ANTP, to protect against desynchronization attacks. To make ANTP suitable for large-scale deployments, it is designed to minimize server-side public key operations by infrequently performing a key exchange using public key cryptography, then relying solely on symmetric cryptography for subsequent time synchronization requests; moreover, it does so without requiring server-side per-connection state. Additionally, ANTP ensures that authentication does not degrade accuracy of time synchronization. We measured the performance of ANTP by implementing it in OpenNTPD using OpenSSL. Compared to plain NTP, ANTP’s symmetric crypto reduces the server throughput (connections/second) for time synchronization requests by a factor of only 1.6. We analyzed the security of ANTP using a novel provable security framework that involves adversary control of time, and show that ANTP achieves secure time synchronization under standard cryptographic assumptions; our framework may also be used to analyze other candidates for securing NTP.

Keywords: time synchronization, Network Time Protocol (NTP), provable security, network security

1 Introduction

The *Network Time Protocol (NTP)* is one of the Internet’s oldest protocols, dating back to RFC 958 [15] published in 1985. In the simplest NTP deployment, a client device

sends a single UDP packet to a server (the *request*), who responds with a single packet containing the time (the *response*). The response contains the time the request was received by the server, as well as the time the response was sent, allowing the client to estimate the network delay and set their clock. If the network delay is *symmetric*, i.e., the travel time of the request and response are equal, then the protocol is perfectly accurate. *Accuracy* means that the client correctly synchronizes its clock with the server (regardless of whether the server clock is accurate in the traditional sense, e.g., synchronized with UTC).

The importance of accurate time for security. There are many examples of security mechanisms which (often implicitly) rely on having an accurate clock:

- *Certificate validation in TLS and other protocols.* Validating a public key certificate requires confirming that the current time is within the certificate’s validity period. Performing validation with a slow or inaccurate clock may cause expired certificates to be accepted as valid. A revoked certificate may also validate if the clock is slow, since the relying party will not check for updated revocation information.
- *Ticket verification in Kerberos.* In Kerberos, authentication tickets have a validity period, and proper verification requires an accurate clock to prevent authentication with an expired ticket.
- *HTTP Strict Transport Security (HSTS) policy duration.* HSTS [10] allows website administrators to protect against downgrade attacks from HTTPS to HTTP by sending a header to browsers indicating that HTTPS must be used instead of HTTP. HSTS policies specify the duration of time that HTTPS must be used. If the browser’s clock jumps ahead, the policy may expire re-allowing downgrade attacks. A related mechanism, *HTTP Public Key Pinning* [7] also relies on accurate client time for security.

For clients who set their clocks using NTP, these security mechanisms (and others) can be attacked by a

network-level attacker who can intercept and modify NTP traffic, such as a malicious wireless access point or an insider at an ISP. In practice, most NTP servers do not authenticate themselves to clients, so a network attacker can intercept responses and set the timestamps arbitrarily. Even if the client sends requests to multiple servers, these may all be intercepted by an upstream network device and modified to present a consistently incorrect time to a victim. Such an attack on HSTS was demonstrated by Selvi [28], who provided a tool to advance the clock of victims in order to expire HSTS policies. Malhotra et al. [12] present a variety of attacks that rely on NTP being unauthenticated, further emphasizing the need for authenticated time synchronization. (Confidentiality, however, is not a requirement for time synchronization, since all time synchronization is public. Similarly, client-to-server authentication is not a goal.)

NTP security today. Early versions of NTP had no standardized authentication method. NTPv3 added an authentication method using pre-shared key symmetric cryptography. An extension field in the NTP packet added a cryptographic checksum, computed over the packet. In NTPv3 negotiation of keys and algorithms must be done out-of-band. For example, NIST offers a secure time server, and (symmetric) keys are transported from server to client by postal mail [21]. Establishing pre-shared symmetric keys with billions of client PCs and other NTP-synchronizing devices would be impractical. NTPv4 introduced a public key authentication mechanism called Autokey which has not seen widespread adoption; and unfortunately, Autokey uses small 32-bit seeds that can be easily brute forced to then forge packets. A more recent proposal is the Network Time Security (NTS) protocol [31], which we discuss in §2.3.

