Message from the Program Co-Chairs.....x

Wednesday, August 10

Low-Level Attacks

Flip Feng Shui: Hammering a Needle in the Software Stack	1
Kaveh Razavi, Ben Gras, and Erik Bosman, <i>Vrije Universiteit Amsterdam</i> ; Bart Preneel, <i>Katholieke Universiteit Leuven</i> ; Cristiano Giuffrida and Herbert Bos, <i>Vrije Universiteit Amsterdam</i>	
One Bit Flips, One Cloud Flops: Cross-VM Row Hammer Attacks and Privilege Escalation	19
Yuan Xiao, Xiaokuan Zhang, Yinqian Zhang, and Radu Teodorescu, <i>The Ohio State University</i>	
PIkit: A New Kernel-Independent Processor-Interconnect Rootkit	37
Wonjun Song, Hyunwoo Choi, Junhong Kim, Eunsoo Kim, Yongdae Kim, and John Kim, <i>Korea Advanced Institute of Science and Technology (KAIST)</i>	

Verification and Timing

Verifying Constant-Time Implementations	53
José Bacelar Almeida, <i>HASLab/INESC TEC and University of Minho</i> ; Manuel Barbosa, <i>HASLab/INESC TEC and DCC FCUP</i> ; Gilles Barthe and François Dupressoir, <i>IMDEA Software Institute</i> ; Michael Emmi, <i>Bell Labs and Nokia</i>	
Secure, Precise, and Fast Floating-Point Operations on x86 Processors	71
Ashay Rane, Calvin Lin, and Mohit Tiwari, <i>The University of Texas at Austin</i>	
ÜBERSPARK: Enforcing Verifiable Object Abstractions for Automated Compositional Security Analysis of a Hypervisor	87
Amit Vasudevan and Sagar Chaki, <i>Carnegie Mellon University</i> ; Petros Maniatis, <i>Google Inc.</i> ; Limin Jia and Anupam Datta, <i>Carnegie Mellon University</i>	

Software Attacks

Undermining Information Hiding (and What to Do about It)	105
Enes Göktaş, <i>Vrije Universiteit Amsterdam</i> ; Robert Gawlik and Benjamin Kollenda, <i>Ruhr Universität Bochum</i> ; Elias Athanasopoulos, <i>Vrije Universiteit Amsterdam</i> ; Georgios Portokalidis, <i>Stevens Institute of Technology</i> ; Cristiano Giuffrida and Herbert Bos, <i>Vrije Universiteit Amsterdam</i>	
Poking Holes in Information Hiding.....	121
Angelos Oikonomopoulos, Elias Athanasopoulos, Herbert Bos, and Cristiano Giuffrida, <i>Vrije Universiteit Amsterdam</i>	
What Cannot Be Read, Cannot Be Leveraged? Revisiting Assumptions of JIT-ROP Defenses.....	139
Giorgi Maisuradze, Michael Backes, and Christian Rossow, <i>Saarland University</i>	

Password and Key-Fingerprints

zxcvbn: Low-Budget Password Strength Estimation	157
Daniel Lowe Wheeler, <i>Dropbox Inc.</i>	
Fast, Lean, and Accurate: Modeling Password Guessability Using Neural Networks	175
William Melicher, Blase Ur, Sean M. Segreti, Saranga Komanduri, Lujo Bauer, Nicolas Christin, and Lorrie Faith Cranor, <i>Carnegie Mellon University</i>	

An Empirical Study of Textual Key-Fingerprint Representations	193
Sergej Dechand, <i>University of Bonn</i> ; Dominik Schürmann, <i>Technische Universität Braunschweig</i> ; Karoline Busse, <i>University of Bonn</i> ; Yasemin Acar and Sascha Fahl, <i>Saarland University</i> ; Matthew Smith, <i>University of Bonn</i>	

Network Security

Off-Path TCP Exploits: Global Rate Limit Considered Dangerous	209
Yue Cao, Zhiyun Qian, Zhongjie Wang, Tuan Dao, and Srikanth V. Krishnamurthy, <i>University of California, Riverside</i> ; Lisa M. Marvel, <i>United States Army Research Laboratory</i>	

Website-Targeted False Content Injection by Network Operators	227
Gabi Nakibly, <i>Rafael—Advanced Defense Systems and Technion—Israel Institute of Technology</i> ; Jaime Schcolnik, <i>Interdisciplinary Center Herzliya</i> ; Yossi Rubin, <i>Rafael—Advanced Defense Systems</i>	

The Ever-Changing Labyrinth: A Large-Scale Analysis of Wildcard DNS Powered Blackhat SEO	245
Kun Du and Hao Yang, <i>Tsinghua University</i> ; Zhou Li, <i>IEEE Member</i> ; Haixin Duan, <i>Tsinghua University</i> ; Kehuan Zhang, <i>The Chinese University of Hong Kong</i>	

A Comprehensive Measurement Study of Domain Generating Malware.....	263
Daniel Plohmann, <i>Fraunhofer FKIE</i> ; Khaled Yakdan, <i>University of Bonn</i> ; Michael Klatt, <i>DomainTools</i> ; Johannes Bader; Elmar Gerhards-Padilla, <i>Fraunhofer FKIE</i>	

Applied Cryptography

Enhancing Bitcoin Security and Performance with Strong Consistency via Collective Signing	279
Eleftherios Kokoris Kogias, Philipp Jovanovic, Nicolas Gailly, Ismail Khoffi, Linus Gasser, and Bryan Ford, <i>École Polytechnique Fédérale de Lausanne (EPFL)</i>	

Faster Malicious 2-Party Secure Computation with Online/Offline Dual Execution	297
Peter Rindal and Mike Rosulek, <i>Oregon State University</i>	

Egalitarian Computing.....	315
Alex Biryukov and Dmitry Khovratovich, <i>University of Luxembourg</i>	

Post-quantum Key Exchange—A New Hope	327
Erdem Alkim, <i>Ege University</i> ; Léo Ducas, <i>Centrum voor Wiskunde en Informatica</i> ; Thomas Pöppelmann, <i>Infineon Technologies AG</i> ; Peter Schwabe, <i>Radboud University</i>	

Thursday, August 11

Software Security

Automatically Detecting Error Handling Bugs Using Error Specifications.....	345
Suman Jana and Yuan Kang, <i>Columbia University</i> ; Samuel Roth, <i>Ohio Northern University</i> ; Baishakhi Ray, <i>University of Virginia</i>	

APISAN: Sanitizing API Usages through Semantic Cross-Checking	363
Insu Yun, Changwoo Min, Xujie Si, Yeongjin Jang, Taesoo Kim, and Mayur Naik, <i>Georgia Institute of Technology</i>	

On Omitting Commits and Committing Omissions: Preventing Git Metadata Tampering That (Re)introduces Software Vulnerabilities.....	379
Santiago Torres-Arias, <i>New York University</i> ; Anil Kumar Ammula and Reza Curtmola, <i>New Jersey Institute of Technology</i> ; Justin Cappos, <i>New York University</i>	

(Thursday, August 11, continues on next page)

Hardware I

Defending against Malicious Peripherals with Cinch397
Sebastian Angel, <i>The University of Texas at Austin and New York University</i> ; Riad S. Wahby, <i>Stanford University</i> ; Max Howald, <i>The Cooper Union and New York University</i> ; Joshua B. Leners, <i>Two Sigma</i> ; Michael Spilo and Zhen Sun, <i>New York University</i> ; Andrew J. Blumberg, <i>The University of Texas at Austin</i> ; Michael Walfish, <i>New York University</i>

Message from the 25th USENIX Security Symposium Program Co-Chairs

It is our pleasure to welcome you to the 25th USENIX Security Symposium in Austin, TX!

We hope you enjoy the outstanding program, which includes a mix of papers, invited talks, fun evening events, and, of course, the “hallway track.” Now in its 25th year, USENIX Security brings together researchers from both academia and industry interested in the latest advances in the security of computer systems and networks. The symposium is a premier venue for security and privacy research, and we look forward to seeing the lasting impact that this year’s papers will have in years to come.

For the first time, USENIX Security is chaired by two people. Given the growth of the symposium in the past few years and the huge number of submitted papers, this change was necessary. It was our great pleasure to chair USENIX Security this year, and now we want to take this opportunity to describe the process of creating the program you will enjoy over the next three days. This entire process was supported by 78 program committee members: 37 volunteers served as attending PC members, while 41 served as remote PC members. The PC spent countless hours not only reviewing papers but also discussing papers with each other online and in person. In total, more than 1,400 reviews and 2,300 comments were entered into the reviewing system, an average of five comments per paper. More specifically, the review process consisted of several rounds as described below.

First round of reviews (Feb. 25–March 24, 2016): We received 468 submissions, a 10% increase over last year. 12 papers were desk rejected due to a violation of submission requirements, and five papers were withdrawn by the authors after the deadline. The remaining 451 papers were assigned to at least two reviewers per submission. The program committee spent two weeks on online discussion once reviews had been collected. As in past years, we decided to finalize decisions in the first round for a subset of papers that had confident reviews and did not appear to have a chance of acceptance. Based on the positive feedback on early reject notifications, a feature introduced last year, we decided to also notify authors early about the status of their papers. All reviews from the first review round were sent out on April 7. In total, 233 papers were rejected in the first round of decisions and the remaining 218 papers moved on to the second review round.

This year, we introduced a new feature: authors had the option to appeal these initial reviews if they contained critical errors. We decided to introduce these appeals to make sure that we did not prematurely reject papers. An appeal was required to clearly and explicitly identify concrete disagreements with factual statements in the initial reviews. We received 19 appeals for papers rejected in the first round, and carefully checked each of them to understand the concerns raised by the authors. After several discussions, we decided to approve seven appeals and move these papers to the second review round. One of these papers was even finally accepted into the program, indicating that the intended process actually works. To our surprise, we also received 70 appeals for papers that were not rejected in the first round. It became clear that the intent of appeals was not clear to many authors, and we decided to make these appeals available to the reviewers so that they could be taken into account during the next phase.

Second round of reviews (April 6–May 3, 2016): In total, 225 papers were reviewed in the second round. Most papers received at least two more reviews, and controversial papers with diverging reviews were assigned at least three more reviews. After the second reviewing deadline had passed, the program committee spent an additional week discussing the papers using HotCRP. Each paper was discussed with the goal of reaching a consensus among the reviewers if the paper had a chance of acceptance into the final program.

Un-blinding papers (May 11, 2016): Outcomes and discussion points were finalized for each paper, and we as the PC co-chairs decided on the list of 88 papers to discuss at the PC meeting based on the recommendations. We arranged these papers into groups with a similar research topic so we could discuss them in batches during the PC meeting. Furthermore, we decided to pre-accept five papers, given that these papers had very strong positive reviews. Before the PC meeting, the author names were made visible to reviewers. The un-blinding was helpful during the meeting to clarify conflicts and to help prevent authors from being punished for failing to cite their own work or from reviewers who might have a bias based on a false assumption regarding the authors’ identity.

PC meeting (May 12–13, 2016, at Google in Mountain View, CA): 39 PC members attended the PC meeting. We allocated six minutes for the discussion of each paper. After going through the list of 88 papers, the PC spent several extra hours discussing tabled papers and papers that were voted to be resurrected. After the final decisions were made, we had accepted 72 papers, 15.4% of the submissions. The quality of these papers is very high—a testimony to the strength of our community!

The technical program would not have been possible without contributions from the program committee members and roughly 50 external reviewers who provided thoughtful reviews and recommendations. Please join us in thanking them for their countless hours of work! We would also like to thank Adrienne Porter-Felt for chairing the invited talks committee; Raluca Popa for serving as the poster session chair; Patrick Traynor for serving as the WiPs chair; student volunteer Paul Pearce for scribing at the PC meeting; Google for sponsoring the PC meeting; the USENIX staff, especially Casey Henderson and Michele Nelson, for all the support throughout the process; and the authors of all 468 papers for submitting their research for consideration. Finally, we would like to thank the USENIX steering committee for allowing us to have this incredible opportunity to work with so many wonderful people.

Abstract

We introduce Flip Feng Shui (FFS), a new exploitation vector which allows an attacker to induce bit flips over *arbitrary* physical memory in a *fully controlled way*. FFS relies on hardware bugs to induce bit flips over memory and on the ability to surgically control the physical memory layout to corrupt attacker-targeted data anywhere in the software stack. We show FFS is possible today with very few constraints on the target data, by implementing an instance using the *Rowhammer bug* and *memory deduplication* (an OS feature widely deployed in production). Memory deduplication allows an attacker to reverse-map any physical page into a virtual page she owns as long as the page’s contents are known. Rowhammer, in turn, allows an attacker to flip bits in controlled (initially unknown) locations in the target page.

We show FFS is extremely powerful: a malicious VM in a practical cloud setting can gain unauthorized access to a co-hosted victim VM running OpenSSH. Using FFS, we exemplify end-to-end attacks breaking OpenSSH public-key authentication, and forging GPG signatures from trusted keys, thereby compromising the Ubuntu/Debian update mechanism. We conclude by discussing mitigations and future directions for FFS attacks.

1 Introduction

The demand for high-performance and low-cost computing translates to increasing complexity in hardware and software. On the hardware side, the semiconductor industry packs more and more transistors into chips that serve as a foundation for our modern computing infrastructure. On the software side, modern operating systems are packed with complex features to support efficient resource management in cloud and other performance-sensitive settings.

Both trends come at the price of reliability and, inevitably, security. On the hardware side, components

are increasingly prone to failures. For example, a large fraction of the DRAM chips produced in recent years are prone to bit flips [34, 51], and hardware errors in CPUs are expected to become mainstream in the near future [10, 16, 37, 53]. On the software side, widespread features such as memory or storage deduplication may serve as side channels for attackers [8, 12, 31]. Recent work analyzes some of the security implications of both trends, but so far the attacks that abuse these hardware/software features have been fairly limited—probabilistic privilege escalation [51], in-browser exploitation [12, 30], and selective information disclosure [8, 12, 31].

In this paper, we show that an attacker abusing modern hardware/software properties can mount much more sophisticated and powerful attacks than previously believed possible. We describe Flip Feng Shui (FFS), a new exploitation vector that allows an attacker to induce bit flips over *arbitrary* physical memory in a *fully controlled way*. FFS relies on two underlying primitives: (i) the ability to induce bit flips in controlled (but not predetermined) physical memory pages; (ii) the ability to control the physical memory layout to reverse-map a target physical page into a virtual memory address under attacker control. While we believe the general vector will be increasingly common and relevant in the future, we show that an instance of FFS, which we term dFFS (i.e., deduplication-based FFS), can already be implemented on today’s hardware/software platforms with very few constraints. In particular, we show that by abusing Linux’ memory deduplication system (KSM) [6] which is very popular in production clouds [8], and the widespread Rowhammer DRAM bug [34], an attacker can *reliably* flip a single bit in *any* physical page in the software stack with known contents.

Despite the complete absence of software vulnerabilities, we show that a practical Flip Feng Shui attack can have devastating consequences in a common cloud setting. An attacker controlling a cloud VM can abuse

memory deduplication to seize control of a target physical page in a co-hosted victim VM and then exploit the Rowhammer bug to flip a particular bit in the target page in a fully controlled and reliable way without writing to that bit. We use dFFS to mount end-to-end corruption attacks against OpenSSH public keys, and Debian/Ubuntu update URLs and trusted public keys, all residing within the page cache of the victim VM. We find that, while dFFS is surprisingly practical and effective, existing cryptographic software is wholly unequipped to counter it, given that “*bit flipping is not part of their threat model*”. Our end-to-end attacks completely compromise widespread cryptographic primitives, allowing an attacker to gain full control over the victim VM.

Summarizing, we make the following contributions:

- We present FFS, a new exploitation vector to induce hardware bit flips over arbitrary physical memory in a controlled fashion (Section 2).
- We present dFFS, an implementation instance of FFS that exploits KSM and the Rowhammer bug and we use it to bit-flip RSA public keys (Section 3) and compromise authentication and update systems of a co-hosted victim VM, granting the attacker unauthorized access and privileged code execution (Section 4).
- We use dFFS to evaluate the time requirements and success rates of our proposed attacks (Section 5) and discuss mitigations (Section 6).

The videos demonstrating dFFS attacks can be found in the following URL:

2 Flip Feng Shui

To implement an FFS attack, an attacker requires a *physical memory massaging primitive* and a *hardware vulnerability* that allows her to flip bits on certain locations on the medium that stores the users’ data. Physical memory massaging is analogous to virtual memory massaging where attackers bring the virtual memory into an exploitable state [23, 24, 55], but instead performed on physical memory. Physical memory massaging (or simply *memory massaging*, hereafter) allows the attacker to steer victim’s sensitive data towards those physical memory locations that are amenable to bit flips. Once the target data land on the intended vulnerable locations, the attacker can trigger the hardware vulnerability and corrupt the data via a controlled bit flip. The end-to-end attack allows the attacker to flip *a bit of choice in data of choice anywhere* in the software stack in a controlled fashion.

With some constraints, this is similar to a typical arbitrary memory write primitive used for software exploitation [15], with two key differences: (i) the end-to-end attack requires no software vulnerability; (ii) the attacker can overwrite arbitrary physical (not just virtual) memory on the running system. In effect, FFS transforms an underlying hardware vulnerability into a very powerful software-like vulnerability via three fundamental steps:

1. *Memory templating*: identifying physical memory locations in which an attacker can induce a bit flip using a given hardware vulnerability.
2. *Memory massaging*: steering targeted sensitive data towards the vulnerable physical memory locations.
3. *Exploitation*: triggering the hardware vulnerability to corrupt the intended data for exploitation.

In the remainder of this section, we detail each of these steps and outline FFS’s end-to-end attack strategy.

2.1 Memory Templating

The goal of the memory templating step is to fingerprint the hardware bit-flip patterns on the running system. This is necessary, since the locations of hardware bit flips are generally unknown in advance. This is specifically true in the case of Rowhammer; every (vulnerable) DRAM module is unique in terms of physical memory offsets with bit flips. In this step, the attacker triggers the hardware-specific vulnerability to determine which physical pages, and which offsets within those pages are vulnerable to bit flips. We call the combination of a vulnerable page and the offset a *template*.

Probing for templates provides the attacker with knowledge of *usable* bit flips. Thanks to Flip Feng Shui, any template can potentially allow the attacker to exploit the hardware vulnerability over physical memory in a controlled way. The usefulness of such an exploit, however, depends on the direction of the bit flip (i.e., one-to-zero or zero-to-one), the page offset, and the contents of the target victim page. For each available template, the attacker can only craft a Flip Feng Shui primitive that corrupts the target data page with the given *flip* and *offset*. Hence, to surgically target the victim’s sensitive data of interest, the attacker needs to probe for matching templates by repeatedly exploiting the hardware vulnerability over a controlled physical page (i.e., mapped in her virtual address space). To perform this step efficiently, our own dFFS implementation relies on a variant of double-sided Rowhammer [51]. Rowhammer allows an attacker to induce bit flips in vulnerable memory locations by repeatedly reading from memory pages located in adjacent rows. We discuss the low-level details

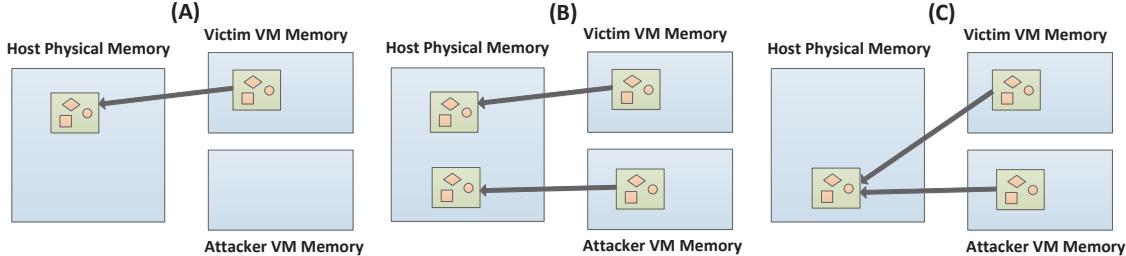

Figure 1: Memory deduplication can provide an attacker control over the layout of physical memory.

of the Rowhammer vulnerability and our implementation in Section 4.2.

2.2 Memory Massaging

To achieve bit flips over arbitrary contents of the victim’s physical memory, FFS abuses modern memory management patterns and features to craft a memory massaging primitive. Memory massaging allows the attacker to map a desired victim’s physical memory page into her own virtual memory address space in a controllable way.

Given a set of templates and the memory massaging primitive, an ideal version of FFS can corrupt any of the victim’s memory pages at an offset determined by the selected template.

While memory massaging may be nontrivial in the general case, it is surprisingly easy to abuse widely deployed memory deduplication features to craft practical FFS attacks that corrupt any of the victim’s memory pages with *known contents* (similar to our dFFS implementation). Intuitively, since memory deduplication merges system-wide physical memory pages with the same contents, an attacker able to craft the contents of any of the victim’s memory pages can obtain a memory massaging primitive and map the target page into her address space.

Figure 1 shows how an attacker can control the physical memory location of a victim VM’s memory page. At first, the attacker needs to predict the contents of the victim VM’s page that she wants to control (Figure 1-A). Once the target page is identified, the attacker VM creates a memory page with the same contents as the victim VM’s memory page and waits for the memory deduplication system to scan both pages (Figure 1-B). Once the two physical pages (i.e., the attacker’s and the victim’s pages) are identified, the memory deduplication system returns one of the two pages back to the system, and the other physical page is used to back both the attacker and the victim’s (virtual) pages. If the attacker’s page is used to back the memory of the victim page, then, in effect, the attacker controls the physical memory location of the victim page (Figure 1-C).

There are additional details necessary to craft a memory massaging primitive using a real-world implementation of memory deduplication (e.g., KSM). Section 4.1 elaborates on such details and presents our implementation of memory massaging on Linux.

2.3 Exploitation

At this stage, FFS already provides the attacker with templated bit flips over the victim’s physical memory pages with known (or predictable) contents. The exploitation surface is only subject to the available templates and their ability to reach interesting locations for the attacker. As we will see, the options are abundant.

While corrupting the memory state of running software of the victim is certainly possible, we have opted for a more straightforward, yet extremely powerful exploitation strategy. We consider an attacker running in a cloud VM and seeking to corrupt interesting contents in the page cache of a co-hosted victim VM. In particular, our dFFS implementation includes two exploits that corrupt sensitive file contents in the page cache in complete absence of software vulnerabilities:

1. Flipping SSH’s `authorized_keys`: assuming the RSA public keys of the individuals accessing the victim VM are known, an attacker can use dFFS to induce an exploitable flip in their public keys, making them prone to factorization and breaking the authentication system.
2. Flipping apt’s `sources.list` and `trusted.gpg`: Debian/Ubuntu’s apt package management system relies on the `sources.list` file to operate daily updates and on the `trusted.gpg` file to check the authenticity of the updates via RSA public keys. Compromising these files allows an attacker to make a victim VM download and install arbitrary attacker-generated packages.

In preliminary experiments, we also attempted to craft an exploit to bit-flip SSH’s `moduli` file containing Diffie-Hellman group parameters and eavesdrop on the victim

VM’s SSH traffic. The maximum group size on current distributions of OpenSSH is 1536. When we realized that an exploit targeting such 1536-bit parameters would require a nontrivial computational effort (see Appendix A for a formal analysis), we turned our attention to the two more practical and powerful exploits above.

In Section 3, we present a cryptanalysis of RSA moduli with a bit flip as a result of our attacks. In Section 4, we elaborate on the internals of the exploits, and finally, in Section 5, we evaluate their success rate and time requirements in a typical cloud setting.

3 Cryptanalysis of RSA with Bit Flips

RSA [49] is a public-key cryptosystem: the sender encrypts the message with the public key of the recipient (consisting of an exponent e and a modulus n) and the recipient decrypts the ciphertext with her private key (consisting of an exponent d and a modulus n). This way RSA can solve the key distribution problem that is inherent to symmetric encryption. RSA can also be used to digitally sign messages for data or user authentication: the signing operation is performed using the private key, while the verification operation employs the public key.

Public-key cryptography relies on the assumption that it is computationally infeasible to derive the private key from the public key. For RSA, computing the private exponent d from the public exponent e is believed to require the factorization of the modulus n . If n is the product of two large primes of approximately the same size, factorizing n is not feasible. Common sizes for n today are 1024 to 2048 bits.

In this paper we implement a fault attack on the modulus n of the victim: we corrupt a single bit of n , resulting in n' . We show that with high probability n' will be easy to factorize. We can then compute from e the corresponding value of d' , the private key, that allows us to forge signatures or to decrypt. We provide a detailed analysis of the expected computational complexity of factorizing n' in the following¹.

RSA performs computations modulo n , where t is the bitlength of n ($t = 1 + \lfloor \log_2 n \rfloor$). Typical values of t lie between 512 (export control) and 8192, with 1024 and 2048 the most common values. We denote the i th bit of n with $n[i]$ ($0 \leq i < t$), with the least significant bit (LSB) corresponding to $n[0]$. The unit vector is written as e_i , that is $e_i[i] = 1$ and $e_i[j] = 0$, for $j \neq i$. The operation of flipping the i th bit of n results in n' , or $n' = n \oplus e_i$. Any integer can be written as the product of primes, hence $n = \prod_{i=1}^s p_i^{\gamma_i}$, where p_i are the prime factors of n , γ_i is the multiplicity of p_i and s is the number of distinct prime

¹A similar analysis for Diffie-Hellman group parameters with bit flips can be found in Appendix A.

factors. W.l.o.g. we assume that $p_1 > p_2 > \dots > p_s$.

In the RSA cryptosystem, the modulus n is the product of two odd primes p_1, p_2 of approximate equal size, hence $s = 2$, and $\gamma_1 = \gamma_2 = 1$. The encryption operation is computed as $c = m^e \bmod n$, with e the public exponent, and $m, c \in [0, n - 1]$ the plaintext respectively the ciphertext. The private exponent d can be computed as $d = e^{-1} \bmod \lambda(n)$, with $\lambda(n)$ the Carmichael function, given by $\text{lcm}(p_1, p_2)$. The best known algorithm to recover the private key is to factorize n using the General Number Field Sieve (GNFS) (see e.g. [42]), which has complexity $O(L_n[1/3, 1.92])$, with

$$L_n[a, b] = \exp((b + o(1))(\ln n)^a (\ln \ln n)^{1-a}).$$

For a 512-bit modulus n , Adrian et al. estimate that the cost is about 1 core-year [3]. The current record is 768 bits [35], but it is clear that 1024 bits is within reach of intelligence agencies [3].

If we flip the LSB of n , we obtain $n' = n - 1$, which is even hence $n' = 2 \cdot n''$ with n'' a $t - 1$ -bit integer. If we flip the most significant bit of n , we obtain the odd $t - 1$ -bit integer n' . In all the other cases we obtain an odd t -bit integer n' . We conjecture that the integer n'' (for the LSB case) and the integers n' (for the other cases) have the same distribution of prime factors as a random odd integer. To simplify the notation, we omit in the following the LSB case, but the equations apply with n' replaced by n'' .

Assume that an attacker can introduce a bit flip to change n into n' with as factorization $n = \prod_{j=1}^{t'} p_i'^{\tilde{\gamma}_i}$. Then $c' = m'^e \bmod n'$. The Carmichael function can be computed as

$$\lambda(n') = \text{lcm}\left(\left\{p_i'^{\tilde{\gamma}_i-1} \cdot (p_i' - 1)\right\}\right).$$

If $\gcd(e, \lambda(n')) = 1$, the private exponent d' can be found as $d' = e^{-1} \bmod \lambda(n')$. For prime exponents e , the probability that $\gcd(e, \lambda(n')) > 1$ equals $1/e$. For $e = 3$, this means that 1 in 3 attacks fails, but for the widely used value $e = 2^{16} + 1$, this is not a concern. With the private exponent d' we can decrypt or sign any message. Hence the question remains how to factorize n' . As it is very likely that n' is not the product of two primes of almost equal size, we can expect that factorizing n' is much easier than factorizing n .

Our conjecture implies that with probability $2/\ln n'$, n' is prime and in that case the factorization is trivial. If n' is composite, the best approach is to find small factors (say up to 16 bits) using a greatest common divisor operation with the product of the first primes. The next step is to use Pollard’s ρ algorithm (or Brent’s variant) [42]: this algorithm can easily find factors up to 40...60 bits. A third step consists of Lenstra’s Elliptic Curve factorization Method (ECM) [38]: ECM can quickly find factors up to 60...128 bits (the record is a factor of about

270 bits²). Its complexity to find the smallest prime factor p'_s is equal to $O(L_{p'_s}[1/2, \sqrt{2}])$. While ECM is asymptotically less efficient than GNFS (because of the parameter 1/2 rather than 1/3), the complexity of ECM depends on the size of the smallest prime factor p'_s rather than on the size of the integer n' to factorize. Once a prime factor p'_i is found, n' is divided by it, the result is tested for primality and if the result is composite, ECM is restarted with as argument n'/p'_i .

The complexity analysis of ECM depends on the number of prime factors and the distribution of the size of the second largest prime factor p'_2 : it is known that its expected value is $0.210 \cdot t$ [36]. The Erdős–Kac theorem [22] states that the number $\omega(n')$ of distinct prime factors of n' is normally distributed with mean and variance $\ln \ln n'$: for $t = 1024$ the mean is about 6.56, with standard deviation 2.56. Hence it is unlikely that we have exactly two prime factors (probability 3.5%), and even less likely that they are of approximate equal size. The probability that n' is prime is equal to 0.28%. The expected size of the second largest prime factor p'_2 is 215 bits and the probability that it has less than 128 bits is 0.26 [36]. In this case ECM should be very efficient. For $t = 2048$, the probability that n' is prime equals 0.14%. The expected size of the second largest prime factor p'_2 is 430 bits; the probability that p'_2 has less than 228 bits is 0.22 and the probability that it has less than 128 bits is about 0.12. Similarly, for $t = 4096$, the expected size of the second largest prime factor p'_2 is 860 bits. The probability that p'_2 has less than 455 bits is 0.22.

The main conclusion is that *if n has 1024-2048 bits, we can expect to factorize n' efficiently with a probability of 12 – 22% for an arbitrary bit flip, but larger moduli should also be feasible*. As we show in Section 5, given a few dozen templates, we can easily factorize any 1024 bit to 4096 bit modulus with one (or more) of the available templates.

4 Implementation

To implement dFFS reliably on Linux, we need to understand the internals of two kernel subsystems, kernel same-page merging [6] (KSM) and transparent huge pages [5], and the way they interact with each other. After discussing them and our implementation of the Rowhammer exploit (Sections 4.1, 4.2, and 4.3), we show how we factorized corrupted RSA moduli in Section 4.4 before summarizing our end-to-end attacks in Section 4.5.

²https://en.wikipedia.org/wiki/Lenstra_elliptic_curve_factorization

4.1 Kernel Same-page Merging

KSM, the Linux implementation of memory deduplication, uses a kernel thread that periodically scans memory to find memory pages with the same contents that are candidates for merging. It then keeps a single physical copy of a set of candidate pages, marks it read-only, and updates the page-table entries of all the other copies to point to it before releasing their physical pages to the system.

KSM keeps two red-black trees, termed “stable” and “unstable”, to keep track of the merged and candidate pages. The merged pages reside in the stable tree while the candidate contents that are not yet merged are in the unstable tree. KSM keeps a list of memory areas that are registered for deduplication and goes through the pages in these areas in the order in which they were registered. For each page that it scans, it checks if the stable tree already contains a page with the same contents. If so, it updates the page-table entry for that page to have it point to the physical page in the stable tree and releases the backing physical page to the system. Otherwise, it searches the unstable tree for a match and if it finds one, promotes the page to the stable tree and updates *the page-table entry of the match to make it point to this page*. If no match is found in either one of the trees, the page is added to the unstable tree. After going through all memory areas, KSM dumps the unstable tree before starting again. Further details on the internals of KSM can be found in [6].

In the current implementation of KSM, during a merge, the physical page in either the stable tree or the unstable tree is always preferred. This means that during a merge with a page in the stable tree, the physical location of the page in the stable tree is chosen. Similarly, the physical memory of the page in the unstable tree is chosen to back both pages. KSM scans the memory of the VMs in order that they have been registered (i.e., their starting time). This means that to control the location of the target data on physical memory using the *unstable tree* the attacker VM should have been started *before* the victim VM. Hence, the longer the attacker VM waits, the larger the chance of physical memory massaging through the unstable tree.

The better physical memory massaging possibility is through the stable tree. An attacker VM can upgrade a desired physical memory location to the stable tree by creating two copies of the target data and placing one copy in the desired physical memory location and another copy in a different memory location. By ensuring that the other copy comes after the desired physical memory location in the physical address-space, KSM merges the two pages and creates a stable tree node using the desired physical memory location. At this point, any other

Figure 2: A SO-DIMM with its memory chips.

page with the same contents will assume the same physical memory location desired by the attacker VM. For this to work, however, the attacker needs to control when the memory page with the target contents is created in the victim VM. In the case of our OpenSSH attack, for example, the attacker can control when the target page is created in the victim VM by starting an SSH connection using an invalid key with the target username.

For simplicity, the current version of dFFS implements the memory massaging using the unstable tree by assuming that the attacker VM has started first, but it is trivial to add support for memory massaging with stable tree. Using either the stable or unstable KSM trees for memory massaging, all dFFS needs to do is crafting a page with the same contents as the victim page and place it at the desired physical memory page; KSM will then perform the necessary page-table updates on dFFS’s behalf! In other words, KSM inadvertently provides us with exactly the kind of memory massaging we need for successful Flip Feng Shui.

4.2 Rowhammer inside KVM

Internally, DRAM is organized in rows. Each row provides a number of physical cells that store memory bits. For example, in an x86 machine with a single DIMM, each row contains 1,048,576 cells that can store 128 kB of data. Each row is internally mapped to a number of chips on the DIMM as shown in Figure 2.

Figure 3 shows a simple organization of a DRAM chip. When the processor reads a physical memory location, the address is translated to an offset on row i of the DRAM. Depending on the offset, the DRAM selects the proper chip. The selected chip then copies the contents of its row i to the row buffer. The contents at the correct offset within the row buffer is then sent on the bus to the processor. The row buffer acts as a cache: if the selected row is already in the row buffer, there is no need to read from the row again.

Each DRAM cell is built using a transistor and a capacitor. The transistor controls whether the contents of the cell is accessible, while the capacitor can hold a charge which signifies whether the stored content is a

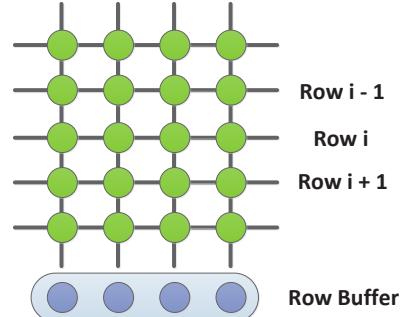

Figure 3: DRAM’s internal organization.

high or low bit. Since capacitors leak charge over time, the processor sends refresh commands to DIMM rows in order to recharge their contents. On top of the refresh commands, every time a row is read by the processor, the chip also recharges its cells.

As DRAM components have become smaller, they keep a smaller charge to signify stored contents. With a smaller charge, the error margin for identifying whether the capacitor is charged (i.e., the stored value) is also smaller. Kim et al. [34] showed that the smaller error margin, in combination with unexpected charge exchange between cells of different rows, can result in the cell to “lose” its content. To trigger this DRAM reliability issue, an attacker needs fast activations of DRAM rows which causes a cell in adjacent rows to lose enough charge so that its content is cleared. Note that due to the row buffer, at least two rows need to activate one after the other in a tight loop for Rowhammer to trigger. If only one row is read from, the reads can be satisfied continually from the row buffer, without affecting the row charges in the DRAM cells.

Double-sided Rowhammer. Previous work [51] reported that if these two “aggressor” rows are selected in a way that they are one row apart (e.g., row $i - 1$ and $i + 1$ in Figure 3), the chances of charge interaction between these rows and the row in the middle (i.e., row i) increases, resulting in potential bit flips in that row. This variant of Rowhammer is named double-sided Rowhammer. Apart from additional speed for achieving bit flips, it provides additional reliability by isolating the location of most bit flips to a certain (victim) row.

To perform double-sided Rowhammer inside KVM, we need to know the host physical addresses inside the VM. This information is, however, not available in the guest: guest physical addresses are mapped to host virtual addresses which can be mapped to any physical page by the Linux kernel. Similar to [30], we rely on transparent huge pages [5] (THP). THP is a Linux kernel feature

that runs in the background and merges virtually contiguous normal pages (i.e., 4 kB pages) into huge pages (i.e., 2 MB pages) that rely on contiguous pieces of physical memory. THP greatly reduces the number of page-table entries in suitable processes, resulting in fewer TLB³ entries. This improves performance for some workloads.

THP is another (weak) form of memory massaging; it transparently allows the attacker control over how the system maps guest physical memory to host physical memory. Once the VM is started and a certain amount of time has passed, THP will transform most of the VM’s memory into huge pages. Our current implementation of dFFS runs entirely in the userspace of the guest and relies on the default-on THP feature of both the host and the guest. As soon as the guest boots, dFFS allocates a large buffer with (almost) the same size as the available memory in the guest. The THP in the host then converts guest physical addresses into huge pages and the THP in the guest turns the guest virtual pages backing dFFS’s buffer into huge pages as well. As a result, dFFS’s buffer will largely be backed by huge pages all the way down to host physical memory.

To make sure that the dFFS’s buffer is backed by huge pages, we request the guest kernel to align the buffer at a 2 MB boundary. This ensures that if the buffer is backed by huge pages, it starts with one: on the x86_64 architecture, the virtual and physical huge pages share the lowest 20 bits, which are zero. The same applies when transitioning from the guest physical addresses to host physical addresses. With this knowledge, dFFS can assume that the start of the allocated buffer is the start of a memory row, and since multiple rows fit into a huge page, it can successively perform double-sided Rowhammer on these rows. To speed up our search for bit flips during double-sided Rowhammer on each two rows, we rely on the row-conflict side channel for picking the hammering addresses within each row [44]. We further employed multiple threads to amplify the Rowhammer effect.

While THP provides us with the ability to efficiently and reliably induce Rowhammer bit flips, it has unexpected interactions with KSM that we will explore in the next section.

4.3 Memory Massaging with KSM

In Section 2.2, we discussed the operational semantics of KSM. Here we detail some of its implementation features that are important for dFFS.

³TLB or translation lookaside buffer is a general term for processor caches for page-table entries to speed up the virtual to physical memory translation

4.3.1 Interaction with THP

As we discussed earlier, KSM deduplicates memory pages with the same contents as soon as it finds them. KSM currently does not support deduplication of huge pages, but what happens when KSM finds matching contents within huge pages?

A careful study of the KSM shows that KSM always prefers reducing memory footprint over reducing TLB entries; that is, KSM breaks down huge pages into smaller pages if there is a small page inside with similar contents to another page.

This specific feature is important for an efficient and reliable implementation of dFFS, but has to be treated with care. More specifically, we can use huge pages as we discussed in the previous section for efficient and reliable double-sided Rowhammer, while retaining control over which victim page we should map in the middle of our target (vulnerable) huge page.

KSM, however, can have undesired interactions with THP from dFFS’s point of view. If KSM finds pages in the attacker VM’s memory that have matching contents, it merges them with each other or with a page from a previously started VM. In these situations, KSM breaks THP by releasing one of its smaller pages to the system. To avoid this, dFFS uses a technique to avoid KSM during its templating phase. KSM takes a few tens of seconds to mark the pages of dFFS’s VM as candidates for deduplication. This gives dFFS enough time to allocate a large buffer with the same size as VM’s available memory (as mentioned earlier) and write unique integers at a pre-determined location within each (small) page of this buffer as soon as its VM boots. The entropy present within dFFS’s pages then prohibits KSM to merge these pages which in turn avoids breaking THP.

4.3.2 On dFFS Chaining

Initially, we planned on chaining memory massaging primitive and FFS to induce an arbitrary number of bit flips at many desired locations of the victim’s memory page. After using the first template for the first bit flip, the attacker can write to the merged memory page to trigger a copy-on-write event that ultimately unmerges the two pages (i.e., the attacker page from the victim page). At this stage, the attacker can use dFFS again with a new template to induce another bit flip.

However, the implementation of KSM does not allow this to happen. During the copy-on-write event, the victim’s page remains in the stable tree, even if it is the only remaining page. This means that subsequent attempts for memory massaging results in the victim page to control the location of physical memory, disabling the attacker’s ability for chaining FFS attacks.

Even so, based on our single bit flip cryptanalysis on public keys and our evaluation in Section 5, chaining is not necessary for performing successful end-to-end attacks with dFFS.

4.4 Attacking Weakened RSA

For the two attacks in this paper, we generate RSA private keys, i.e., the private exponents d' corresponding to corrupted moduli n' (as described in Section 3). We use d' to compromise two applications: OpenSSH and GPG.

Although the specifics of the applications are very different, the pattern to demonstrate each attack is the same and as follows:

1. Obtain the file containing the RSA public key (n, e) . This is application-specific, but due to the nature of public key cryptosystems, generally unprotected. We call this the input file.
2. Using the memory templating step of Section 2.1 we obtain a list of templates that we are able to flip within a physical page. We flip bits according to the target templates to obtain corrupted keys. For every single bitflip, we save a new file. We call these files the corrupted files. According to the templating step, dFFS has the ability to create any of these corrupted files in the victim by flipping a bit in the page cache.
3. One by one, we now read the (corrupted) public keys for each corrupted file. If the corrupted file is parsed correctly *and* the public key has a changed modulus $n' \neq n$ and the same e , this n' is a candidate for factorization.
4. We start factorizations of all n' candidates found in the previous step. As we described in Section 3, the best known algorithm for our scenario is ECM that finds increasingly large factor in an iterative fashion. We use the Sage [19] implementation of ECM for factorizing n' . We invoke an instance of ECM per available core for each corrupted key with a 1 hour timeout (all available implementations of ECM run with a single thread).
5. For all successful factorizations, we compute the private exponent d' corresponding to (n', e) and generate the corresponding private key to the corrupted public key. How to compute d' based on the factorization of n' is described in Section 3. We can then use the private key with the unmodified application. This step is application-specific and we will discuss it for our case studies shortly.

We now describe our end-to-end attacks that put all the pieces of dFFS together using two target applications: OpenSSH and GPG.

4.5 End-to-end Attacks

Attacker model. The attacker owns a VM co-hosted with a victim VM on a host with DIMMs susceptible to Rowhammer. We further assume that memory deduplication is turned on—as is common practice in public cloud settings [8]. The attacker has the ability to use the memory deduplication side-channel to fingerprint low-entropy information, such as the IP address of the victim VM, OS/library versions, and the usernames on the system (e.g., through `/etc/passwd` file in the page cache) as shown by previous work [32, 43, 56]. The attacker’s goal is to compromise the victim VM without relying on any software vulnerability. We now describe how this model applies with dFFS in two important and widely popular applications.

4.5.1 OpenSSH

One of the most commonly used authentication mechanisms allowed by the OpenSSH daemon is an RSA public key. By adding a user’s RSA public key to the SSH `authorized_keys` file, the corresponding private key will allow login of that user without any other authentication (such as a password) in a default setting. The public key by default includes a 2048 bit modulus n . The complete key is a 372-byte long base64 encoding of (n, e) .

The attacker can initiate an SSH connection to the victim with a correct victim username and an arbitrary private key. This interaction forces OpenSSH to read the `authorized_keys` file, resulting in this file’s contents getting copied into the page cache at the right time as we discussed in Section 4.1. Public key cryptosystems by definition do not require public keys to be secret, therefore we assume an attacker can obtain a victim public key. For instance, GitHub makes the users’ submitted SSH public keys publicly available [27].

With the victim’s public key known and in the page cache, we can initiate dFFS for inducing a bit flip. We cannot flip just any bit in the memory page caching the `authorized_keys`; some templates *will* break the base64 encoding, resulting in a corrupted file that OpenSSH does not recognize. Some flips, however, decode to a valid (n', e) key that we can factorize. We report in Section 5 how many templates are available on average for a target public key.

Next, we use a script with the PyCrypto RSA cryptographic library [39] to operate on the corrupted public keys. This library is able to read and parse OpenSSH public key files, and extract the RSA parameters (n, e) .

It can also generate RSA keys with specific parameters and export them as OpenSSH public (n', e) and private (n', d') keys again. All the attacker needs to do is factorize n' as we discussed in Section 4.4.

Once we know the factors of n' , we generate the private key (n', d') that can be used to login to the victim VM using an unmodified OpenSSH client.

4.5.2 GPG

The GNU Privacy Guard, or GPG, is a sophisticated implementation of, among others, the RSA cryptosystem. It has many applications in security, one of which is the verification of software distributions by verifying signatures using trusted public keys. This is the larger application we intend to subvert with this attack.

Specifically, we target the `apt` package distribution system employed by Debian and Ubuntu distribution for software installation and updates. `apt` verifies package signatures after download using GPG and trusted public keys stored in `trusted.gpg`. It fetches the package index from sources in `sources.list`.

Our attack first steers the victim to our malicious repository. The attacker can use dFFS to achieve this goal by inducing a bit flip in the `sources.list` file that is present in the page cache after an update. `sources.list` holds the URL of the repositories that are used for package installation and update. By using a correct template, the attacker can flip a bit that results in a URL that she controls. Now, the victim will seek the package index and packages at an attacker-controlled repository.