Most NTP servers do not support NTP authentication, and NTP clients in desktop and laptop operating systems will set their clocks based on unauthenticated NTP responses. On Linux and OS X, by default the client either polls a server periodically, or creates an NTP request when the network interface is established. In both cases the system clock will be set to any time specified by the NTP response. On Windows, by default clients will synchronize their clock every nine hours (using `time.microsoft.com`), and ignore responses that would change the clock by more than 15 hours. These two defaults reduce the opportunity for a man-in-the-middle (MITM) attacker to change a victim clock and the amount by which it may be changed, but cumulative small-scale changes can build over time to large-scale time inaccuracies. Teichel et al. used this technique when attacking time-synchronization secured by TESLA-like protocols [33]. In Windows domains (a network of computers, often in an enterprise), the domain controller provides the time with an authenticated variant of NTPv3 [14].

1.1 Contributions

We present the ANTP protocol for authenticated network time synchronization, along with results on its performance and security. ANTP protocol messages are transported in the extension fields of NTP messages. ANTP allows a server to authenticate itself to a client using public key certificates and public key exchange, and provides cryptographic assurance using symmetric cryptography that no modification of the packets has occurred in transit. Like other authenticated time synchronization protocols using public keys [31], we assume an out-of-band method for certificate validation exists, as certificate validation requires an accurate clock. We follow the direction set by the IETF Informational document “Security Requirements of Time Protocols in Packet-Switched Networks” (RFC 7384) [20] to determine what cryptographic, computational, and storage properties ANTP should achieve.

ANTP has three phases. In the *negotiation phase*, the client and server agree on which cryptographic algorithms to use; this phase would be carried out quite infrequently, on the order of monthly or less. In the *key exchange phase*, the client and server use public key cryptography to establish a symmetric key that the server will use to authenticate later time synchronization responses; this phase would also be carried out infrequently, say monthly. In the *time synchronization phase*, the client sends a time synchronization request, and the server replies with an NTP response that is symmetrically authenticated using the key established in the key exchange phase; this may be done frequently, perhaps daily or more often. Notably, the server need not keep per-client state: the server offloads any such state to the client by encrypting and authenticating it under a long-term symmetric key, and the client sends that ciphertext back to the server with each subsequent request.

The time synchronization phase of ANTP can be run in a “no-cryptographic-latency” mode: here, the server sends two response packets, the first being the unauthenticated NTP packet, and the second being the same NTP packet (with unchanged timestamps) along with the ANTP extensions providing authentication. The client measures the roundtrip time based on the unauthenticated response, but does not update its clock until authenticating the response. In this way, no time synchronization inaccuracy is added by the time required to compute the authentication tag over the outgoing timestamp. Since the latency of ANTP’s time synchronization phase is nearly as fast as unauthenticated simple NTP time synchronization (only 21 microseconds slower at 50% load in our implementation as reported below), we make this mode optional since plain ANTP may be sufficiently accurate for general use.

ANTP performance. Performance constraints on time synchronization protocols are driven by the fact that time

Phase	Throughput	Latency within LAN (μs)		Latency across US (ms)	
		50% load	90% load	50% load	90% load
ANTP – Negotiation – RSA	58 240	186 \pm 26	202 \pm 44	76.3 \pm 0.1	77.5 \pm 0.1
ANTP – Negotiation – ECDH	146 808	172 \pm 35	233 \pm 133	75.3 \pm 0.1	75.3 \pm 0.1
ANTP – Key Exchange – RSA	1 754	891 \pm 125	997 \pm 348	75.8 \pm 0.2	76.9 \pm 0.5
ANTP – Key Exchange – ECDH	13 210	197 \pm 56	344 \pm 142	74.7 \pm 0.2	75.4 \pm 0.4
ANTP – Time Synchronization	175 644	168 \pm 35	230 \pm 160	73.5 \pm 0.1	73.7 \pm 0.1
ANTP – All 3 phases – RSA	–	2255 \pm 587	2646 \pm 345	226.6 \pm 6.2	258.0 \pm 35
ANTP – All 3 phases – ECDH	–	1325 \pm 499	2252 \pm 1 172	231.8 \pm 10.5	223.3 \pm 6.7
NTP	291 926	147 \pm 34	181 \pm 136	72.4 \pm 0.1	74.0 \pm 0.1