Next, we use our exploit to target the GPG trusted keys database. As this file is part of the software distribution, the stock contents of this file is well-known and we assume this file is unchanged or we can guess the new changes. (Only the pages containing the keys we depend on need be either unchanged or guessed.) This file resides in the page cache every time the system tries to update as a result of a daily cron job, so in this attack, no direct interaction with the victim is necessary for bringing the file in the page cache. Our implicit assumption is that this file remains in the page cache for the next update iteration.

Similar to OpenSSH, we apply bit flip mutations in locations where we can induce bit flips according to the memory templating step. As a result, we obtain the corrupted versions of this file, and each time check whether GPG will still accept this file as a valid keyring and that one of the RSA key moduli has changed as a result of our bit flip. Extracting the key data is done with the GPG `--list-keys --with-key-data` options.

For every bitflip location corresponding to a corrupted modulus that we can factorize, we pick one of these

mutations and generate the corresponding (n', d') RSA private key, again using PyCrypto. We export this private key using PyCrypto as PEM formatted key and use `pem2openpgp` [26] to convert this PEM private key to the GPG format. Here we specify the usage flags to include signing and the same generation timestamp as the original public key. We can then import this private key for use for signing using an unmodified GPG.

It is important that the Key ID in the private keyring match with the Key ID in the `trusted.gpg` file. This Key ID is not static but is based on a hash computed from the public key data, a key generation timestamp, and several other fields. In order for the Key ID in the private keyring to match with the Key ID in the public keyring, these fields have to be identical and so the setting of the creation timestamp is significant.

One significant remark about the Key ID changing (as a result of a bit flip) is that this caused the self-signature on the public keyring to be ignored by GPG! The signature contains the original Key ID, but it is now attached to a key with a different ID due to the public key mutation. As a result, *GPG ignores the attached signature as an integrity check of the bit-flipped public key and the self-signing mechanism fails to catch our bit flip*. The only side-effect is harmless to our attack – GPG reports that the trusted key is not signed. `apt` ignores this without even showing a warning. After factorizing the corrupted public key modulus, we successfully verified that the corresponding private key can generate a signature that verifies against the bit-flipped public key stored in the original `trusted.gpg`.

We can now sign our malicious package with the new private key and the victim will download and install the new package without a warning.

5 Evaluation

We evaluated dFFS to answer the following three key questions:

- What is the success probability of the dFFS attack?
- How long does the dFFS attack take?
- How much computation power is necessary for a successful dFFS attack?

We used the following methodology for our evaluation. We first used a Rowhammer testbed to measure how many templates are available in a given segment of memory and how long it takes us to find a certain template. We then executed the end-to-end attacks discussed in Section 4.5 and report on their success rate and their start-to-finish execution time. We then performed an analytical large-scale study of the factorization time, success probability, and computation requirements of 200

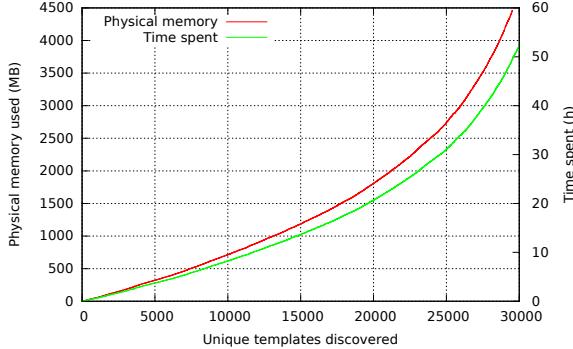

Figure 4: Required time and memory for templating.

RSA public keys for each of the 1024, 2048 and 4096-bit moduli with 50 bit flips at random locations (i.e., 30,000 bit flipped public keys in total).

We used the following hardware for our Rowhammer testbed and for the cluster that we used to conduct our factorization study:

Rowhammer testbed. Intel Haswell i7-4790 4-core processor on an Asus H97-Pro mainboard with 8 GB of DDR3 memory.

Factorization cluster. Up to 60 nodes, each with two Intel Xeon E5-2630 8-core processors with 64 GB of memory.

5.1 dFFS on the Rowhammer Testbed

Memory templating. Our current implementation of Rowhammer takes an average of 10.58 seconds to complete double-sided Rowhammer for each target row. Figure 4 shows the amount of time and physical memory that is necessary for discovering a certain number of templates. Note that, in our testbed, we could discover templates for almost any bit offset (i.e., 29,524 out of 32,768 possible templates). Later, we will show that we only need a very small fraction of these templates to successfully exploit our two target programs.

Memory massaging. dFFS needs to wait for a certain amount of time for KSM to merge memory pages. KSM scans a certain number of pages in each waking period. On the default version of Ubuntu, for example, KSM scans 100 pages every 20 milliseconds (i.e., 20 MB). Recent work [12] shows that it is possible to easily detect when a deduplication pass happens, hence dFFS needs to wait at most the sum of memory allocated to each co-hosted VM. For example, in our experiments with one

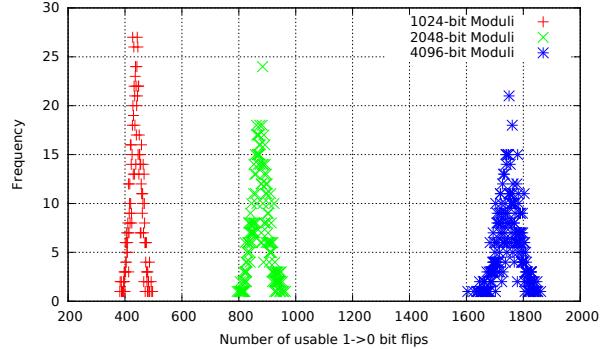

Figure 5: Number of usable 1-to-0 bit flips usable in the SSH authorized_keys file for various modulus sizes.

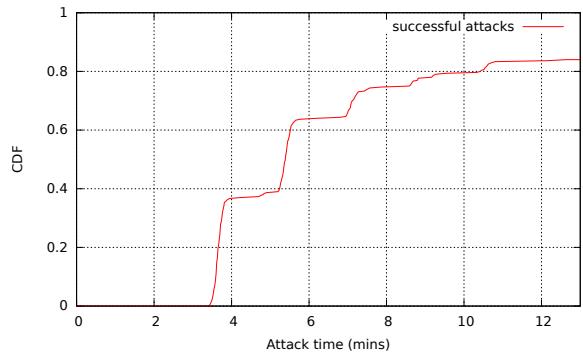

Figure 6: CDF of successful automatic SSH attacks.

attacker VM and one victim VM each with 2 GB of memory, KSM takes at most around 200 seconds for a complete pass.

5.2 The SSH Public Key Attack

Figure 5 shows the number of possible templates to perform the dFFS attack on the SSH authorized_keys file with a single randomly selected RSA public key, for 1024, 2048 and 4096-bit public keys. For this experiment, we assumed 1-to-0 bit flips since they are more common in our testbed. For DRAM chips that are susceptible to frequent 0-to-1 bit flips, these numbers double. For our experiment we focused on 2048-bit public keys as they are the default length as generated by the ssh-keygen command.

To demonstrate the working end-to-end attack, measure its reliability, and measure the elapsed time distribution, we automatically performed the SSH attack 300 times from an attacker VM on a victim VM, creating the keys and VM's from scratch each time. Figure 6 shows the CDF of successful attacks with respect to the time they took. In 29 cases (9.6%), the Rowhammer operation did not change the modulus at all (the attacker needs

Table 1: Examples of domains that are one bit flip away from `ubuntu.com` that we purchased.

<code>ubuftu.com</code>	<code>ubunt5.com</code>	<code>ubunte.com</code>
<code>ubunuu.com</code>	<code>ubunvu.com</code>	<code>ubunpu.com</code>
<code>ubun4u.com</code>	<code>ubuntw.com</code>	<code>ubuntt.com</code>

to retry). In 19 cases (6.3%), the Rowhammer operation changed the modulus other than planned. The remaining 252 (84.1%) were successful the first time. All the attacks finished within 12.6 minutes with a median of 5.3 minutes.

5.3 The Ubuntu/Debian Update Attack

We tried factorizing the two bit-flipped 4096 bit **Ubuntu Archive Automatic Signing** RSA keys found in the `trusted.gpg` file. Out of the 8,192 trials (we tried both 1-to-0 and 0-to-1 flips), we could factorize 344 templates. We also need to find a bit flip in the URL of the Ubuntu or Debian update servers (depending on the target VM’s distribution) in the page cache entry for apt’s `sources.list` file. For `ubuntu.com`, 29 templates result in a valid domain name, and for `debian.org`, 26 templates result in a valid domain name. Table 5.2 shows examples of domains that are one bit flip away from `ubuntu.com`.

Performing the update attack on our Rowhammer testbed, we could trigger a bit flip in the page cache entry of sources `sources.list` in 212 seconds, converting `ubuntu.com` to `ubunvu.com`, a domain which we control. Further, we could trigger a bit flip in the page cache entry of `trusted.gpg` that changed one of the RSA public keys to one that we had pre-computed a factorization in 352 seconds. At this point, we manually sign the malicious package with our GPG private key that corresponds to the mutated public key. When the victim then updates the package database and upgrades the packages, the malicious package is downloaded and installed without warning. Since the current version of dFFS runs these steps sequentially, the entire end-to-end attack took 566 seconds. We have prepared a video of this attack which is available at: <https://vusec.net/projects/flip-feng-shui>

Growingly concerned about the impact of such practical attacks, we conservatively registered all the possible domains from our Ubuntu/Debian list.

5.4 RSA Modulus Factorization

Figure 7 shows the average probability of successful factorizations based on the amount of available compute

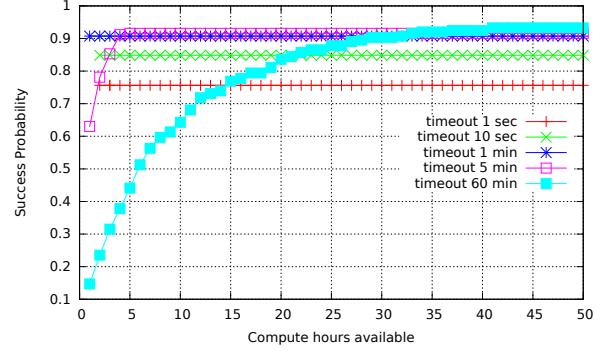

Figure 7: Compute power and factorization timeout tradeoff for 2048-bit RSA keys.

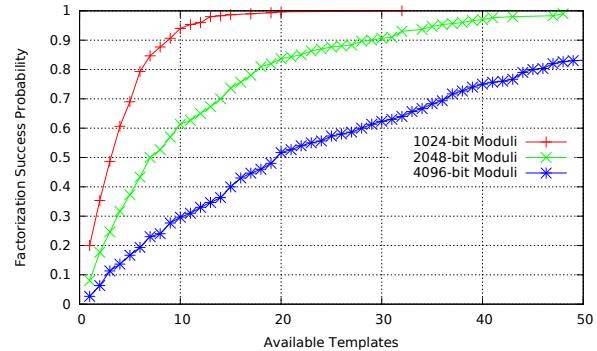

Figure 8: CDF of success rate with increasing templates.

hours. We generated this graph using 200 randomly generated 2048-bit RSA keys, each with a bit flip in 50 distinct trials (i.e., 10,000 keys, each with a bit flip). For this experiment, we relied on the ECM factorization tool, discussed in Section 3, and varied its user-controlled timeout parameter between one second and one hour. For example, with a timeout of one second for a key with a bit flip, we either timeout or the factorization succeeds immediately. In both cases, we move on to the next trial of the same key with a different bit flip.

This graph shows that, with 50 bit flips, the average factorization success probability is between 0.76 for a timeout of one second and 0.93 for a timeout of one hour. Note that, for example, with a timeout of one second, we can try 50 templates in less than 50 seconds, while achieving a successful factorization in as many as 76% of the public keys. A timeout of one minute provides a reasonable tradeoff and can achieve a success rate of 91% for 2048-bit RSA keys.

Figure 8 shows the cumulative success probability of factorization as more templates become available for 1024-bit, 2048-bit and 4096-bit keys. For 4096-bit keys, we need around 50 templates to be able to factorize a key with high probability (0.85) with a 1-hour timeout.

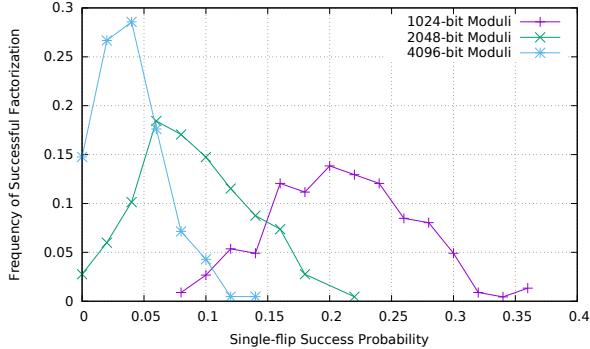

Figure 9: Probability mass function of successful factorizations with one flip.

With bit-flipped 2048-bit RSA public keys, with only 48 templates, we achieved a success probability of 0.99 with a 1 hour timeout. This proves that for 2048-bit keys (`ssh-keygen`'s default), *only a very small fraction of the templates from our testbed is necessary for a successful factorization*. For 1024-bit keys, we found a successful factorization for all keys after just 32 templates.

Some DRAM modules may only have a small number of bit flips [34], so an interesting question is: what is the chance of achieving a factorization using only a single template? Figure 9 answers this question for 1024-bit, 2048-bit and 4096-bit moduli separately. To interpret the figure, fix a point on the horizontal axis: this is the probability of a successful factorization using a single bit flip within 1 hour. Now read the corresponding value on the vertical axis, which shows the probability that a public key follows this success rate. For example, on average, 15% of 2048-bit RSA public keys can be factored using only a single bit flip with probability 0.1. As is expected, the probability to factor 4096-bit keys with the same 1-hour timeout is lower, and for 1024-bit keys higher. The fact that the distributions are centered around roughly 0.22, 0.11, and 0.055 are consistent with our analytical results in 3, which predict the factorization cost is linear in the bitlength of the modulus.

6 Mitigations

Mitigating Flip Feng Shui is not straightforward as hardware reliability bugs become prevalent. While there is obviously need for new testing methods and certification on the hardware manufacturer's side [4], software needs to adapt to fit Flip Feng Shui in its threat model. In this section, we first discuss concrete mitigations against dFFS before suggesting how to improve software to counter FFS attacks.

Table 2: Memory savings with different dedup strategies.

Strategy	Required memory	Savings
No dedup	506 GB	0%
Zero-page dedup	271 GB	46%
Full dedup	108 GB	79%

6.1 Defending against dFFS

We discuss both hardware and software solutions for defending against dFFS.

6.1.1 In Hardware

We recommend DRAM consumers perform extensive Rowhammer testing [2] to identify vulnerable DRAM modules. These DRAM modules should be replaced, but if this is not possible, reducing DRAM refresh intervals (e.g., by half) may be sufficient to protect against Rowhammer [51]. However, this also reduces DRAM performance and consumes additional power.

Another option is to rely on memory with error-correcting codes (ECC) to protect against single bit flips. Unfortunately, we have observed that Rowhammer can occasionally induce multiple flips in a single 64-bit word confirming the findings of the original Rowhammer paper [34]. These multi-flips can cause corruption even in presence of ECC. More expensive multi-ECC DIMMs can protect against multiple bit flips, but it is still unclear whether they can completely mitigate Rowhammer.

A more promising technology is *directed row refresh*, which is implemented in low-power DDR4 [7] (LPDDR4) and some DDR4 implementations. LPDDR4 counts the number of activations of each row and, when this number grows beyond a particular threshold, it refreshes the adjunct rows, preventing cell charges from falling below the error margin. Newer Intel processors support a similar feature for DDR3, but require compliant DIMMs. While these fixes mitigate Rowhammer, replacing most of current DDR3 deployments with LPDDR4 or secure DDR4 DIMMs (some DDR4 DIMMs are reported to be vulnerable to Rowhammer [1]), is not economically feasible as it requires compatible mainboards and processors. As a result, a software solution is necessary for mitigating Rowhammer in current deployments.

6.1.2 In Software

The most obvious mitigation against dFFS is disabling memory deduplication. In fact, this is what we recommend in security-sensitive environments. Disabling memory deduplication completely, however, wastes a

substantial amount of physical memory that can be saved otherwise [6, 46, 54].

Previous work [12] showed that deduplicating zero pages alone can retain between 84% and 93% of the benefits of full deduplication in a browser setting. Limiting deduplication to zero pages and isolating their Rowhammer-prone surrounding rows was our first mitigation attempt. To understand whether zero-page deduplication retains sufficient memory saving benefits in a cloud setting, we performed a large-scale memory deduplication study using 1,011 memory snapshots of *different* VMs from community VM images of Windows Azure [48]. Table 2 presents our results. Unfortunately, zero-page deduplication only saves 46% of the potential 79%. This suggests that deduplicating zero pages alone is insufficient to eradicate the wasteful redundancy in current cloud deployments. Hence, we need a better strategy that can retain the benefits of full memory deduplication without resulting in a memory massaging primitive for the attackers.

A strawman design A possible solution is to rely on a deduplication design that, for every merge operation, randomly allocates a new physical page to back the existing duplicate pages. When merge operations with existing shared pages occur, such design would need to randomly select a new physical page and update all the page-table mappings for all the sharing parties.

This strawman design eliminates the memory massaging primitive that is necessary for dFFS under normal circumstances. However, this may be insufficient if an attacker can find different primitives to control the physical memory layout. For example, the attacker’s VM can corner the kernel’s page allocator into allocating pages with predictable patterns if it can force the host kernel into an out-of-memory (OOM) situation. This is not difficult if the host relies on over-committed memory to pack more VMs than available RAM, a practice which is common in cloud settings and naturally enabled by memory deduplication. For example, the attacker can trigger a massive number of unmerge operations and cause the host kernel to approach an OOM situation. At this point, the attacker can release vulnerable memory pages to the allocator, craft a page with the same contents as the victim page, and wait for a merge operation. Due to the near-OOM situation, the merge operation happens almost instantly, forcing the host kernel to predictably pick one of the previously released vulnerable memory pages (i.e., templates) to back the existing duplicate pages (the crafted page and the victim page). At this stage, the attacker has again, in effect, a memory massaging primitive.

A better design To improve on the strawman design, the host needs to ensure enough memory is available not

to get cornered into predictable physical memory reuse patterns. Given a desired level of entropy h , and the number of merged pages m_i for the i th VM, the host needs to ensure $A = 2^h + \text{Max}(m_i)$ memory pages are available or can easily become available (e.g., page cache) to the kernel’s page allocator at all times. With an adequate choice of h , it may become difficult for an attacker to control the behavior of the memory deduplication system. We have left the study of the right parameters for h and the projected A for real systems to future work. We also note that balancing entropy, memory, and performance when supporting a truly random and deduplication-enabled physical memory allocator is challenging, and a promising direction for future work.

6.2 Mitigating FFS at the Software Layer

The attacks presented in this paper provide worrisome evidence that even the most security-sensitive software packages used in production account for no attacker-controlled bit flips as part of their threat model. While there is certainly room for further research in this direction, based on our experience, we formulate a number of suggestions to improve current practices:

- Security-sensitive information needs to be checked for integrity in software right before use to ensure the window of corruption is small. In all the cases we analyzed, such integrity checks would be placed on a slow path with essentially no application performance impact.
- Certificate chain formats such as X.509 are automatically integrity checked as certificates are always signed [17]. This is a significant side benefit of a certification chain with self-signatures.
- The file system, due to the presence of the page cache, should not be trusted. Sensitive information on stable storage should include integrity or authenticity information (i.e., a security signature) for verification purposes. In fact, this simple defense mechanism would stop the two dFFS attacks that we presented in this paper.
- Low-level operating system optimizations should be included with extra care. Much recent work [11, 12, 29, 40, 58] shows that benign kernel optimizations such as transparent huge pages, vsyscall pages, and memory deduplication can become dangerous tools in the hands of a capable attacker. In the case of FFS, any feature that allows an untrusted entity to control the layout or reuse of data in physical memory may provide an attacker with a memory massaging primitive to mount our attacks.

7 Related Work

We categorize related work into three distinct groups discussed below.

7.1 Rowhammer Exploitation

Pioneering work on the Rowhammer bug already warned about its potential security implications [34]. One year later, Seaborn published the first two concrete Rowhammer exploits, in the form of escaping the Google Native Client (NaCl) sandbox and escalating local privileges on Linux [51]. Interestingly, Seaborn’s privilege escalation exploit relies on a weak form of memory massaging by probabilistically forcing a OOMing kernel to reuse physical pages released from user space. dFFS, in contrast, relies on a deterministic memory massaging primitive to map pages from co-hosted VMs and mount fully reliable attacks. In addition, while mapping pages from kernel space for local privilege escalation is possible, dFFS enables a much broader range of attacks over nearly arbitrary physical memory.

Furthermore, Seaborn’s exploits relied on Intel x86’s CLFLUSH instruction to evict a cache line from the CPU caches in order to read directly from DRAM. For mitigation purposes, CLFLUSH was disabled in NaCl and the same solution was suggested for native CPUs via a microcode update. In response to the local privilege exploit, Linux disabled unprivileged access to virtual-to-physical memory mapping information (i.e., `/proc/self/pagemap`) used in the exploit to perform double-sided Rowhammer. Gruss et al. [30], however, showed that it is possible to perform double-sided Rowhammer from the browser, without CLFLUSH, and without pagemap, using cache eviction sets and transparent huge pages (THP). dFFS relies on nested THP (both in the host and in the guest) for reliable double-sided Rowhammer. In our previous work [12], we took the next step and implemented the first reliable Rowhammer exploit in the Microsoft Edge browser. Our exploit induces a bit flip in the control structure of a JavaScript object for pivoting to an attacker-controlled counterfeit object. The counterfeit object provides the attackers with arbitrary memory read and write primitives inside the browser.

All the attacks mentioned above rely on one key assumption: the attacker already *owns* the physical memory of the victim to make Rowhammer exploitation possible. In this paper, we demonstrated that, by abusing modern memory management features, it is possible to completely lift this assumption with alarming consequences. Using FFS, an attacker can seize control of nearly arbitrary physical memory in the software stack, for example compromising co-hosted VMs in complete absence of software vulnerabilities.

7.2 Memory Massaging

Sotirov [55] demonstrates the power of controlling virtual memory allocations in JavaScript, bypassing many protections against memory errors with a technique called Heap Feng Shui. Mandt [41] demonstrates that it is possible to control reuse patterns in the Windows 7 kernel heap allocator in order to bypass the default memory protections against heap-based attacks in the kernel. Inspired by these techniques, our Flip Feng Shui demonstrates that an attacker abusing benign and widespread memory management mechanisms allows a single bit flip to become a surprisingly dangerous attack primitive over physical memory.

Memory spraying techniques [25, 33, 47, 50] allocate a large number of objects in order to make the layout of memory predictable for exploitation purposes, similar, in spirit, to FFS. Govindavajhala and Appel [28] sprayed the entire memory of a machine with specially-crafted Java objects and showed that 70% of the bit flips caused by rare events cosmic rays and such will allow them to escape the Java sandbox. This attack is by its nature probabilistic and, unlike FFS, does not allow for fully controllable exploitation.

Memory deduplication side channels have been previously abused to craft increasingly sophisticated information disclosure attacks [8, 12, 29, 32, 43, 56]. In this paper, we demonstrate that memory deduplication has even stronger security implications than previously shown. FFS can abuse memory deduplication to perform attacker-controlled page-table updates and craft a memory massaging primitive for reliable hardware bit flip exploitation.

7.3 Breaking Weakened Cryptosystems

Fault attacks have been introduced in cryptography by Boneh et al. [9]; their attack was highly effective against implementations of RSA that use the Chinese Remainder Theorem. Since then, many variants of fault attacks against cryptographic implementations have been described as well as countermeasures against these attacks. Seifert was the first to consider attacks in which faults were introduced in the RSA modulus [52]; his goal was limited to forging signatures. Brier et al. [14] have extended his work to sophisticated methods to recover the private key; they consider a setting of uncontrollable faults and require many hundreds to even tens of thousands of faults. In our attack setting, the attacker can choose the location and observe the modulus, which reduces the overhead substantially.

In the case of Diffie-Hellman, the risk of using it with moduli that are not strong primes or hard-to-factor integers was well understood and debated extensively dur-

ing the RSA versus DSA controversy in the early 1990s (e.g., in a panel at Eurocrypt’92 [18]). Van Oorschot and Wiener showed how a group order with small factors can interact badly with the use of small Diffie-Hellman exponents [57]. In 2015, the Logjam attack [3] raised new interest in the potential weaknesses of Diffie-Hellman parameters.

In this paper, we performed a formal cryptanalysis of RSA public keys in the presence of bit flips. Our evaluation of dFFS with bit-flipped default 2048-bit RSA public keys confirmed our theoretical results. dFFS can induce bit flips in RSA public keys and factorize 99% of the resulting 2048-bit keys given enough Rowhammer-induced bit flips. We further showed that we could factor 4.2% of the two 4096 bit **Ubuntu Archive Automatic Signing Keys** with a bit flip. This allowed us to generate enough templates to successfully trick a victim VM into installing our packages. For completeness, we also included a formal cryptanalysis of Diffie-Hellman exponents in the presence of bit flips in Appendix A.

8 Conclusions

Hardware bit flips are commonly perceived as a vehicle of production software failures with limited exploitation power in practice. In this paper, we challenged common belief and demonstrated that an attacker armed with Flip Feng Shui (FFS) primitives can mount devastatingly powerful end-to-end attacks even in complete absence of software vulnerabilities. Our FFS implementation (dFFS) combines hardware bit flips with novel memory templating and massaging primitives, allowing an attacker to controllably seize control of arbitrary physical memory with very few practical constraints.

We used dFFS to mount practical attacks against widely used cryptographic systems in production clouds. Our attacks allow an attacker to completely compromise co-hosted cloud VMs with relatively little effort. Even more worryingly, we believe Flip Feng Shui can be used in several more forms and applications pervasively in the software stack, urging the systems security community to devote immediate attention to this emerging threat.

Disclosure

We have cooperated with the National Cyber Security Centre in the Netherlands to coordinate disclosure of the vulnerabilities to the relevant parties.

Appendix A Cryptanalysis of Diffie-Hellman with Bit Flips

This section describes how one can break Diffie-Hellman by flipping a bit in the modulus. Similar to RSA, Diffie-Hellman cryptosystem performs computations modulo n . In the Diffie-Hellman key agreement scheme [21], however, the modulus n is prime or $s = \gamma_1 = 1$. It is very common to choose strong primes, which means that $q = (n - 1)/2$ is also prime; this is also the approach taken by OpenSSH. Subsequently a generator g is chosen of order q . In the Diffie-Hellman protocol the client

chooses a random $x \in [1, n - 1]$ and computes $g^x \bmod n$ and the server chooses a random $y \in [1, n - 1]$ and computes $g^y \bmod n$. After exchanging these values, both parties can compute the shared secret $g^{xy} \bmod n$. The best known algorithm to recover the shared secret is to solve the discrete logarithm problem to find x or y using the GNFS, which has complexity $O(L_n[1/3, 1.92])$. For a 512-bit modulus n , the pre-computation cost is estimated to be about 10 core-years; individual discrete logarithms $\bmod n$ can subsequently be found in 10 minutes [3]. The current record is 596 bits [13]; again 1024 bits seems to be within reach of intelligence agencies [3].

By flipping a single bit of n , the parties compute $g^x \bmod n'$ and $g^y \bmod n'$. It is likely that recovering x or y is now much easier. If we flip the LSB, $n' = n - 1 = 2q$ with q prime and g will be a generator. In the other cases n' is a t -bit or $(t - 1)$ -bit odd integer; we conjecture that its factorization has the same form as that of a random odd integer of the same size. It is not necessarily the case the g is a generator $\bmod n'$, but with very high probability g has large multiplicative order.

The algorithm to compute a discrete logarithm in $Z_{n'}$ to recover x from $y = g^x \bmod n'$ requires two steps.

1. Step 1 is to compute the factorization of n' . This is the same problem as the one considered in Section 3.
2. Step 2 consists in computing the discrete logarithm of $g^x \bmod n'$: this can be done efficiently by computing the discrete logarithms modulo $g^x \bmod p_i'^{\tilde{\gamma}_i}$ and by combining the result using the Chinese remainder theorem. Note that except for the small primes, the $\tilde{\gamma}_i$ are expected to be equal to 1 with high probability. Discrete logarithms $\bmod p_i'^{\tilde{\gamma}_i}$ can in turn be computed starting from discrete logarithms $\bmod p_i'$ ($\tilde{\gamma}_i$ steps are required). If $p_i' - 1$ is smooth (that is, it is of the form $p_i' = \prod_{j=1}^r q_j^{\delta_j}$ with q_j small), the Pohlig-Hellman algorithm [45] can solve this problem in time $O\left(\sum_{j=1}^r \delta_j \sqrt{q_j}\right)$. If n' has prime factors p_i' for which $p_i' - 1$ is not smooth, we have to use for those primes GNFS with complexity $O(L_{p_i'}[1/3, 1.92])$.

The analysis is very similar to that of Section 3, with a difference that for RSA we can use ECM to find all small prime factors up to the second largest one p_2' . With a simple primality test we verify that the remaining integer is prime and if so the factorization is complete. However, in the case of the discrete logarithm algorithm we have to perform in Step 2 discrete logarithm computations modulo the largest prime p_1' . This means that if n' would prime (or a small multiple of a prime), Step 1 would be easy but we have not gained anything with the

bit flip operation. It is known that the expected bitlength of the largest prime factor p_1' of n' is $0.624 \cdot t$ [36] (0.624 is known as the Golomb–Dickman constant). A second number theoretic result by Dickman shows that the probability that all the prime factors p_i' of an integer n' are smaller than $n'^{1/u}$ has asymptotic probability u^{-u} [20].

For $t = 1024$, the expected size of the largest prime factor p_1' of n' is 639 bits and in turn the largest prime factor of $p_1' - 1$ is expected to be 399 bits ($1024 \cdot 0.624^2$). Note that $p_1' - 1$ can be factored efficiently using ECM as in the RSA case. If $p_1' - 1$ has 639 bits, the probability that it is smooth (say has factors less than 80 bits) is $8^{-8} = 2^{-24}$, hence Pohlig-Hellman cannot be applied. We have to revert to GNFS for a 399-bit integer. However, with probability $2^{-2} = 1/4$ all the factors of n' are smaller than 512 bits: in that case the largest prime factor of $p_1' - 1$ is expected to be 319 bits, but again with probability $1/4$ all prime factors are smaller than 256 bits. Hence with probability $1/16$ GNFS could solve the discrete logarithm in less than 1 core hour.

For $t = 2048$, the expected size of the largest prime factor p_1' of n' is 1278 bits and the largest prime factor of $p_1' - 1$ is expected to be 797 bits – this is well beyond the current GNFS record. However, with probability $3 \cdot 10^{-3} = 0.037$ all prime factors of n' are smaller than 638 bits. Factoring $p_1' - 1$ is feasible using ECM, given that its second largest prime factor is expected to be 134 bits. The largest prime factor of $p_1' - 1$ is expected to be 398 bits. The discrete logarithm problem modulo the largest factor can be solved using GNFS in about 1 core-month. With probability $4 \cdot 10^{-4} = 3.9 \cdot 10^{-3}$ all prime factors of n' are smaller than 512 bits, and in that case the largest prime factor of $p_1' - 1$ is expected to be 319 bits, which means that GNFS would require a few core-hours.

Even if it would not be feasible to compute the complete discrete logarithm there are special cases: if x or y have substantially fewer than t bits, it is sufficient to recover only some of the discrete logarithms $\bmod p_i'$ and the hardest discrete logarithm p_1 can perhaps be skipped; for more details, see [3, 57].

The main conclusion is that breaking discrete logarithms with the bit flip attack is more difficult than factorizing, but for 1024 bits an inexpensive attack is feasible, while for 2048 bits the attack would require a moderate computational effort, the results of which are widely applicable. It is worth noting that this analysis is applicable to the DH key agreement algorithm in use by OpenSSH, defaulting to 1536-bit DH group moduli in the current OpenSSH (7.2), bitflipped variants of which can be pre-computed by a moderately equipped attacker, and applied to all OpenSSH server installations. The consequences of such an attack are decryption of a session, including the password if used, adding another attractive facet to attacks already demonstrated in this paper.

One Bit Flips, One Cloud Flops: Cross-VM Row Hammer Attacks and Privilege Escalation

Abstract

Row hammer attacks exploit electrical interactions between neighboring memory cells in high-density dynamic random-access memory (DRAM) to induce memory errors. By rapidly and repeatedly accessing DRAMs with specific patterns, an adversary with limited privilege on the target machine may trigger bit flips in memory regions that he has no permission to access directly. In this paper, we explore row hammer attacks in cross-VM settings, in which a malicious VM exploits bit flips induced by row hammer attacks to crack memory isolation enforced by virtualization. To do so with high fidelity, we develop novel techniques to determine the physical address mapping in DRAM modules at runtime (to improve the effectiveness of double-sided row hammer attacks), methods to exhaustively hammer a large fraction of physical memory from a guest VM (to collect exploitable vulnerable bits), and innovative approaches to break Xen paravirtualized memory isolation (to access arbitrary physical memory of the shared machine). Our study also suggests that the demonstrated row hammer attacks are applicable in modern public clouds where Xen paravirtualization technology is adopted. This shows that the presented cross-VM row hammer attacks are of practical importance.

1 Introduction

Security of software systems is built upon correctly implemented and executed hardware-software contracts. Violation of these contracts may lead to severe security breaches. For instance, operating system security relies on the assumption that data and code stored in the memory subsystems cannot be altered without mediation by the software running with system privileges (*e.g.*, OS kernels, hypervisors, *etc.*). However, the recently demonstrated row hammer attacks [23], which are capable of inducing hardware memory errors without access-

ing the target memory regions, invalidate this assumption, raising broad security concerns.

Row hammer attacks exploit a vulnerability in the design of dynamic random-access memory (DRAM). Modern high-capacity DRAM has very high memory cell density which leads to greater electrical interaction between neighboring cells. Electrical interference from neighboring cells can cause accelerated leakage of capacitor charges and, potentially, data loss. Although these so-called “disturbance errors” have been known for years, it has only recently been shown that these errors can be triggered by software. In particular, [23] has demonstrated that malicious programs may issue specially crafted memory access patterns, *e.g.*, repeated and rapid activation of the same DRAM rows, to increase the chances of causing a disturbance error in neighboring rows.

Row hammer vulnerabilities have been exploited in security attacks shortly after its discovery [4, 10, 16, 20]. In particular, Seaborn [4] demonstrated two privilege escalation attacks that exploit row hammer vulnerabilities: One escaped from Google’s NaCl sandbox and the other gained kernel memory accesses from userspace programs running on Linux operating systems. Other studies [10, 16, 20] aim to conduct row hammer attacks from high-level programming languages, *e.g.*, JavaScript, so that an adversary can induce memory errors and escalate privileges remotely, by injecting malicious JavaScript code into the target’s web traffic (*e.g.*, by hosting malicious websites, cross-site scripting, man-in-the-middle attacks, *etc.*).

In contrast to the client-side bit flip exploitations, server-side row hammer attacks are much less understood. One particularly interesting scenario where server-side row hammer attacks are of importance is in multi-tenant infrastructure clouds, where mutually-distrusting cloud tenants (*i.e.*, users of clouds) may co-locate their virtual machines (VM) on the same physical server, therefore sharing hardware resources, including

DRAMs. Although server-grade processors and more expensive DRAMs are believed to be less vulnerable to row hammer attacks [23], studies have suggested that even servers equipped with error correcting (ECC) memory are not immune to such attacks [12, 23].

In this paper, we aim to explore row hammer attacks in cross-VM settings, and shed some light on the security, or lack thereof, in multi-tenant infrastructure clouds. The goal of this research is *not* to extensively study how vulnerable the cloud servers are. Rather, we explore whether the isolation of cloud software systems—virtual machines and hypervisors—can be circumvented by row hammer attacks (and if so, how?), should the underlying hardware become vulnerable.

Towards this end, we demonstrate cross-VM row hammer attacks with high fidelity and determinism, which can be achieved in the following pipelined steps.

First, determine physical address mapping in DRAM. Double-sided row hammer attacks target a specific memory row by hammering its two neighboring rows to enhance the effectiveness of the attack [4, 23]. Conducting such attacks, however, requires knowledge of the physical memory mapping in DRAMs (*i.e.*, bits in physical addresses that determine memory channels, DIMMs, ranks, banks, and rows). This enables the identification of addresses in neighboring rows of the same bank. However such information is not publicly available for Intel processors and memory controllers. Moreover, the same memory controller may map physical addresses to DRAMs in different ways, depending on how DRAM modules are configured.

To address this issue, we developed a novel algorithm to determine the memory mapping at runtime (Section 3). Each bank in a DRAM chip has a row buffer that caches the most recently used row in a bank. Therefore, by alternately accessing two rows in the same bank, we expect a higher memory access latency due to row buffer conflicts. The increase in access latency serves as the basis for a *timing channel* which can be used to determine if two physical memory addresses are mapped to the same DRAM bank. Building on the timing-channel primitive, we developed a novel graph-based algorithm which models each bit in a physical address as a node in a graph and establishes relationships between nodes using memory access latency. We show that the algorithm is capable of accurately detecting the row bits, column bits and bank bits. We empirically show the algorithm can accurately identify the DRAM mapping schemes automatically within one or two minutes on the machines we tested.

Second, conduct effective double-sided row hammer attacks. With knowledge of the DRAM address mapping, we conduct double-sided row hammer attacks from

Xen guest VMs. We first empirically study which row hammer attack methods (*i.e.*, accessing memory with or without `mfence` instructions, see Section 4) are most effective and lead to most bit flips. Then, in order to guarantee that sufficient exploitable bit flips (*i.e.*, located at specific memory locations and can be repeatedly induced in row hammer attacks) are found, we conduct exhaustive row hammer attacks from a guest VM to test all DRAM rows that are accessible to the VM. Because each VM is limited to a small portion of the entire physical memory, we also develop methods to explore more physical memory than assigned to our VM initially. In addition, we design a safe mode that makes bit flips induced by row hammer attacks less likely to crash the system.

Third, crack memory isolation enforced by virtualization. Unlike prior work, which sprays large numbers of page tables and conducts random row hammer attacks hoping that bit flips will occur in a page table entry (PTE) [4], in our approach (Section 5), we use hypercalls to map page directories in the OS kernel of our own VM to physical pages containing memory cells that are vulnerable to row hammer attacks. We then conduct row hammer attacks to deterministically flip the vulnerable bit at anticipated positions in a page directory entry (PDE), making it point to a different page table. In the context of this paper, we call such attack techniques *page table replacement* attacks to indicate that the original page table has been replaced with a forged one. We empirically demonstrate in Section 6 that such attacks allow a Xen guest VM to have both read and write access to any memory pages on the machine. We demonstrate two examples to illustrate the power of the cross-VM row hammer attacks: private key exfiltration from an HTTPS web server and code injection to bypass password authentication of an OpenSSH server. We emphasize that with the attack techniques we propose in this paper, the attacker’s capability is only limited by imagination.

We note our attacks primarily target Xen paravirtualized VMs, which, although are gradually superseded by hardware-assisted virtualization, are still widely used as cloud substrates in public cloud like Amazon EC2. This offers the adversary easy-to-break targets on servers with vulnerable hardware. Given the existing evidence of successful co-location attacks in public clouds [30, 32], we recommend discontinuing the use of such virtualization technology in cloud hosting services.

Contributions. This paper makes the following contributions to the field:

- A novel graph-based algorithm incorporating timing-based analysis to automatically reverse engineer the mapping of the physical addresses in DRAMs.
- A novel *page table replacement* technique that allows a malicious guest VM to have read and write accesses

to arbitrary physical pages on the shared machine.

- Implementation of effective double-sided row hammer attacks from guest VMs, and a systematic evaluation of the proposed techniques.
- Demonstration of two concrete examples to illustrate the power of the cross-VM attacks: private key extraction from HTTPS servers and code injection into OpenSSH servers to bypass authentication.

Roadmap. We will first summarize related work in the field and introduce background knowledge to set the stage for our discussion (Section 2). We will then describe a novel graph-based algorithm for detecting physical address mapping in DRAMs (Section 3). We then present a few technical details in our row hammer attack implementation (Section 4) and a *page table replacement* attack that enables arbitrary cross-VM memory accesses (Section 5). Next, we evaluate the proposed techniques (Section 6). Finally, we discuss existing countermeasures (Section 7) and conclude (Section 8).

2 Background and Related Work

2.1 DRAM Architecture

Modern memory systems are generally organized in multiple memory channels, each handled by its own dedicated memory controller. A channel is partitioned into multiple ranks. A rank consists of several DRAM chips that work together to handle misses or refill requests from the processor’s last-level cache. Each rank is also partitioned into multiple banks. Each bank has a row buffer to store the last accessed row in that bank. All banks and ranks can generally support independent transactions, allowing parallel accesses to the DRAM chips. A typical memory system is illustrated in Figure 1.

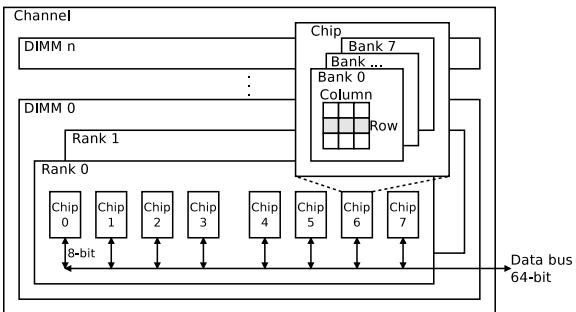

Figure 1: DRAM architecture.

DRAM chips are large arrays of memory cells with additional support logic for data access (read/write) and refresh circuitry used to maintain data integrity. Memory arrays are organized in rows (wordlines) and columns (bitlines) of memory cells.

Each memory cell consists of a capacitor that can be charged and discharged to store a 0 or a 1. An access transistor in each cell allows reads and writes to its content. The transistor is controlled through the wordline. When the wordline is activated, the content of all the capacitors on that row are discharged to the bitlines. Sense amplifier circuitry on each bitline amplifies the signal and stores the result in the row buffer.

Additional circuitry in the memory arrays includes address decoding logic to select rows and columns and internal counters to keep track of refresh cycles. In addition to the cells dedicated for data storage, DRAM chips often include additional storage for ECC (error-correction codes) or parity bits, to enable detection and/or correction of errors in the data array.

DRAM Refresh. The charge in the DRAM cell capacitor drains over time due to leakage current. To prevent data loss the content of the cell requires periodic “refresh.” The refresh interval ranges between 32 and 64 milliseconds and is specified as part of the DDR memory standard. Refresh operations are issued at rank granularity in recent designs. Before issuing a refresh operation, the memory controller precharges all banks in the rank. It then issues a single refresh command to the rank. DRAM chips maintain a row counter to keep track of the last row that was refreshed – this row counter is used to determine the rows that must be refreshed next.

DRAM address mapping. Given a physical memory address, the location of the data in the DRAM chips is determined by the DRAM address mapping schemes used by the memory controllers. This information, while available for some processors [3], is not revealed by major chip companies like Intel or ARM. Some preliminary exploration to determine DRAM address mapping on older Intel processors has been conducted by Seaborn [5]. Concurrently to our work, Pessl et al. [29] proposed methods to reverse-engineer physical address mapping in DRAM on both Intel and ARM platforms. Similar to our work, a timing-based approach was used to determine whether two addresses were mapped to two different rows of the same DRAM bank. Unlike our work, brute-force approaches were taken to (1) collect sets of memory addresses that are mapped to the same banks by randomly selecting addresses from a large memory pool and conducting the timing-based tests to cluster them, and (2) to determine the XOR-schemes (see Section 3) that are used by memory controllers, by testing all possible combinations of XOR-schemes against all sets of addresses.

The advantage of their approach over ours is that it exhaustively searches XOR-schemes without the need to reason about the complex logic behind them, as is done in our paper. However, our method targets specific bit

combinations and therefore is more efficient. Specially, it has been reported in [29] that it took about 20 minutes to reverse engineer the DRAM mapping on a normally-loaded system. Our approach, on the other hand, takes less than two minutes (see Section 6). In addition, Pessl et al. [29] also indicated that completeness is not guaranteed as it depends on random addresses. Hence, a complete test using their approach may take even longer.

2.2 Row Hammer and DRAM Bit Flips

Modern DRAM chips tend to have larger capacity, and hence higher density of memory cells. As a result, a memory cell may suffer from disturbance errors due to electrical interference from its neighboring cells. Moreover, certain memory access patterns, such as repeated and frequent row activation (“row hammering”), may easily trigger disturbance errors. The “row hammer” problem caught Intel’s attention as early as 2012 and was publicly disclosed around 2014 [13–15, 19]. Independent of Intel’s effort, Kim et al. [23] also reported that random bit flips can be observed by specially crafted memory access patterns induced by software programs.

The first practical row hammer exploit was published by Seaborn from Google [4], who demonstrated privilege escalation attacks exploiting row hammer vulnerabilities to break the sandbox of Google’s NaCl, and to obtain kernel memory accesses from userspace programs running on Linux operating systems. The study was quickly followed up by others [10, 16, 20], who demonstrated row hammer attacks using Javascript code, which meant that the attacks could be conducted without special privileges to execute binary code on target machines. This paper follows the same line of research, but our focus is server-side row hammer attacks, although some of the proposed techniques will also be useful in other contexts.