Table 1: Performance results for each phase of ANTP (top), a complete 3-phase execution of ANTP (middle), and NTP (bottom). Throughput: mean completed phases per second. Latency: mean and standard deviation of the latency of server responses at either 50% or 90% server load on a local area network (reported in microseconds) and across the United States (between Virginia and California) (reported in milliseconds). All are computed over 5 trials, top and bottom over 100 seconds each; see Section 4.2 for details.

servers are heavily loaded, and must provide responses promptly. ANTP’s design allows it to achieve high performance while maintaining high security. The frequently performed time synchronization phase uses only symmetric cryptography, making it only slightly more expensive than simple NTP time synchronization. Since the session key established in the key exchange phases is reused across many time synchronization phases, expensive public key operations are amortized, and can be separately load-balanced. And, as noted above, ANTP offloads state to clients, leaving the server stateless.

We implemented ANTP in OpenNTPD’s [34] implementation of NTP, using OpenSSL’s libcrypto library (but not SSL/TLS) [35] for cryptographic computations. Table 1 reports the performance of our implementation, compared with unauthenticated simple NTP. ANTP does decrease throughput and increase latency, but the impact is quite reasonable. On a single core of a server, ANTP can support 175k authenticated time synchronization phase connections per second, a factor of 1.6 fewer than the 291k unauthenticated simple NTP connections per second. Latency for time synchronization (over a 1 gigabit per second local area network) at 50% load increases from 147 microseconds for unauthenticated simple NTP to 168 microseconds for ANTP’s time synchronization phase. The other two phases, negotiation and key exchange, will be performed far less frequently on average by clients. Throughput of negotiation phases is bandwidth-, not CPU-, limited. For exchange, we implemented methods: 2048-bit RSA key transport and static-ephemeral elliptic curve Diffie–Hellman key exchange using the NIST P-256 curve; as expected, both of these are substantially more expensive than time synchronization phases, but are also performed far less frequently.

Protocol	Auth. type	Security	Server operations	Round trips
NTPv0-v2	—	—	—	1
NTPv3	sym. key	no proof	1 hash	1
sym. key				
NTPv4	pub. key	flaws (§. 2.3)	$\frac{2}{n}$ pub. key, $\frac{1}{n} + 1$ sym. key	4
Autokey				
tsdate [3]	pub. key	relies on TLS	$\frac{2}{n}$ pub. key [†] $\frac{5}{n} + 7$ sym. key [†]	4 stateful
NTS [31]	pub. key	ProVerif proof [32]	$\frac{3}{n}$ pub. key, $\frac{2}{n} + 2$ sym. key	4
ANTP	pub. key (Fig. 3)	proof (Sec. 6)	$\frac{1}{n}$ pub. key, $\frac{6}{n} + 2$ sym. key	3

Table 2: Comparison of time synchronization protocols. Server operations per time synchronization includes public key decryptions, symmetric key encryptions/decryptions, and hashes/KDFs/MACs. $\frac{a}{n} + b$ denotes a operations that can be amortized over n time synchronizations plus b operations per time sync.

[†] tsdate operation counts vary based on ciphersuite.

Details of our implementation and testing methodology, as well as more results, appear in Section 4.

ANTP compares well with other authentication methods for NTP, as seen in Table 2. ANTP uses fewer amortized public key operations compared to NTPv4 Autokey and NTS and has fewer rounds. NTPv3 using symmetric key operations is more lightweight, but is highly restricted in that it only supports symmetric authentication via pre-established symmetric keys, making it unsuitable for deployment with billions of devices.

Because ANTP is designed-for-purpose, it is also more