It has been claimed that server-grade processors and DRAM modules are less vulnerable to row hammer attacks [23], especially when the server is equipped with ECC-enabled DRAM modules. However, ECC is not the ultimate solution to such attacks. The most commonly used ECC memory modules implement single error-correction, double error-detection mechanisms, which can correct only one single-bit of errors within a 64-bit memory block, and detect (but not correct) 2-bit errors in the same 64-bit block. More bit errors cannot be detected and data and code in memory will be corrupted silently [23].

Dedicated defenses against row hammer vulnerabilities by new hardware designs have been studied in [22]. Particularly, Kim et al. [22] proposes Counter-Based Row Activation (CRA) and Probabilistic Row Activation (PRA) to address row hammer vulnerabilities. CRA counts the frequency of row activations and proactively

activates neighboring rows to refresh data; PRA enables memory controllers to activate neighboring rows with a small probability for every memory access.

3 DRAM Addressing

Prior work [4] has indicated that double-sided row hammer attacks are much more effective than single-sided ones. We therefore focus on developing a software tool to conduct double-sided row hammer attacks from within virtual machines. To make the attack possible, we first must find the physical memory address mapping in the target DRAMs, and do so without physical accesses to the machines. More precisely, we hope to determine which bits in a physical address specify its mapping to DRAM banks, rows and columns.

This information, however, is not available in the system configuration or in the memory controller or DRAM datasheets. Intel never discloses the mapping algorithm in their memory controllers; moreover, the same memory controller will likely map the same physical address to a different DRAM location if the number or size of DRAM chips is changed. Therefore, in this section, we present a method to reverse engineer the physical address mapping in DRAM at runtime. We call this procedure *bit detection*. It is important to note that we do not need to differentiate address bits for banks, ranks, or channels as long as their combination uniquely addresses the same DRAM bank.

3.1 A Timing-Channel Primitive

We resort to a known timing channel [27] to develop our bit detection primitive. The timing channel is established due to the row buffer in each DRAM bank. When two memory addresses mapped to the same DRAM bank in different rows are alternatively accessed in rapid succession, the accesses will be delayed due to conflicts in the row buffer (and subsequent eviction and reload of the row buffer). Therefore, by conducting fast and repeated accesses to two memory addresses, one can learn that the two address are located in different rows of the same bank if one observes longer access latency.

The algorithm is described in Algorithm 1. The input to the algorithm, LATENCY(), is a set of bit positions in the physical address space. We use I to denote the input. For example, $I = \{b_3, b_{17}\}$ represents the 3rd and 17th right-most bits of the physical address. LATENCY() randomly selects 100 pairs¹ of memory addresses from a large memory buffer, so that each pair of addresses differs only in the bit positions that are specified by the input, I : in each pair, one address has ‘1’s at all these bit

¹A sample size that is large enough to achieve statistical significance.

Algorithm 1: LATENCY()

```
Input: { $b_i$ } : a set of physical address bits
Output: Access latency: 1 (high) or 0 (low)
begin
    Randomly select 100 pairs of memory addresses that differ only in { $b_i$ }: One address in each pair with all  $b_i = 1$  and the other with all  $b_i = 0$ . Place all 100 pairs in address_pairs{ }
    for each pair k in address_pairs{ } do
        Start time measurement
        for j in  $10^3$  do
            Access both addresses in k
            cflush both addresses
            insert memory barrier
        end
        Stop time measurement
    end
    Return the average access latency compared to baselines
end
```

positions and the other address has ‘0’s at all these positions.

The algorithm enumerates each pair of addresses by measuring the average access latency to read each address once from memory. Specifically, it accesses both addresses and then issues `clflush` instructions to flush the cached copies out of the entire cache hierarchy. Hence the next memory access will reach the DRAM. A memory barrier is inserted right after the memory flush so that the next iteration will not start until the flush has been committed. The total access time is measured by issuing `rdtsc` instructions before and after the execution. The algorithm returns 1 (*high*) or 0 (*low*) to indicate the latency of memory accesses. $\text{LATENCY}()=1$ suggests the two physical addresses that differ only at the bit positions specified in the input are located on different rows of the same DRAM bank.

3.2 Graph-based Bit Detection Algorithms

Using the $\text{LATENCY}()$ timing-channel primitive we develop a set of graph-based bit detection algorithms. Specifically, we consider each bit in a physical address as a node in a graph; the edges in the graph are closely related to the results of $\text{LATENCY}()$: The set of bits are connected by edges, if, when used as the input to $\text{LATENCY}()$, yields high access latency. But the exact construction of these edges may differ in each of the graphs we build, as will be detailed shortly. We define all such nodes as set $V = \{b_i\}_{i \in [1, n]}$, where n is the total number of bits in a physical address on the target machine. In the following discussion, we use b_i to refer to an address bit position and a node interchangeably.

Our bit detection algorithms works under the assumption that Intel’s DRAM address mapping algorithms may use XOR-schemes to combine multiple bits in physical addresses to determine one of the bank bits. An XOR-scheme is a function which takes a set of bits as input

and outputs the XORed value of all the input bits. This assumption is true for Intel’s DRAM address mapping, which is evident according to prior studies [5, 25, 33]. Our empirical evaluation also confirms this assumption.

Detecting row bits and column bits. We first define a set of nodes $R = \{b_i | \text{LATENCY}(\{b_i\}) = 1, b_i \in V\}$. Because $\text{LATENCY}(\{b_i\}) = 1$, any two memory addresses that differ only in b_i are located in different rows of the same bank. Therefore, bit b_i determines in which rows the addresses are located, *i.e.*, b_i is a *row bit*. But as the two addresses are mapped to the same bank, b_i is not used to address DRAM banks.

Next, we define set $C = \{b_j | \text{LATENCY}(\{b_i, b_j\}) = 1, \forall b_i \in R, b_j \notin R\}$. It means that when accessing two addresses that differ only in a bit in C and a bit in R , we experience high latency in the $\text{LATENCY}()$ test—indicating that the two addresses are in the same bank but different rows. Therefore, the bits in C are not at all involved in DRAM bank indexing (otherwise changing bits in C will yield a memory address in a different bank). The bits in C are in fact *column bits* that determine which column in a row the address is mapped to.

Detecting bank bits in a single XOR-scheme. We consider an undirected graph G_1 constructed on the subset of nodes $V - R - C$. If $\text{LATENCY}(\{b_i, b_j\}) = 1$, node b_i is connected with node b_j by edge $e(b_i, b_j)$. There could be three types of connected components in such a graph: In the type I connected components, *only* two nodes are connected (Figure 2a). Because $\text{LATENCY}(\{b_i, b_j\}) = 1$, changing bits b_i and b_j together will yield an address in a different row of the same bank. Hence, at least one of b_i and b_j (usually only the more significant bit—the one on the left²) will be the row bit; the XOR of the two is a bank bit. More formally, if $e(b_i, b_j)$ is an edge in component type I (shown in Figure 2a), and $i > j$, b_i is a row bit, $b_i \oplus b_j$ determines one bank bit.

In the type II connected components, a set of nodes are connected through a hub node (Figure 2b). For instance, nodes b_j , b_k , and b_l are connected via node b_i . Particularly in Figure 2b, $i = 20, j = 15, k = 16, l = 17$. Due to the property of the $\text{LATENCY}()$ test, $b_i \oplus b_j$ must be a bank bit and at least one of the pair is a row bit. The same arguments apply to $b_i \oplus b_k$ and $b_i \oplus b_l$. We can safely deduce that $b_i \oplus b_j \oplus b_k \oplus b_l$ is a common XOR-scheme in which the four bits are involved: Otherwise, without loss of generality, we assume $b_i \oplus b_j \oplus b_k$ and $b_i \oplus b_l$ are two separate XOR-schemes. When two addresses differ only in b_i and b_j , although the value of $b_i \oplus b_j \oplus b_k$ does not change for the two addresses,

²The timing-channel approach cannot determine which bit is actually the row bit in this case. However, because memory controllers need to minimize row conflicts in the same bank, row bits are usually more significant bits in a physical address [5, 33]. Our hypothesis turned out to be valid in all the case studies we have conducted (see Table 1).

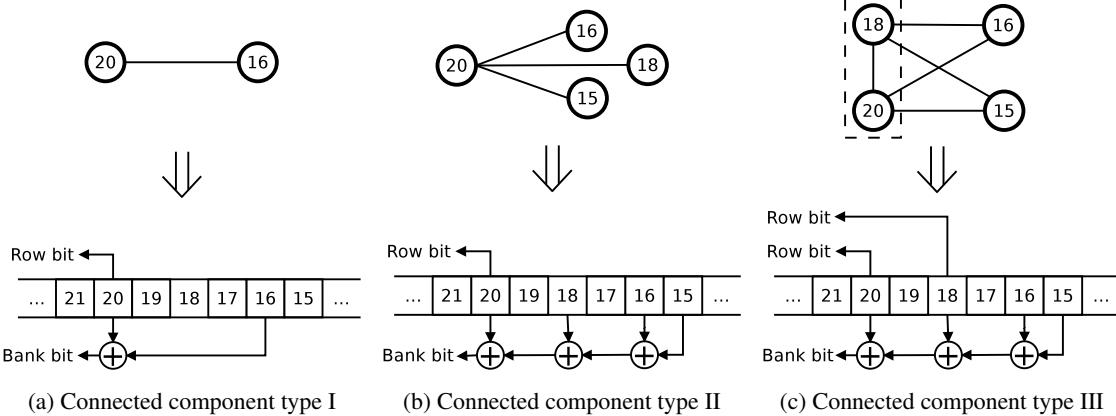

Figure 2: Detecting bits in a single XOR-scheme.

$b_i \oplus b_l$ will be different, thus making the two addresses in different banks. However, this conclusion contradicts the fact that $\text{LATENCY}(\{b_i, b_j\}) = 1$. Moreover, we can conclude that only b_i is the row bit, because otherwise if another bit is also a row bit, e.g., b_j , we should observe $\text{LATENCY}(\{b_j, b_k\}) = 1$ (because b_j and b_k are involved in the XOR-scheme $b_i \oplus b_j \oplus b_k \oplus b_l$ and b_j is a row bit). However that is not the case here. To summarize, if $e(b_i, b_j)$, $e(b_i, b_k)$ and $e(b_i, b_l)$ constitute a type II connected component in Figure 2b, b_i is a row bit and $b_i \oplus b_j \oplus b_k \oplus b_l$ determines one bank bit.

In the type III connected components, a clique of nodes replaces the single hub node in type II components—each node in the clique is connected to all other nodes in type III components (Figure 2c). As a simple example, we assume nodes b_i and b_j are connected by edge $e(b_i, b_j)$, and both of them are connected to nodes b_k and b_l , which are not connected directly. Particularly in Figure 2c, $i = 18$, $j = 20$, $k = 15$, $l = 16$. From the analysis of type II components, nodes b_i , b_k and b_l must follow that b_i is a row bit and $b_i \oplus b_k \oplus b_l$ determines one bank bit. Similarly, we can conclude that b_j is a row bit and $b_j \oplus b_k \oplus b_l$ determines one bank bit. Moreover, we can deduce that $b_i \oplus b_k \oplus b_l$ and $b_j \oplus b_k \oplus b_l$ determine the same bank bit, otherwise two addresses that differ in b_i and b_j will be in two different banks, which conflicts with $\text{LATENCY}(\{b_i, b_j\}) = 1$. Therefore, $b_i \oplus b_j \oplus b_k \oplus b_l$ is a bank bit. As such, in a type III component in Figure 2c, all nodes in the clique represent row bits, and the XOR-scheme that involves all bits in the components produces one bank bit.

Detecting bank bits in two XOR-schemes. On some processors, certain bits can be involved in more than one XOR-schemes. For instance, a bit b_i can be used in both $b_i \oplus b_j \oplus b_k$ and $b_i \oplus b_m \oplus b_n$. To detect such bit configuration, we consider another undirected graph G_2 constructed on the subset of nodes $V - R - C$. If

$\text{LATENCY}(\{b_i, b_j, b_m\}) = 1$, the three nodes are connected with each other by edges $e(b_i, b_j)$, $e(b_i, b_m)$, $e(b_j, b_m)$. If none of the three edges exist in graph G_1 —the graph we constructed in the single-XOR-scheme-bit detection—it means these three nodes are involved in two XOR-schemes $b_i \oplus b_j$ and $b_i \oplus b_m$: if two addresses differ in only two bits (out of the three), at least one of these two XOR-schemes will specify a different bank index; however, if two addresses differ in all three bits, the outcome of both XOR-schemes are the same for the two addresses, so they are in the same bank. One of these three bits (the most significant among the three) will be used in both XOR-schemes and serve as a row bit.

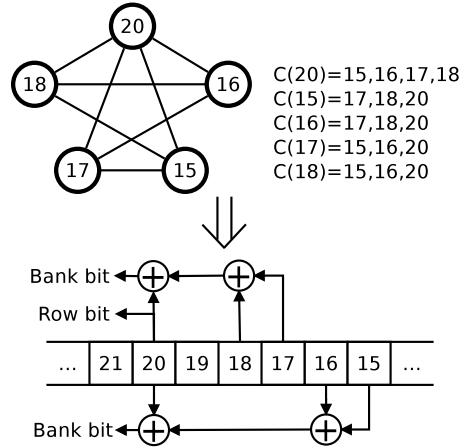

Figure 3: Detecting bits in two XOR-schemes.

Let's look at a more general example where five nodes are involved (Figure 3). In this example, the five nodes in the connected components of G_2 are b_{15} , b_{16} , b_{17} , b_{18} and b_{20} . They are connected by four triangles: (b_{15}, b_{18}, b_{20}) , (b_{16}, b_{17}, b_{20}) , (b_{16}, b_{18}, b_{20}) , (b_{15}, b_{17}, b_{20}) . Following the discussion in the previous paragraph, four XOR-schemes should be used

to index banks: $b_{20} \oplus b_{15}$, $b_{20} \oplus b_{16}$, $b_{20} \oplus b_{17}$ and $b_{20} \oplus b_{18}$. However, because $b_{20} \oplus b_{15}$ and $b_{20} \oplus b_{16}$ implies $\text{LATENCY}(\{b_{15}, b_{16}, b_{20}\}) = 1$, but a triangle (b_{15}, b_{16}, b_{20}) doesn't exist in our analysis, some of these XOR-schemes need to be merged together. To complete the analysis in the graph, we categorize nodes according to the set of nodes they are connected with. For instance, b_{20} is connected with $\{b_{15}, b_{16}, b_{17}, b_{18}\}$ (*i.e.*, $C(b_{20}) = b_{15}, b_{16}, b_{17}, b_{18}$). The node with the most connected neighbors is the one involved in both XOR-schemes (in this case, b_{20}) and therefore is a row bit. The nodes with the same set of neighboring nodes are used in the same XOR-scheme: b_{15} and b_{16} are both connected with $\{b_{17}, b_{18}, b_{20}\}$, and therefore one XOR-scheme will be $b_{15} \oplus b_{16} \oplus b_{20}$; similarly, the other XOR-scheme will be $b_{17} \oplus b_{18} \oplus b_{20}$.

Detecting bank bits in more XOR-schemes. If a bit is involved in more than two XOR-schemes, we can extend the method for detecting two XOR-schemes to detect it. Particularly, on the subset of nodes V – R – C, we enumerate all combination of four bits and look for $\text{LATENCY}(\{b_i, b_j, b_k, b_l\}) = 1$, which, following the reasoning steps in the prior paragraph, suggests that one of the bits is involved in three XOR-schemes. Again, we need to study the connected components to determine the configuration of actual XOR-schemes, which can be done by following a similar process as for two-XOR-scheme-bit detection. For concision we don't repeat the discussion here. However, it is worth noting we have not observed any bits that are used in more than two XOR-schemes on the machines we have tested.

4 Effective Row Hammer Attacks

In this section, we discuss several facets of constructing effective row hammer attacks in practice.

Row hammer code with or without `mfence`. prior work has proposed two ways of conducting row hammer attacks, pseudo code shown in Figure 4. Particularly, in each loop of the attacks, after accessing two memory blocks in two rows and flushing them out of the cache using `clflush` instructions, the attack code can choose to proceed with or without an `mfence` instruction before entering the next loop. The benefit of having an additional `mfence` instruction is to force the `clflush` instructions to take effect before the beginning of the next loop, while the downside is that it will slow down the execution of the program and thus reduce the frequency of memory accesses. We will empirically evaluate the two methods in Section 6.2.

Deterministic row hammer attacks. Prior studies [5] on row hammer exploitation randomly selected DRAM rows to attack and counted on luck to flip memory bits

```
loop:
    mov (X), %r10
    mov (Y), %r10
    clflush (X)
    clflush (Y)
    mfence
    jmp loop
```

(a) `clflush w/o mfence` (b) `clflush w/ mfence`

Figure 4: Pseudo code for row hammer attacks.

that happen to alter page tables. These approaches are non-deterministic and thus hard to guarantee success. In our paper, we propose to search exploitable bit flips that can be repeated in multiple runs. As will be discussed in Section 5, only bit flips at certain positions within a 64-bit memory block can be exploited; also, only a fraction of them are repeatable in row hammer attacks (we will empirically evaluate the fraction of vulnerable bits that are both exploitable and repeatable in Section 6.2.3). As such, on those less vulnerable machines, especially cloud servers, it is important to design methods to exhaustively search for vulnerabilities so that at least one of the vulnerable bit satisfies all the requirements.

Exhaustive row hammering. To enumerate as many DRAM rows as possible to look for vulnerable bits, we developed the following data structure and algorithm to conduct double-sided row hammer attacks on every row in every bank: Especially, as will be shown later in Table 1, some of the 12 least significant address bits are bank bits, which means the same 4KB memory page are not always mapped to the same row. As such, we designed a new data structure to represent memory blocks in the same row. Our key observation is that cache-line-aligned memory blocks are always kept in the same row for performance reasons. We call a cache-line-aligned, 64B in size, memory block a *memory unit*, which is the smallest unit of memory blocks for the purpose of book-keeping. We design a three dimension array: The first dimension represents the bank index, the second dimension is the row index and the third dimension stores an array of memory units mapped to the same row. For example, on a Sandy Bridge processor with 2 memory channels, 1 DIMM per channel, 1 rank per DIMM, and 8 banks per rank (totally 4GB memory), there are $2^4 = 16$ elements (*i.e.*, 2×8 banks) in the first dimension, $2^{16} = 65536$ elements (*i.e.*, number of rows per bank) in the second dimension, $2^7 = 128$ elements (*i.e.*, number of memory units per row) in the third dimension.

Another observation we had for conducting efficient row hammer attacks is to avoid hammering on rows in sequential order. According to our experiments, a recently-hammered row is harder to induce bit flips when its neighboring rows are hammered. This is probably be-

cause the cells in this row has been recently charged many times. Therefore, we targeted each row in a pseudorandom order. Specially, we first generate a pseudorandom permutation of all rows in a bank, and then sequentially test one row from each bank from the first to the last one and start over, where rows in the same bank are tested according to the pseudorandom order.

If no vulnerable bits were found in the first round of the attack, one can reboot the VM to obtain access to other DRAM rows and conduct row hammer attacks again. Even in public clouds, we found that rebooting the guest VMs will relaunch the VM on the same host, and possibly assigned to different (but largely overlapping) physical memory. As such, although each VM only has access to a small fraction of DRAM banks and rows, using such an approach will greatly increase the tested portion of the DRAM. We will empirically evaluate this technique in Section 6.2.

Safe mode. To safely conduct row hammer attacks without crashing the co-located VMs and the host machine, we optionally conduct the row hammer attacks in a safe mode: In Figure 5, only when we control all *memory units* in row n , $n+2$ and $n-2$ do we conduct the double-sided row hammer attacks on row $n+1$ and $n-1$. As rarely would the row hammer attacks affect rows beyond row $n \pm 2$, this method provides a safe mode to conducting row hammer attacks, which is particularly useful in attacks conducted in public clouds.

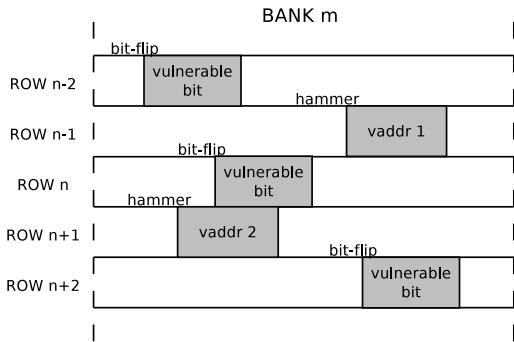

Figure 5: A safe mode of row hammer attacks.

5 Cracking Memory Isolation

In this section, we present methods to conduct cross-VM attacks enabled by DRAM row hammer vulnerabilities, which will allow a malicious paravirtualized VM to break VM isolation and compromise integrity and confidentiality of co-located VMs or even the VMM.

5.1 Xen Memory Management

Xen paravirtualization keeps three types of memory address spaces: a virtual address space for each process, a pseudo-physical address space for each VM, and a machine address space for the entire physical machine [17]. To be compatible with native OS kernels, a paravirtualized OS kernel (*e.g.*, already a part of mainstream Linux kernel) maintains a contiguous pseudo-physical memory address space; the mapping between pseudo-physical memory addresses and virtual addresses are maintained at page-granularity, following the same semantic as its non-virtualized counterparts. The major difference in a Xen paravirtualized VM is the page frame number (PFN) embedded in a page table entry (PTE): it is filled with machine addresses rather than pseudo-physical addresses. This is because Xen paravirtualization does not maintain a shadow page table in the hypervisor [17]. Address translation conducted by the CPU only traverses one layer of page tables. Such a memory management mechanism is called *direct paging* [11]. The mapping between each VM’s pseudo-physical memory pages to machine memory pages is also kept in the hypervisor, but guest VMs are allowed to query the mapping information by issuing hypercalls (*e.g.*, HYPERVISOR_memory_op()). The mapping between virtual memory pages, pseudo-physical memory pages and machine memory pages are illustrated in Figure 6.

To enable security isolation, the Xen hypervisor keeps track of the *type* of each memory page: page tables, segment descriptor page and writable pages. The hypervisor enforces an invariant that only *writable* pages can be modified by the guest VM. Whenever a page table hierarchy is loaded into the *CR3* register upon context switch, the hypervisor validates the memory types of the page tables to ensure the guest VM does not subvert the system by modifying the content of the page tables. On Intel’s x86-64 platforms, the page tables are organized in four-levels: PGD, PUD, PMD, PT³. Particularly of interest to us are the entries of PMD and PT, which are dubbed page directory entries (PDE) and page table entries (PTE), respectively. The structures of PDEs and PTEs are illustrated in Figure 7.

It is worthwhile noting that besides Xen paravirtualization technology, recent Xen hypervisors also support hardware-assisted virtualization, dubbed HVM in Xen’s term [18]. The memory management in Xen HVM is different from that in PVM in many aspects. Most notably, in HVM, guest VMs can no longer learn the physical address of the pseudo-physical memory pages, due to the intervention of a second-layer page table that is only ac-

³We use Linux terminology in this paper. Intel manuals call them page map level 4 (PML4, or PGD), page directory pointer tables (PDPT, or PUD), page directory tables (PDT, or PMD), page tables [6]. In Xen’s terminology, they are called L4, L3, L2 and L1 page tables [11].

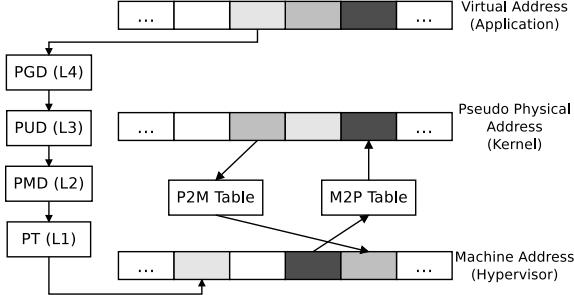

Figure 6: Memory management of Xen paravirtualized VMs.

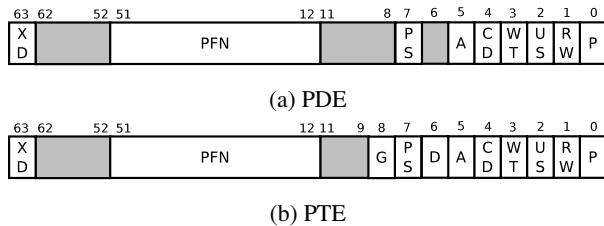

Figure 7: Structures of PDE, PTE.

cessible by the hypervisor. As such, much of the attack techniques discussed in this section only works in Xen paravirtualized machines.

5.2 Page Table Replacement Attacks

In this section, we present a method for a malicious guest VM to exploit the bit flips induced by row hammer attacks to gain arbitrary accesses to memory on the host machine. Instead of relying on an unreliable trial-and-error approach used in prior studies [4, 20], in which a large number of page tables are sprayed to increase the chances of bit flips taking place in PTEs, we propose a novel approach that, given a set of DRAM bit flips that an attacker could repeatedly induce, deterministically exploits the repeatable bit flips and gains access to physical memory pages of other VMs or even the hypervisor.

To access the entire machine address space with both read and write permissions, the attacker VM could do so by modifying a page table entry within its own VM so that the corresponding virtual address could be translated to a machine address belonging to other VMs or the hypervisor. However, direct modification of PTEs in this manner is prohibited. Every PTE update must go through the hypervisor via hypercalls, and thus will be declined. We propose a novel attack that achieves this goal by replacing the entire page tables in a guest VM without issuing hypercalls, which we call the *page table replacement* attacks.

For the convenience of discussion, we first define the

following primitives:

- $\text{Addr}(v)$ returns the machine address of a vulnerable bit.
- $\text{Offset}(v)$ returns the bitwise offset within a byte of a vulnerable bit (the right-most bit has an offset of 0).
- $\text{Direction}(v)$ could be one of $0 \rightarrow 1$, $1 \rightarrow 0$, or $0 \leftrightarrow 1$, indicating the most likely bit flip directions.
- $\text{Position}(v) = 64 - ((\text{Addr}(v) \% 8) \times 8 + 8 - \text{Offset}(v))$, indicating the index of the bit in a 64-bit aligned memory block (e.g., a page table entry). The right-most bit has a position of 0.
- $\text{Virt}(p)$ returns the virtual address of the beginning of a page p .
- $\text{Differ}(P_1, P_2)$ returns a set of indices of bits in which the machine addresses of two memory pages P_1 and P_2 differ.

Specially, when the vulnerable bit v satisfies $\text{Position}(v) \in [12, M]$, where M is the highest bit of the physical addresses on the target machine, the attacker could exploit the flippable bit to replace an existing page table with a carefully-crafted page table containing entries pointing to physical pages external to the guest VM via the following steps (Figure 8):

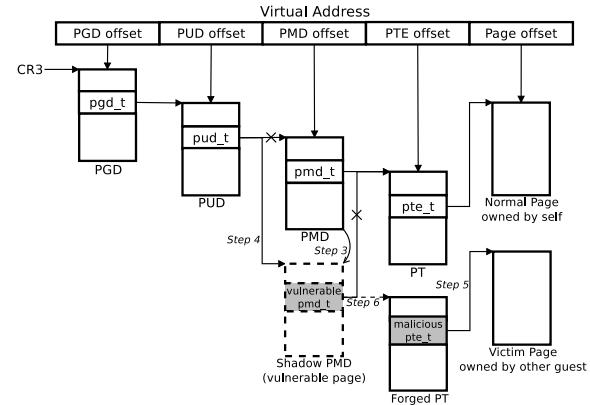

Figure 8: Page table replacement attacks.

- **Step 1:** In the attacker’s VM, allocate and map one virtual memory page (denoted p), so that the vulnerable bit v has the same page offset as one of the PFN bits in p ’s corresponding PDE. More accurately, $\text{Virt}(p)/2^{(9+12)} = \text{Addr}(v)/8 \bmod 2^9$. This can be achieved by allocating 1GB (*i.e.*, $512 \times 512 \times 4\text{KB}$) virtual pages in user space and map one of the pages that satisfies the requirement.
- **Step 2:** In guest kernel space, select two physical pages, P_1 and P_2 , where $\text{Differ}(P_1, P_2) = \{\text{Position}(v)\}$ and $\text{Position}(v)$ of P_1 is the original state of the vulnerable bit (*e.g.*, 0 if

- $\text{Direction}(v) = 0 \rightarrow 1$). Copy p 's PT to P_1 . Then deallocate all mappings to P_1 and make it read-only.
- **Step 3:** Copy p 's PMD to the physical page (denoted P_v) that contains the vulnerable bit v . Then change the PDE (on P_v) that contains v to point to P_1 . Then deallocate all mappings to P_v and make it read-only.
 - **Step 4:** Issue hypercalls to update p 's corresponding PUD entry with P_v 's machine address, so that P_v will become the new PMD. The Hypervisor will check the validity of the new PMD and all page tables it points to. Although p 's PDE has been changed to point to P_1 , because P_1 is exact the same as p 's original PT, this step will also pass the security check by the hypervisor.
 - **Step 5:** Construct fake PTEs on P_2 so that they point to physical pages outside the attacker VM. These are the target memory pages that the attacker would like to access.
 - **Step 6:** Conduct row hammer attacks on the two neighboring rows of the vulnerable bit v , until bit flip is observed. p 's PDE will be flipped so that it will point to P_2 instead of P_1 .
 - **Step 7:** Now the attacker can access p and the other 511 virtual pages controlled by the same page table P_2 to access physical memory outside his own VM. The attacker can also modify the PTEs in P_2 without issuing hypercalls as he has the write privilege on this forged page table.

Theoretically, $(52 - 12)/64 = 62.5\%$ vulnerable bits can be exploited in *page table replacement* attacks, regardless of flippable directions. In practice, because physical addresses on a machine is limited by the available physical memory, which is much less than the allowed $(2^{52} - 1)\text{B}$. For example, with 128GB memory, the most significant bit in a physical address is bit 38. Therefore the fraction of vulnerable bits that are exploitable is about 41%. We will empirically show the fraction of vulnerable bits that are exploitable in our attacks in Section 6.

6 Evaluation

In this section, we will first evaluate the effectiveness and efficiency of the bit detection algorithms (described in Section 3) in Section 6.1, our row hammer attacks (described in Section 4) in Section 6.2, and the cross-VM memory access attacks (described in Section 5) in Section 6.3.

6.1 Bit Detection Efficiency and Accuracy

We ran the bit detection algorithm detailed in Section 3 on a set of local machines. The processor and DRAM

configurations, together with the detected physical address mapping in the DRAMs, are shown in Table 1. For instance, on a machine equipped with an Intel Westmere processor, Xeon E5620, and one DRAM chip (with 2 memory channels, 1 DIMM, 2 ranks, 8 banks, and 2^{15} rows per bank), we ran our algorithm and found the bits that determine bank indices are $b_6 \oplus b_{16}$, b_{13} , b_{14} , b_{20} , b_{21} , and the bits that determine row indices are bits b_{16} to b_{19} , and bits b_{22} to b_{32} (totally 15 bits). We can see from these results that older processors, such as Westmere and Sandy Bridge, tend to have simpler XOR-schemes. More recent processors may have complex schemes (probably due to *channel hashing* [21]). For example, on an Intel Haswell Xeon E5-1607 v3 processor, we observed that complicated XOR-schemes, such as $b_7 \oplus b_{12} \oplus b_{14} \oplus b_{16} \oplus b_{18} \oplus b_{26}$ and $b_8 \oplus b_{13} \oplus b_{15} \oplus b_{17} \oplus b_{27}$ are used to determine DRAM banks. Moreover, only on recent processors (e.g., Intel Broadwell Core i5-5300U) did we observe the same address bit involved in two XOR-schemes (e.g., b_{18} and b_{19}); other bits are at most used in one XOR-scheme. In addition, row bits are mostly contiguous bits, and on some processors can be split into two segments. For example, on an Intel Xeon E5-2640 v3 processor we tested on, the row bits are $b_{15} \sim b_{17}$ and $b_{21} \sim b_{35}$.

Efficiency evaluation. Figure 9 shows the execution time of the bit detection algorithms. Results for five local machines (Intel Sandy Bridge Core i3-2120 with 4GB memory, Intel Broadwell Core i5-5300U with 8GB memory, Intel Westmere Xeon E5620 with 4GB memory, Intel Haswell Xeon E5-2640 v3 with 32GB memory, and Intel Haswell Xeon E5-1607 v3 with 16GB memory) and three cloud machines (one machine in Cloudlab, Emulab d820, with 128GB memory, and two machines on Amazon EC2, one c1.medium instance and one c3.large instance, total memory size unknown) are shown in Figure 9. Most of these experiments can finish within one minute, with one exception of Xeon E5-2640 v3 which takes almost two minutes. The longer latency for testing E5-2640 v3 may be caused by its use of DDR4 memory, while the others are equipped with DDR3 memory chips.

Validation. Because Intel does not publish the memory mapping algorithms of their memory controllers, we do not have ground truth to validate our algorithm. However, we show that our algorithm is very likely to produce valid results for two reasons: First, in Table 1, the total number of bank bits and row bits detected are consistent with the DRAM configuration that we learned using several third-party software tools, including `dmidecode`, `decode-dimmms` and `HWiNFO64`. Second, we conducted double-sided row hammer attacks on some of the local machines we have in our lab: Machine A, Sandy Bridge

Processor Family	Processor Name	Channels	DIMMs	Ranks	Banks	Rows	Bank bits	Row bits
Westmere	Intel Xeon E5620	2	1	2	8	2^{15}	$b_6 \oplus b_{16}, b_{13}, b_{14}, b_{20}, b_{21}$	$b_{16} \sim b_{19}$ $b_{22} \sim b_{32}$
Sandy Bridge	Intel Core i3-2120	2	1	1	8	2^{15}	$b_6, b_{14} \oplus b_{17}, b_{15} \oplus b_{18}, b_{16} \oplus b_{19}$	$b_{17} \sim b_{31}$
Haswell	Intel Core i5-2500	2	1	1	8	2^{15}	$b_6, b_{14} \oplus b_{17}, b_{15} \oplus b_{18}, b_{16} \oplus b_{19}$	$b_{17} \sim b_{31}$
Haswell	Intel Xeon E5-1607 v3	4	1	1	8	2^{15}	$b_7 \oplus b_{12} \oplus b_{14} \oplus b_{16} \oplus b_{18} \oplus b_{26},$ $b_8 \oplus b_{13} \oplus b_{15} \oplus b_{17} \oplus b_{27},$ $b_{19} \oplus b_{23}, b_{20} \oplus b_{24}, b_{21} \oplus b_{25}$	$b_{23} \sim b_{34}$
	Intel Xeon E5-2640 v3	2	1	2	16	2^{18}	$b_6 \oplus b_{21}, b_{13}, b_{34},$ $b_{18} \oplus b_{22}, b_{19} \oplus b_{23}, b_{20} \oplus b_{24}$	$b_{15} \sim b_{17}$ $b_{21} \sim b_{35}$
Broadwell	Intel Core i5-5300U	2	1	1	8	2^{16}	$b_7 \oplus b_8 \oplus b_9 \oplus b_{12} \oplus b_{13} \oplus b_{18} \oplus b_{19},$ $b_{14} \oplus b_{17}, b_{15} \oplus b_{18}, b_{16} \oplus b_{19}$	$b_{17} \sim b_{32}$

Table 1: Identifying physical address mapping in DRAMs.

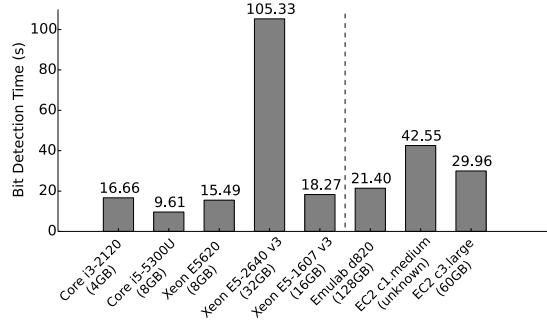

Figure 9: Efficiency of bit detection.

i3-2120, Machine B, Sandy Bridge i3-2120, Machine C, Sandy Bridge i5-2500, and Machine D, Broadwell i5-5300U⁴. Particularly on each of these machines, we indexed each row of the same bank from 1 to 2^k , where k is the number of detected row bits; the index of a row is given by the value presented by all row bits in the same order as they are in the physical address. Then we conducted row hammer attacks on row $n + 1$ and $n - 1$ of the same bank, where n ranged from 3 to $2^{15} - 2$. If the bit detection algorithm are correct, we should find more bit flips in row n than row $n + 2$ and $n - 2$, because double-sided row hammer attacks have been reported to be more effective [4]. It is apparent in Figure 10 that on all these machines, much more bit flips were found in row n than the other rows. For example, on machine A, 52.4% bit flips were found in row n , while only 28.6% and 19.0% flippable bits were found in row $n - 2$ and $n + 2$, respectively. These results suggest that our algorithm to detect the row bits and bank bits (including XOR-schemes) are consistent with the true configuration with the DRAM. We believe these evidence are strong enough to show the

validity of our bit detection method.

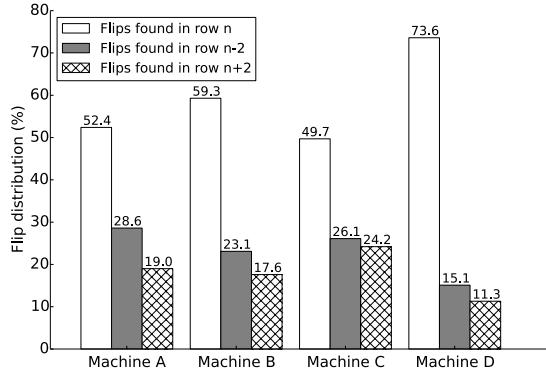

Figure 10: Location of bit flips in double-sided row hammer attacks. Row $n + 1$ and $n - 1$ are frequently accessed to induce disturbance errors.

6.2 Effectiveness of Row Hammer Attacks

We evaluated the effectiveness of our row hammer attacks in two aspects: (1) whether the attacker controlled physical memory can cover a significant portion of the overall physical memory on the machine, and (2) the number of bit flips induced by our double-sided row hammer attacks compared with single-sided attacks.

6.2.1 Physical Memory Coverage

We experimented on four servers to evaluate the physical memory coverage. The first machine is a desktop in our lab. It is equipped with a 3.3GHz Intel Core i3-2120 processor and 8GB of memory, of which 1GB is assigned to the virtual machine. The second machine is another desktop with a 3.7GHz Intel Core i5-2500 processor and 4GB of memory. The VM owns 1GB of the

⁴These set of machines, and the same naming convention, are also used in the following experiments.

memory. The third machine is a server in Cloudlab, which is equipped with a 2.2GHz Intel Xeon E5-4620 processor with 128GHz of memory. The VM runs on this machine is allowed to control 4GB of memory. The fourth machine is a dedicated cloud server in Amazon EC2. It has 128GB of memory and operates on a 2.8GHz Intel E5-2680 v2 processor. Our VM was allocated 8GB of memory.

We conducted the experiments as follows. On each of these VMs, we ran a program to measure the physical pages that are accessible to the guest VM. Then we rebooted our VM and measured the accessible physical memory again. After each reboot, some new physical pages will be observed (but some old pages will be deallocated from this VM). We rebooted the VM several times until no more new memory pages are observed after reboot. In Figure 11, the x-axis shows the number of VM reboots (the first launch counted as one reboot) and the y-axis shows the fraction of physical memory that can be accessed by the VM. In the two local machines, because no other VMs are competing for the physical memory, the sets of accessible pages are relatively stable. But still after reboots, more memory pages are accessible to the guest VMs. In the two cloud tests (one in EC2 and one in Cloudlab), the total physical memory sizes are very large (*i.e.*, 128GB). Although our VM were only allocated 6.25% (in the EC2 test) and 3.125% (in the Cloudlab test) physical memory initially, after several reboots, our VM could access as much as 17.8% (in the EC2 test) and 22.3% (in the Cloudlab test) of the total memory. The results suggest that row hammer attacks are possible to enumerate a large fraction of the physical memory even though the VM can only control a small portion of it at a time. Therefore, by doing so, the chances for a guest VM to induce exploitable and repeatable bit flips are not bound by the fixed size of physical memory allocated to the VM.

6.2.2 Row Hammer Induced Bit Flips

To show that our double-sided row hammer attacks are more effective than single-sided versions, we empirically test how fast each method can induce memory bit flips. In addition, we also tested with row hammer code both with and without `mfence` to empirically evaluate the effectiveness of the two types of attack techniques

Particularly, we implemented four types of row hammer attack tools: double-sided row hammer without `mfence` instruction, double-sided row hammer with `mfence`, single-sided row hammer without `mfence`, and single-sided row hammer with `mfence`. In Figure 12, we show the number of bit flips induced per hour by one of these approaches on four machines: Machine A, Sandy Bridge i3-2120, Machine B, Sandy Bridge

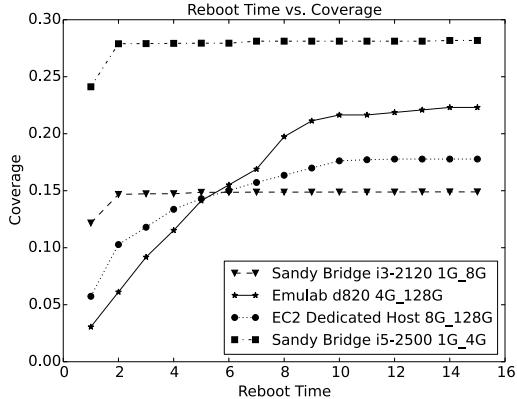

Figure 11: Physical memory coverage after VM rebooting.

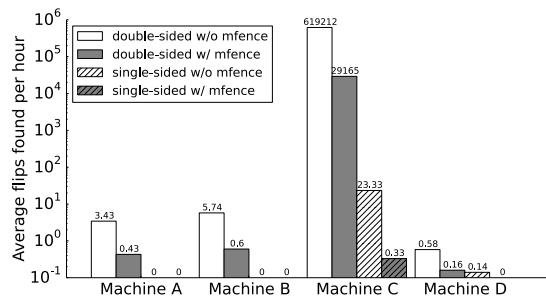

Figure 12: Efficiency of double-sided row hammer attacks.

i3-2120, Machine C, Sandy Bridge i5-2500, and Machine D, Broadwell i5-5300U (memory configurations are listed in Table 2).

We can see from the figure that our double-sided row hammer is much more effective than the single-sided row hammer attacks used in prior studies: Using single-sided attacks, on machine A and machine B, no bit flips could be observed, whether or not `mfence` was used. In contrast, using our double-sided row hammer attacks without `mfence`, 4 or 5 bits can be flipped per hour. On the most vulnerable machine C⁵, our double-sided row hammer attacks can find as many as over 600k bit flips per hour, while the best single-sided attacks can only find 23 bit flips per hour. We also find that row hammer without `mfence` is more effective than with it. The trend is apparent on all the four machines we tested on. As such, we conclude that although `mfence` ensures that all memory accesses reach the memory, the slowdown to the program execution it brings about reduces the effectiveness of row

⁵Some machines are expected to be more vulnerable than others (see Table 3, [23]), possibly due to higher memory density or lower DRAM refreshing frequency.

hammer attacks. Our double-sided row hammer attacks without `mfence` represent the most effective attack technique among the four.

While Figure 12 illustrates the rate of inducing bit flips, Table 2 demonstrates the overall effectiveness of our double-sided row hammer attacks (without `mfence`). Particularly, the total execution time of the experiments above and the total number of induced bit flips are shown in Table 2. In each of the tests we stopped the row hammer attacks once we have examined 50% of all DRAM rows (all rows that are accessible by the VM without reboot). We can see in the table the experiments took about 10 to 20 hours on machine A, B, and C. The total numbers of vulnerable bits found on machine A and B were 63 and 91, respectively. In contrast to zero bit flips induced by single-sided attacks that ran for 30 hours, our double-sided attacks make these machines vulnerable. On machine C, 5,622,445 vulnerable bits were found within 10 hours. Machine D is the least vulnerable among the four: only 25 vulnerable bits were found in about 43 hours. The results show that different machines are vulnerable to row hammer attacks to different extent.

Machine configuration	Execution time (hours)	Vulnerable bits found
(Machine A) Sandy Bridge i3-2120 (4GB)	18.37	63
(Machine B) Sandy Bridge i3-2120 (4GB)	15.85	91
(Machine C) Sandy Bridge i5-2500 (4GB)	9.08	5622445
(Machine D) Broadwell i5-5300U (8GB)	42.88	25

Table 2: Execution time and detected vulnerable bits in exhaustive row hammer attacks.

6.2.3 Vulnerable Bits Usability and Repeatability

We first report the fraction of vulnerable bits we found on the four machines, machine A, B, C and D (configurations listed in Table 2), that are usable in the *page table replacement* attacks we discussed in Section 5. The total number of bits that are used for analysis on these four machines are listed in Table 2⁶. The results are shown in Figure 13a: 36.5%, 31.9%, 32.8%, 40.0% of these bits are in the PFN range of a page table entry, thus are usable in *page table replacement* attacks.

Prior studies [23] have shown that many of the bit flips are repeatable. We try to confirm this claim in our own

⁶We selected a subset of vulnerable bits, 100031 vulnerable bits, on machine C for analysis because the entire set was too large to handle.

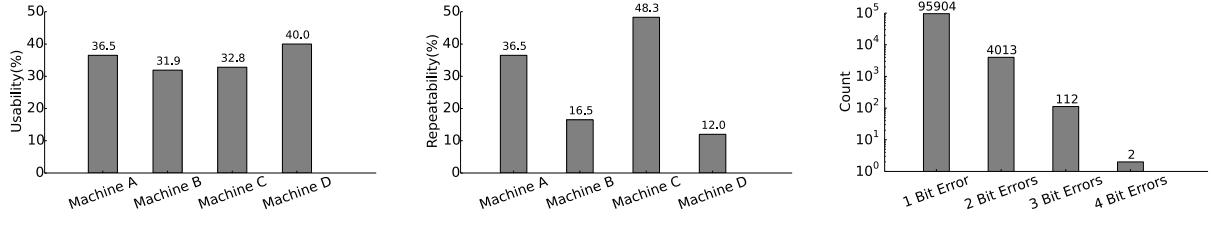

experiments. Specially, on these four machines, we repeated the row hammer attacks (10 times) against the rows in which vulnerable bits were found during the first sweep. We show, in Figure 13b, that 36.5%, 16.5%, 48.3%, and 12.0% of the vulnerable bits induced in the first run could be flipped again (at least once) on these four machines, respectively. These repeatable bit flips can be exploited in our cross-VM exploits.

In addition, on machine C, we have found more than one bit flippable within the same 64-bit memory block, which are beyond correction even with ECC memory. The distribution of vulnerable bits found in a 64-bit block is shown in Figure 13c. Particularly, we found 95904 single-bit errors, 4013 two-bit errors, 112 three-bit errors and 2 four-bit errors in the same 64-bit block.

6.3 Cross-VM Row Hammer Exploitation

We implemented our attack in a kernel module of Linux operating system (kernel version 3.13.0) that ran on Xen guest VMs. The hypervisor was Xen 4.5.1 (latest as of January 2016). We conducted the attacks on machine D, which is quipped with a Broadwell i5-5300U processor and 8GB of DRAM. However, we note that the attacks should also work on other machines and software versions as long as exploitable bits can be induced by row hammer attacks. Particularly, we demonstrated the power of the cross-VM row hammer attacks in two examples: In the first example, we demonstrated a confidentiality attack where the adversary exploited the techniques to steal TLS private keys from an Apache web server; in the second example, we showed an integrity attack, in which the attacker altered the program code of an OpenSSH server to bypass the user authentication and logged in the server without knowledge of credentials.

Arbitrary memory accesses. The first step of both attacks is to obtain arbitrary accesses to the target memory page. To do so, the adversary controlling a guest VM first runs the bit detection algorithm described in Section 3 to determine the row bits and bank bits of the machine, and then performs row hammer attacks until he finds a exploitable and repeatable bit flip at desired bit position—the PFN range of a PDE. We repeated the row hammer attacks 10 times and on average it took 2.13 hours to find the first useable bit flip. We emphasize machine D, the one we experimented with, is the least vulnerable machine among all (see Figure 12). Then the adversary replaces one of his own page tables with a forged one, using *page table replacement* attack techniques, and maps 512 of his virtual pages to 512 different physical pages. The adversary scans all these pages directly because they are mapped to his own address space. For each page, he compares the content of the page with a specific pattern. If the pattern is not found in these 512 pages, the ad-

Figure 13: Statistics of the induced flippable bits.

versary modifies the PTEs directly as he already has the write privilege on the forged page table, and searches in another 512 physical pages. The translation lookaside buffer (TLB) is flushed as needed to accommodate the page table changes.

To speed up the searching, the adversary obtained a list of machine page number (MFN) controlled by his own VM from `struct start_info.mfn_list` and excluded them from the list of physical pages to scan. As an extension of this implemented approach, the adversary may also reboot the VM several times to increase the physical memory space that is accessible to his own VM (as done in Section 4), thus reducing the search space of the victim. Alternatively, we also believe it is feasible to exploit cache-based side-channel analysis to learn the cache sets (physical address modulus the number of cache sets) of the targets [26] to narrow down the search space. We leave this optimization as future work.

6.3.1 Confidentiality Attacks

We show in this example that using the cross-VM row hammer attacks, the adversary may learn the private key of the Apache web servers of the neighboring VMs. Particularly, we set up two VMs on the same machine. The victim ran an Apache web server in which an HTTPS server was configured to support SSL/TLS using one pair of public/private keys. The attacker VM conducted the cross-VM row hammer attacks described above to obtain read access to the physical memory owned by the victim VM. When scanning each of the physical pages belonging to another VM, the adversary checked at each byte of the memory if it was the beginning of a `struct RSA`, by first checking if some of its member variables, such as `version` and `padding`, are integers, and others, such as `p`, `q`, `n` are pointers, and, if so, calling the `RSA_check_key()` function provided by OpenSSL. The function takes as argument a pointer to `struct RSA` and validates (1) whether `p` and `q` are both prime numbers, and (2) whether $n = p \times q$ and (3) whether $(x^e)^d \equiv x \pmod{n}$. If the location passes the checks, it

is the beginning of an RSA structure, the private key can be extracted. In fact, because at most memory locations, the basic checks will not pass, the expensive `RSA_check_key()` will not be called. If the adversary is lucky enough to successfully guess the machine address of the target memory page in the first trial, the average time to complete the attack was 0.32s (including the time to manipulate page tables, conduct row hammer attacks to induce the desired bit flip, read the memory page and check the validity of the private key, and write the extracted key to files). The overall execution time of the attack depends on the number of physical pages scanned before finding the target one, but on average scanning one additional memory pages took roughly 5ms.

6.3.2 Integrity Attacks

In this example, we show how to exploit row hammer vulnerabilities to log in an OpenSSH server without passwords. Particularly, the victim was the management domain in Xen, the Dom0. In our testbed, Dom0 is configured to use Pluggable Authentication Modules (PAM) for password authentication. PAM offers Linux operating systems a common authentication scheme that can be shared by different applications. Configuring `sshd` to use PAM is a common practice in Red Hat Linux [8]. We pre-configured one legitimate user on the OpenSSH server, and enabled both public key authentication and password authentication. The adversary controls a regular guest VM, a DomU, that ran on the machine. We assume the adversary has knowledge of the username and public key of the legitimate user, as such information is easy to obtain in practice.

To initiate the attack, the adversary first attempted to log in as a legitimate user of the OpenSSH server from a remote client using public/private keys. This step, however, is merely to create a window to conduct row hammer attacks against the `sshd` process, which is created by the `sshd` service daemon upon receiving login requests. By receiving the correct public key for the legitimate user, the server tries to locate the public key in the lo-

<pre>callq pam_authenticate test %eax, %eax jne <error_handling></pre>	<pre>mov \$0, %eax test %eax, %eax jne <error_handling></pre>
--	---

(a) Code before attacks. (b) Code after attacks.

Figure 14: Pseudo code to illustrate attacks against the OpenSSH server.

cal file (`~/ .ssh/authorized_keys`) and, if a match is found, a challenge encrypted by the public key is sent to the client. Then the OpenSSH server awaits the client to decrypt his encrypted private key file and then use the private key to decrypt the challenge and send a response back to the server. In our attack, the adversary paused on this step while he instructed the DomU attacker VM to conduct the cross-VM row hammer attacks to obtain access to the physical memory of Dom0. The steps to conduct the row hammer attacks were the same as described in the previous paragraphs. Particularly, here the adversary searched for a piece of binary code of `sshd`—a code snippet in the `sshpam_auth_passwd()` function. The signature can be extracted from offline binary disassembling as we assume the binary code of the OpenSSH server is also available to the adversary.

Once the signature was found, the adversary immediately replaced a five-byte instruction “`0xe8 0x1b 0x74 0xfd 0xff`” (binary code for “`callq pam_authenticate`”) with another five-byte instruction “`0xb8 0x00 0x00 0x00 0x00`” (binary code for “`mov $0 %eax`”). Note here even though the memory page is read-only in the victim VM, Dom0, the adversary may have arbitrary read/write access to it without any restriction. Then the code snippet will be changed from Figure 14a to Figure 14b. Upon successful authentication, `pam_authenticate()` will return 0 in register `%eax`. The modified code assigned `%eax` value 0 directly, without calling `pam_authenticate()`, so the authentication will be bypassed.

Then the adversary resumed the login process by entering password to decrypt the private key. The private key was incorrect so this step would fail anyway. Then password authentication would be used as a fallback authentication method, in which the adversary can log in the server with any password, because it was not really checked by the server.

Again, the time to complete the OpenSSH attack depends on the number of physical pages scanned before meeting the targeted one. If the target physical page is the first to be examined by the adversary, the average time to complete the attack was 0.322s, which included the time to manipulate page tables, conduct row hammer attacks to induce the desired bit flip, search the target page for specific patterns, and inject code in the target

memory. If additional memory pages need to be scanned, the average time to complete the pattern recognition in a 4KB memory page was 58μs.

We note the two examples only illustrate some basic uses of our presented cross-VM row hammer attacks as attack vectors. Other innovative attacks can be enabled by the same techniques. We leave the exploration of other interesting attacks as future work.

6.4 Prevalence of Xen PVM in Public Clouds

As shown in prior sections, Xen PVMs (paravirtualized VMs) are very vulnerable to privilege escalation attacks due to row hammer vulnerabilities. However, they are still widely used in public clouds. Amazon EC2⁷ as a leading cloud provider still offer PV guests in many of its instance types (see Table 3). Other popular cloud providers such as Rackspace⁸ and IBM Softlayer⁹ are also heavily relying on PV guests in their public cloud services. In addition, PVMs are also the primary virtualization substrate in free academic clouds like Cloudlab¹⁰.

The prevalence of PV guests provides adversaries opportunities to perform bit detection, and hence double-sided row hammer attacks in public clouds. With detected bit flips, it also allows malicious page table manipulation to enable arbitrary cross-VM memory accesses. This kind of hardware attack is beyond control of the hypervisor. Victims will suffer from direct impairment of the system integrity or more sophisticated exploits of the vulnerability from attackers.

cloud	instance types
Amazon EC2 [7]	t1, m1, m2, m3, c1, c3, hs1
Rackspace [28]	General purpose, Standard
Softlayer	Single/Multi-tenant Virtual Server
Cloudlab	d430, d810, d820, C220M4, C220M4, c8220(x), r320, dl360

Table 3: Prevalence of Xen paravirtualized VMs in public clouds.

7 Discussion on Existing Countermeasures

In this section, we discuss the existing software and hardware countermeasures against the demonstrated cross-VM row hammer attacks.

Row hammer resistance with hardware-assisted virtualization.

Many of the attacks presented in this paper (*e.g.*, bit detection, double-sided row hammering, and also cross-VM memory accesses enabled by page table manipulation) require the adversary to know the machine address of his virtual memory. One way to prevent physical address disclosure to guest VMs is to adopt hardware-assisted virtualization, such as Intel’s VT-x [31] and AMD’s AMD-V [2]. Particularly, VT-x employs Extended Page Tables and AMD-V introduces Nested Page Tables [1] to accelerate the processor’s accesses to two layers of page tables, one controlled by the guest VM and the other controlled by the hypervisor. In this way, the guest VMs may no longer observe the real physical addresses, as they are not embedded in the PTEs any more. Hardware-assisted virtualization also prevents direct manipulation of page tables, and thus the privilege escalation attacks presented in this paper are not feasible.

The transition from Xen paravirtualization to hardware-assisted virtualization in public clouds started a few years ago, but the progress has been very slow. One reason is that paravirtualization used to have better performance than hardware-assisted virtualization in terms of networking and storage [9]. However, with the recent advances in hardware-assisted virtualization technology, some HVM-based cloud instances (*especially PV on HVM*) are considered having comparable, if not better, performance [7]. Even so, given the prevalence of paravirtualization in public clouds as of today, we anticipate it will take many years before such technology can gradually phase out. We hope our study offers to the community motivation to accelerate such trends.

Row hammer resistance with ECC-enabled DRAMs. As discussed in Section 2, the most commonly implemented ECC mechanism is single error-correction, double error-detection. Therefore, it can correct only one single-bit of errors within a 64-bit memory block, and detect (but not correct) 2-bit errors, causing the machines to crash. ECC memory will make the row hammer attacks much harder. Because 1-bit error and 2-bit errors are more common than multi-bit errors (*e.g.*, see Figure 13c), and it is very likely the privilege escalation attack will be thwarted either by bit correction or machine crashes before it succeeds. However, ECC memory does not offer strong security guarantees against row hammer attacks¹¹. It is still possible for an adversary to trigger multiple (> 3) bit flips in the same 64-bit word so that errors can be silently induced and later exploited. Particularly, if the true physical address of an extremely vulnerable rows is known to the adversary, hammering around this specific row will greatly increase the adver-

sary’s chances of success.

We believe a combination of hardware and software based defense will offer better security against row hammer attacks. On the one hand, hardware protection raises the bar of conducting row hammer attacks, and on the other hand, software isolation prevents successful exploitation once such vulnerability is found by the adversary.

8 Conclusion

In conclusion, we explored in this paper row hammer attacks in the cross-VM settings, and successfully demonstrated software attacks that exploit row hammer vulnerabilities to break memory isolation in virtualization. Many techniques presented in this paper are novel: Our graph-based bit detection algorithm can reliably determine row bits and XOR-schemes that are used to determine bank bits within one or two minutes. This novel method enables the construction of double-sided attacks, which significantly improves the fidelity of the attacks. The page table replacement attacks present a deterministic exploitation of row hammer vulnerabilities. The two examples we demonstrated in the paper, private key exfiltration from an HTTPS web server and code injection to bypass password authentication on an OpenSSH server, illustrate the power of the presented cross-VM row hammer attacks. The high-level takeaway message from this paper can be summarized as: (1) Row hammer attacks can be constructed to effectively induce bit flips in vulnerable memory chips, and (2) cross-VM exploitation of row hammer vulnerabilities enables a wide range of security attacks. We also believe that although server-grade processors and memory chips are more expensive and in contrast are less vulnerable to row hammer attacks, security guarantees needs to be achieved by both hardware and software solutions.

Abstract

The goal of rootkit is often to hide malicious software running on a compromised machine. While there has been significant amount of research done on different rootkits, we describe a new type of rootkit that is *kernel-independent* – i.e., no aspect of the kernel is modified and no code is added to the kernel address space to install the rootkit. In this work, we present *PIkit* – Processor-Interconnect rootkit that exploits the vulnerable hardware features within multi-socket servers that are commonly used in datacenters and high-performance computing. In particular, PIkit exploits the DRAM address mapping table structure that determines the destination node of a memory request packet in the processor-interconnect. By modifying this mapping table appropriately, PIkit enables access to victim’s memory address region without proper permission. Once PIkit is installed, only user-level code or payload is needed to carry out malicious activities. The malicious payload mostly consists of memory read and/or write instructions that appear like “normal” user-space memory accesses and it becomes very difficult to detect such malicious payload. We describe the design and implementation of PIkit on both an AMD and an Intel x86 multi-socket servers that are commonly used. We discuss different malicious activities possible with PIkit and limitations of PIkit, as well as possible software and hardware solutions to PIkit.

1 Introduction

Rootkits are used by attackers for malicious activities on compromised machines by running software without being detected [47]. Different types of rootkits can be installed at the application-level, kernel-level, boot loader level, or hypervisor level. There has been significant amount of research done on different types of rootkits [57, 28, 25, 24] as well as different rootkit detections [21, 31, 11]. Recently, there have been other types of rootkits [20, 50] that exploit vulnerable hardware features such as de-synchronized TLB structures and un-

used interrupt vector. Prior work on rootkit can be classified based on whether the payload consists of user-level or kernel-level code and whether rootkit is installed in the software or with the support of the hardware (Table 1). In this work, we propose a new type of rootkit that modifies hardware state but enables malicious activities with simple user-level code that consists of read/write memory accesses to user-level memory space. While prior work on user-level software rootkit often modified existing files [35, 48, 23], this work does not modify the kernel or any existing files. Since this work does not require any code modification or code injection to the kernel, traditional approaches to detect software rootkit, such as kernel integrity monitoring [42, 31, 53] or code signature-based detection [1, 2] can not be used for detection.

In this work, we present PIkit, processor-interconnect rootkit, that exploits hardware vulnerability in x86 multi-socket servers. x86 is the most dominant server processor in datacenters and high-performance computing [36] and a recent survey found over 80% of the x86 servers are *multi-socket servers*. The multi-socket servers contain a processor-interconnect that connects the sockets together (e.g., Intel QPI [37], AMD Hypertransport [10]) and we exploit the processor-interconnect to implement PIkit. Once PIkit is installed, the payload or the malicious code to carry out an attack exists in user space and appears like a “normal” user program – i.e., all of the memory accesses from the payload are legal memory accesses and it becomes very difficult to identify such user code as “malicious” code. As a result, PIkit is a seri-

ous threat to multi-socket servers that is difficult to detect with currently available rootkit detection mechanisms.

PIkit that we propose is implemented on x86 servers from both AMD and Intel to demonstrate how PIkit enables an attacker to continuously access the victim’s memory region without proper permission.¹ In particular, we exploit the configurability in the DRAM mapping table that enables a memory request packet to be routed to a different node by modifying a packet’s destination node. We also exploit the extra entries available in the DRAM mapping table to define an *attack memory region* when installing PIkit. As a result, user-level memory read or write requests to the attack memory region get re-routed to another memory region or the *victim’s memory region*. To the best of our knowledge, this represents the first rootkit where with the support of hardware state modification, user-level code or payload is sufficient to carry out malicious activities.

Most rootkits often modify some components of the OS while other rootkits add malicious payload to the kernel without modifying the OS to carry out malicious activities. However, such approaches can be exposed by signature-based detection and integrity checking. In comparison, PIkit only requires user-level payloads with the support of hardware state modifications as no malicious payloads to the kernel space are added or modified (Figure 1). In addition, any signature scan of the memory that contains the user-level payload can not identify the user code as “malicious” since the memory accesses appear to be legal accesses as the malicious access is only achieved through the support of the hardware modifications. As a result, PIkit demonstrates how a very stealthy rootkit can be achieved compared to previously proposed rootkits.

The proposed PIkit is a non-persistent rootkit [20, 45, 41] and does not remain after the server is restarted. However, servers are rarely rebooted to minimize the impact on availability – for example, one study measured the average time between reboot in the server room to be 481 days [22]. Thus, PIkit poses a serious threat to servers while powered on. Prior work on non-persistent rootkit [20] has argued that non-persistence can also significantly reduce the detectability of rootkits.

In particular, the contributions of this work include the followings.

- We show that the DRAM address mapping table structure in the processor-interconnect of multi-socket servers has security vulnerability that can be exploited maliciously in both an AMD and an Intel-based x86 server.

¹This work can also be viewed as a “backdoor” since once PIkit is installed, it provides a covert mechanism for the attacker to gain privileged access to the system.

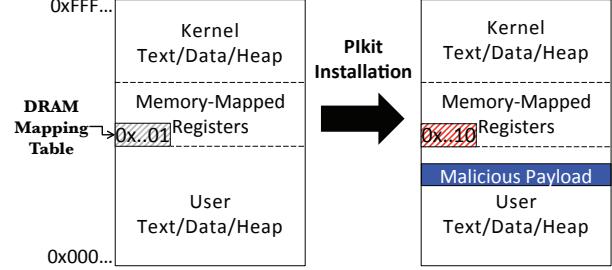

Figure 1: High-level overview of PIkit showing DRAM address mapping table modification and user-level malicious payload added for malicious activities.

- We describe a new type of rootkit that is *kernel-independent* that requires only hardware state modification with user-level payload, no modification or addition to the kernel is necessary. In particular, we present PIkit, Processor-Interconnect rootkit, that exploits the mapping table vulnerability to enable the malicious attacker privileged access (both read and write) to a victim memory address region with only user-level access.
- Once PIkit is installed, we demonstrate how different malicious activities can be carried out including bash shell credential object attack, shared library attack, and keyboard buffer attack with only user-level memory accesses.
- We describe alternative solutions, including a software-based, short-term solution to detect PIkit as well as hardware-based, long-term solutions to prevent PIkit.

We responsibly disclosed this vulnerability to CERT before publishing this paper. The rest of the paper is organized as follows. We first describe our threat model in Section 2 and background into processor-interconnect as well as related work. The DRAM address mapping table structure is described and analyzed in Section 3. The design and implementation of PIkit that modifies the mapping table structure is described in Section 4 and we illustrate different malicious activities in Section 5. We provide some discussion on different solutions as well as limitations of PIkit in Section 6 and we conclude in Section 7.

2 Background

2.1 Threat Model

In this work, we assume an attacker and a victim share the same multi-socket server that is commonly used in cloud servers and high-performance computing. We assume an attacker has no physical access to the hardware and also assume the same threat model as prior work on rootkit attack – the attacker, through some vulnerabilities (e.g., vulnerabilities in commodity OSes [39, 16, 6] or perhaps through an administrator (or an insider) who

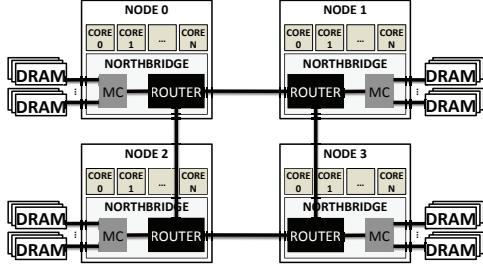

Figure 2: Block diagram of a processor-interconnect in a 4-socket server. (MC: memory controller)

maliciously provides one-time root access [54]) or social engineering, is assumed to have privileged access for rootkit installation. Once this is achieved, the next goal is to avoid detection of intrusion while carrying out malicious activity, similar to other rootkits. After PIkit is installed, it becomes very difficult to detect or determine the source of the attack as there are no changes to the kernel in the target system.

2.2 Processor-Interconnect Overview

A high-level block diagram of a processor-interconnect is shown in Figure 2. The processor-interconnect provides connectivity between multiple nodes (or sockets) in a NUMA (non-uniform memory access) server with each node containing multiple cores. The router within the Northbridge is used to connect to other nodes and it is also used to access local memory. For simplicity, the example in Figure 2 shows a ring topology to interconnect the 4 nodes together but for a small-scale system, all of the nodes can be fully connected as well. Given the processor-interconnect and its topology, the routing algorithm determines the path taken by a packet to its destination [19]. To provide flexibility, a routing table is commonly used in the processor-interconnect to implement the routing algorithm. Based on the destination of the packet, a routing table look-up is done to determine the appropriate router output port that the packet needs to be routed through. However, the routing table is only used to determine which router output port should be used (and the routing path); the routing table is not responsible for determining the packet destination.

The packet destination information is determined by the packet header. The format of messages (or packets²) in the processor-interconnect is similar to other interconnection networks [19] as shown in Figure 3. A packet is the high-level message that is sent between the nodes, which can include memory requests, cache line replies, coherence message, etc. A packet is often partitioned into one or more *flits* or flow control units within the interconnection networks – thus, a packet can be partitioned into a head flit, one or more body flits, and a

²A message can consist of multiple packets but within the processor-interconnect, messages are often single packet.

tail flit. The head flit contains additional “header” information, which can include the packet type and both the source and destination node information of the packet. The body/tail flits do not contain destination information but only the payload and simply follows the head flit from the source to its destination.

2.3 Related Work

To the best of our knowledge, very few prior research have investigated security vulnerabilities within the hardware of the processor-interconnect in multi-socket servers. Song et al. [49] demonstrated the security vulnerability of the routing table in a multi-socket server. This vulnerability enabled performance attacks by sending packets through longer routes and degrading both interconnect latency and bandwidth. In addition, it also enabled system attacks by creating a livelock in the network to crash the system. However, the routing table did not modify the *destination* of a packet and thus, the scope of the attack was limited. In this work, we show how the *destination* of a packet can be changed by modifying the DRAM mapping table to enable a rootkit attack.

Rootkit Attacks: User-level, software rootkits (upper left box in Table 1) often modify existing system utilities to enable malicious codes. Lrk5 [48], T0rn [35] and Dica [23] replace the system binaries (e.g., ls, ps and netstat) with modified versions to hide files, processes or network connections. SAdoor [40] is a non-listening daemon that grabs packets directly from the NIC and watches for special key and command packets before executing a pre-defined command (e.g., /bin/sh). However, it has been shown that these rootkit are often easily detected by integrity checking for the system binaries.

Traditional kernel-level, software rootkits (upper right box in Table 1) exploit the control hijacking and interception, modifying static kernel data structures (e.g., system call table) to jump to malicious codes indirectly. DKOM [15] introduced a more advanced kernel-level rootkit approach which exploits dynamic (non-control) kernel data structures (e.g., processor descriptors) to install the rootkit. Hofmann et al. [24] introduced a rootkit which allows for malicious control flows by replacing pointer variables. Hund et al. [25] introduced a return-oriented rootkit based on Return-Oriented Programming [14] to bypass integrity checking for the kernel code. However, these kernel-level, software rootkits require modifications to the kernel and can be detected with protecting return addresses on the stack and critical data structures from the modification.

In addition to software rootkits, hardware-supported rootkits have been proposed (lower right box in Table 1). ShadowWalker [50] hid the trace of the rootkit by hooking the page tables while Cloaker [20] exploited ARM-specific architectural feature to conceal the rootkit with-

Figure 3: Packet format in interconnection networks with packet consisting of multiple flits.

out altering existing kernel code. However, these work require adding malicious payload to the kernel which can be prevented by guaranteeing the execution of only verified kernel code or detected by checking the flow of the hijacked code. In comparison, while PIkit also leverages a hardware-vulnerability, PIkit enable malicious activity with only user-level code.

The rootkits that we categorized in Table 1 and described earlier focus mostly on the software or hardware (CPU)-related rootkits. There have also been other device-specific rootkits such as network interface card [51], hard-drives [57], USB mouse [33], and printers [18]. In addition, rootkits involving BIOS [56] have also been proposed. However, these rootkits also involve modifying existing firmware to carry out the attack. Subvirt [28] presented a more stealthy rootkit by using virtual machine monitor (VMM) but Subvirt can also be detected with physical memory signature scans. Run-DMA [44] is a DMA (direct memory access) rootkit attack that enables a “malicious computation” where attacker modifies data inputs to induce arbitrary computation, in comparison to a more traditional “malicious code” model attack. The PIkit that we present in this work is not necessarily limited to either malicious computation or malicious code model since any region in the memory can be modified as long as the memory mapping can be determined by the attacker.

Rootkit Detection: The rootkit detection can be largely divided into two types, checking the integrity of kernel codes and data structures and detecting malicious control flows (e.g., hooking system call table and interrupt vector table). Copilot [42] detects the modification of kernel and jump tables with the separated PCI card monitor. However, such approaches do not guarantee hardware register integrity, such as the register modified in Cloaker [20] or the DRAM address mapping table modified in this work. KI-mon [31] introduced a hardware-assisted monitor, which snoops all bus traffic to verify updates of the kernel objects with the address filter while Shark [53] proposed an architectural supported rootkit monitor. However, since PIkit does not access the kernel objects directly, such approaches cannot detect PIkit.

3 Analysis of Processor-Interconnect in Multi-Socket Servers

In this section, we describe the *DRAM address mapping table* structure within the Northbridge (or the un-

	Base Address	Limit Address	Destination ID

7	RESERVED	RESERVED	RESERVED

Figure 4: An example of DRAM address mapping table for a 4-node system.

core) that we analyze in detail and then describe how it can be exploited to enable a hardware vulnerability-based rootkit attack through the processor-interconnect.

3.1 DRAM Address Mapping Table

One of the critical information in packet’s header is the destination information; this information is often based on the destination memory address in modern multi-socket servers. The destination node is determined by a memory address mapping table structure between the core and the processor-interconnect router – we refer to this as the *DRAM Address Mapping Table*.³ Based on the destination address of the packet, the DRAM address mapping table determines the destination. As a result, regardless of the address, the packet is simply forwarded to the destination based on the packet header information within the processor-interconnect.

A separate copy of DRAM address mapping table structure exists within each node of a multi-socket system, between the core (or the last level cache) and the router. Each entry in the mapping table contains a DRAM physical memory address range, often including the start (or the base) address and the limit address. Each entry also contains the destination node information – thus, if an address falls within the address range, the destination node information is appended to the packet. An example of a DRAM address mapping table is shown in Figure 4.

The number of entries in the DRAM address mapping table should be equal to or greater than the maximum number of nodes in the system. In the AMD system that we evaluate (AMD Opteron 6128), the system contains 4 nodes but the system is scalable up to 8 nodes. Thus, the DRAM mapping table contains 8 entries with only 4 of the entries used and the remaining 4 entries not used (or shown as RESERVED in Figure 4).

The DRAM address mapping table is initialized by the BIOS at boot time. Since the table entries are memory-mapped registers, the BIOS uses memory operations to initialize the memory mapping table. The contents of

³In Intel-based NUMA systems, this structure is referred to as the DRAM address decoder [5] while in AMD- multi-socket systems, similar structures are referred to as DRAM address map register [13].

the address mapping table entries are dependent on the DRAM capacity installed on each node. To determine the address range for each entry (and each node), the BIOS calculates the current memory capacity by obtaining DRAM information such as the number of rows, banks and ranks from the SPD (Serial Presence Detect) [4] on the DRAM.

3.2 Vulnerable Hardware Features

To implement PIkit, we exploit the following three aspects of the DRAM address mapping table in multi-socket servers.

Configurability: The memory mapping table needs to be configurable since the memory capacity per system (and per node) is flexible and determined by the system user.

Extra entries: Since the system needs to be designed for scalability, the number of entries in the DRAM address mapping table needs to equal to or greater than the largest system configuration. For most multi-socket servers today, the maximum number of nodes in the system is often 8; however, the most dominant NUMA servers on the market are often 2 or 4 nodes [26] and thus, there are memory mapping table entries that are unused.

Discrepancy: The DRAM mapping table content values can be modified after the initialization such that the values are not consistent with the original values. This discrepancy may or may not cause a problem, depending on how the table is modified.⁴

Thus, given these three hardware vulnerabilities, *the destination node information of packets in the processor-interconnect can be modified such that the packets are sent to a different node (and its corresponding victim's memory address) to allow an attacker to access unauthorized memory space without proper permission*. In the following section, we describe the challenges in the design and implementation of PIkit.

4 PIkit Design & Implementation

PIkit installation procedure that includes modifying the DRAM address mapping table is described in this section. We first provide an overview and describe how the attack address region needs to be prepared by the attacker, and then modify the DRAM mapping table based on the attack address region. Our initial design and implementation are shown for an AMD-based server but we also discuss how PIkit can be implemented on Intel-based servers as well.

⁴Steps to ensure that the discrepancy does not cause a problem is discussed in Section 4.3 (for AMD) and Section 4.5 (for Intel).

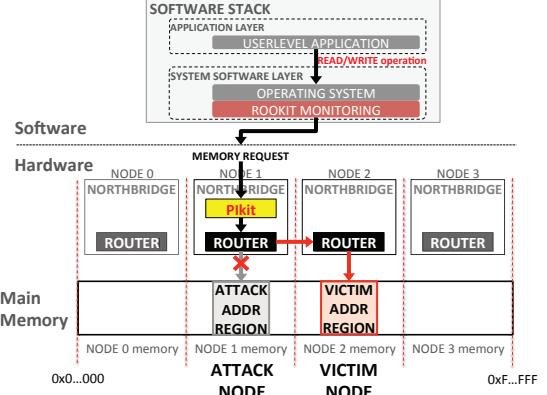

Figure 5: High-level description of the proposed PIkit on a 4-node multi-socket server.

4.1 Overview

In this work, we define the *attack node* as the node in the multi-socket system where the DRAM address mapping table is modified to implement PIkit, and the *victim node* is the node where its memory is maliciously accessed, through user-level read or write operations without proper permission. The address region that is modified in the memory mapping table in the attack node is defined as the *attack address region* while the corresponding address in the victim node is the *victim address region*, as shown in Figure 5. The PIkit and the modification in the DRAM address mapping table result in read/write memory requests to the attack address region being routed to the victim address region. The high-level diagram in Figure 5 also shows how the PIkit relates to the entire system. Most rootkit monitoring mechanisms (or solutions) exist at the software-level but the PIkit that we propose in this work is at the hardware-level (within the processor-interconnect) and exploiting vulnerability in the mapping table structure.

After the core injects a memory request into the Northbridge and before the packet is actually routed through the processor-interconnect by the router, a packet header is created based on the physical address of the memory request as shown in Figure 6. The processor-interconnect does not observe the memory address as that is included in the packet payload⁵ and is only observed at the destination (i.e., memory controller). The processor-interconnect only observes the destination node information that is appended at the interface between the core and the router. The PIkit that we propose in this work exploits this vulnerability of modifying the *destination* of a packet – in particular, the DRAM address mapping table structure to modify the packet’s destination.

⁵Packet payload refers to the non-header or the data portion of the packet while the payload terminology used in the rest of this paper refers to the malicious code used after rootkit is installed.

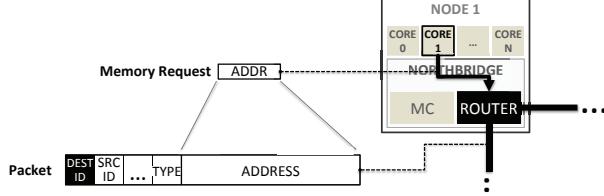

Figure 6: Hardware overview of memory request and packet header.

4.2 Defining Attack Address Region

Before the PIkit installation, the attacker first needs to prepare the attack address region such that only the attacker has access to that particular memory region. This step is critical to ensure that PIkit and the DRAM address mapping table modification do not cause any unknown system behavior including crashing the system. For example, if another program (or user) attempts to access the attack memory region after the PIkit is installed, the memory access will be routed to the victim node and unexpected system behavior will occur if a memory write is being done on an unintended memory address – i.e., it can cause critical data in kernel space to be overwritten.

The memory address range of the attack address region needs to be equal to granularity or the *resolution* of the memory mapping table. Although each entry in the DRAM address mapping table specifies both the base and the limit addresses, the full width of the address (i.e., 48 bits) is not stored as some of the lower bits are not specified in the DRAM address mapping table. For example, in the AMD Opteron 6128 system that we evaluate, the granularity of the memory mapping table is 16 MBs as only 24 most-significant bits are stored – thus, the attacker needs to obtain at least 16 MBs of physically contiguous memory region. To achieve this, we take advantage of huge pages that are commonly available. In the system that we evaluate, we used 1 GB huge page. After successful `malloc` for a huge page, an address range within the contiguous memory region allocated can be used as the attack address region, as long as the process that received the memory allocation is continuously running.

4.3 Modifying the DRAM Address Mapping Table

The DRAM address mapping table consists of physical addresses while the attack address region obtained in the previous section are virtual addresses. Thus, an attacker needs to obtain the translated physical address of the attack region before modifying the DRAM address mapping table. The translation of the virtual to physical address can be determined by using `/proc/(pid)/pagemap` interface from the Linux kernel. Based on this translation information, the DRAM address mapping table can be modified using the corresponding physical address of

	Base Address	Limit Address	Destination ID
0	0x0000000000	0x041F000000	0
1	RESERVED	RESERVED	RESERVED
2	0x0820000000	0x0C1F000000	2
3	0x0C20000000	0x101F000000	3
4	0x0420000000	0x07BF000000	1
5	0x07C0000000	0x07C1000000	2
6	0x07C2000000	0x081F000000	1
7	RESERVED	RESERVED	RESERVED

Figure 7: A modified DRAM address mapping table where entry 5 (highlighted) is used as the attack address region.

the attack region.

An example of a modified mapping table is shown in Figure 7, based on the original DRAM address mapping table shown earlier in Figure 4. We assume the attack node is node 1 and the victim node is node 2, with the attack address region defined as the address between 0x07C0000000 and 0x07C1000000 in node 1. In Figure 7, the entry 1 of the table which originally identified node 1 memory region has been removed. Instead, the same address range has been partitioned across entries 4, 5, and 6 of the modified DRAM mapping table (Figure 7). The key difference compared with the original mapping table is that for entry 5, the destination node ID has been modified such that it is no longer node 1 but modified to node 2 – thus, entry 5 represents the *attack address region*. Any address requests between 0x07C0000000 and 0x07C1000000 from node 1 have a destination of node 2 added to the packet header, instead of the original destination of node 1. When this particular packet arrives at node 2, the DRAM memory controller within the node 2 will receive this packet and convert the address within the payload of the packet into the actual *victim address region*. For example, in the AMD system that we evaluate, address 0x07C0000000 from node 1 ends up being mapped to address 0x0840000000 in node 2. As a result of the mapping table modification, the physical memory connected to node 1 that originally corresponded to the address range between 0x07C0000000 and 0x07C1000000 can no longer be physically accessed from node 1.

Since the table entries are memory-mapped registers, the entries can be modified through system read/write commands (e.g., `setpci` utility). However, to properly modify the DRAM address mapping table entries, the following caution must be taken.

1. The new entries must be written before the old entry is removed (e.g., in Figure 7, entries 4, 5, 6 must be written before entry 1 is cleared).
2. For the new entries added, the base address register must be written before the limit address register.
3. For the existing old entry that needs to be removed, the limit address register must be cleared first, before the base address register.

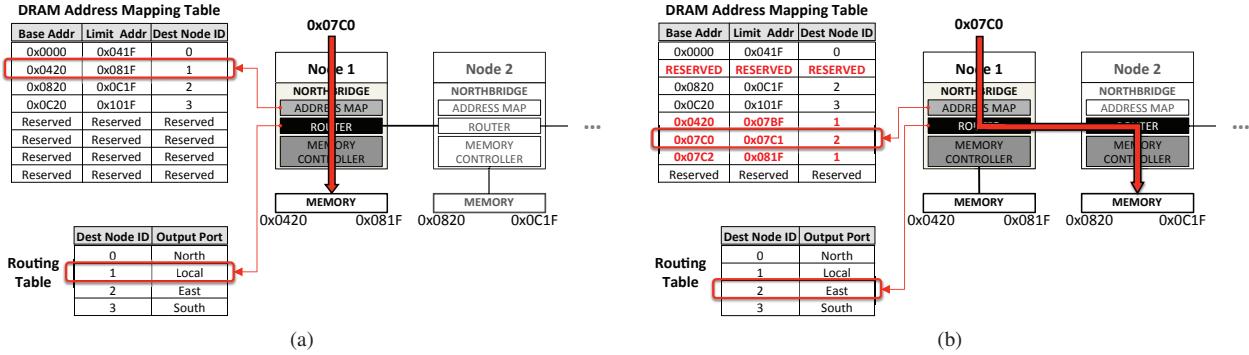

Figure 8: Example of PIkit (a) before and (b) after PIkit is installed on an AMD Opteron 6128 server.

Since memory accesses continuously occur in the system, randomly changing the mapping table in any order can result in a memory request that is not able to match an entry in the mapping table and result in a system crash.

4.4 Example

A complete example of PIkit is shown in Figure 8 for a 4-node system with only 2 nodes shown in the figure for simplicity. The same DRAM address mapping tables shown earlier in Figure 4 and Figure 7 are used in the example.⁶ Assume a read access to address 0x07C0000000 is made by a core in node 1. With an unmodified DRAM address mapping table, the address 0x07C0000000 finds a match in entry 1 and determines that the destination should be node 1. Based on this information, a routing table look-up is done for the node 1 to determine the output port. Since the current node is the local node, the output port determined by the routing table is the “Local” port and the memory request is routed appropriately to the local node’s memory.

However, with the modified DRAM address mapping table (Figure 8(b)), the same request to address 0x07C0000000 finds a match to entry 5 where the destination is now node 2. Based on this new destination node ID information, the routing table look-up is done within the router and the output port returned is the “East” port – thus, the packet is routed to node 2. Within the node 2, the packet is simply treated as a packet that was destined for node 2 (or the “Local” output port) and will be routed to the memory controller. Since the processor-interconnect only looks at the destination node information to determine where to send the packet, the PIkit shown in Figure 8(b) results in packets accessing a memory region where it does not have proper permission. If this packet was a read request, the packet would read data from the corresponding victim memory address while if this packet was a write request, the packet would modify or overwrite existing data in the victim memory address.

⁶For simplicity, the lower 3 bytes of the address are not shown in Figure 8.

Figure 9: Example of how the Source Address Decoder (SAD) can be modified on the attack node to implement PIkit on an Intel Sandybridge architecture.

4.5 Extending PIkit to Intel Architecture

In the previous sections, we described how PIkit is implemented on an AMD multi-socket server and in this section, we discuss how PIkit can be extended to an Intel-based server. A structure similar to the memory mapping table exists within Intel x86 server architecture and is referred to as the *Source Address Decoder (SAD)* [5]. A key difference with the AMD architecture in the memory mapping table is that instead of specifying both the base and the limit memory address for each entry, only the limit address is specified. In addition, a valid bit per entry exists in the SAD which specifies if the entry is enabled or not. As a result, the “base” address is implied from the previous entry limit address and PIkit design needs to properly add/modifies entries of SAD to ensure proper behavior for memory accesses. An example of how the SAD table can be modified is shown in Figure 9. The initial entries are first duplicated in the table (step (2)) and then, the initial entries are invalidated (step (3)) before the addresses are modified (step (4)) and then, the modified addresses are made valid (step (5)) to create an attack address region with entry 1 of the SAD table.

Another key difference in the Intel architecture compared with the AMD system is the *Target Address Decoder (TAD)* which is accessed before the address is sent to the memory controller at the destination node.⁷ TAD is an additional table that is responsible for mapping discontinuous address regions [5] and includes both a limit address and an offset. While the purpose of the “offset” within the TAD is to relocate the memory location as necessary, it enables PIkit to be implemented by defining

⁷While a similar structure existed in the AMD system that we evaluated, it only had a single entry and could not be exploited for PIkit.

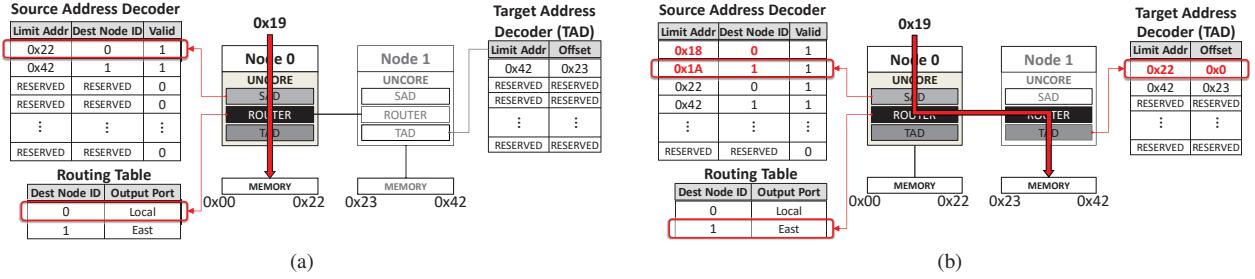

Figure 10: PIkit example on an Intel Sandybridge-based server (a) before and (b) after PIkit is implemented. For simplicity, the TAD on Node 0 and SAD 0 on Node 1 are not shown.

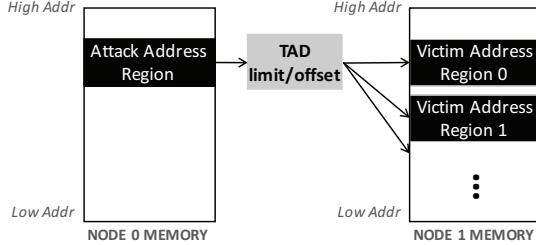

Figure 11: Impact of the Target Address Decoder (TAD) on the mapping of the attack memory region to the victim memory region.

the victim memory address region based on the attack address region. The impact of TAD offset is shown in Figure 11. Since the offset is subtracted from the address, by varying offset entry, the attack memory address region can be mapped to different victim memory region based on the offset value and enables a more “controlled” attack by providing control over the memory mapping (i.e., victim’s address range). One constraint is that since the offset is being subtracted, the victim memory address region can only be equal or smaller than the attack memory address region.

A PIkit example for an Intel-based architecture is shown in Figure 10 based on the SAD modification shown in Figure 9. The PIkit consists of both the SAD modification in the attack node and the TAD modification in the victim node. Thus, the same vulnerability that was exploited for PIkit on the AMD-based system is available in the Intel-based servers – the table structures are memory-mapped registers that are configurable and extra number of entries are available. Based on documentations [5], the number of entries for SAD is 20 and thus, it is more than sufficient for a 2-node multi-socket system.

5 Malicious User-level Payloads

After PIkit is installed, PIkit enables access to the victim address region regardless of the privilege level. In this section, we describe different malicious activities with user-level payloads that can exploit PIkit. While many different attacks (and payloads) have been proposed as part of rootkit attacks, previous attacks often require

Description	Value
System	AMD Opteron 6128

# of HT Links	4 per node
OS version	Linux Kernel 3.6.0

Table 2: Dell PE R815 server used in our evaluation.

leveraging (or modifying) some OS capability or creating additional payload to mimic the OS. In comparison, the *malicious payload for PIkit is fundamentally different as the payload is relatively simple with the source code mostly consisting of memory read and write commands.*⁸ The main challenge with PIkit payload is determining the attack (or the corresponding victim) address region to carry out the malicious activity.

5.1 Bash Shell Credential Object Attack

In the operating system, a process is represented by a process control block (PCB) data structure in the privileged memory space. The process control block has critical information such as memory information, open-file lists, process contexts and priorities, etc. In particular, we exploit the credential kernel data structure which is contained within the PCB and is responsible for access controls of a process in the Linux kernel. If the attacker locates the credential data structure in the victim address region, the attacker can modify any value within the credential data structure with PIkit. In this work, we modify the UID or the EUID of a bash shell process to achieve root privilege escalation. An overview of the malicious activity is shown in Figure 12. We demonstrate this attack on a 4-node AMD server described in Table 2.

5.1.1 Scanning the Fingerprint

In this attack, we assume the attacker uses a common user-level application, *Bash Shell*, to obtain root privilege. After the PIkit is installed on the attack node, the attacker starts the bash shell on the *victim* node and attempt to modify the credential data structure for privi-

⁸Pseudo-code for the malicious payload is shown in Appendix for the three different malicious activities described in this section.

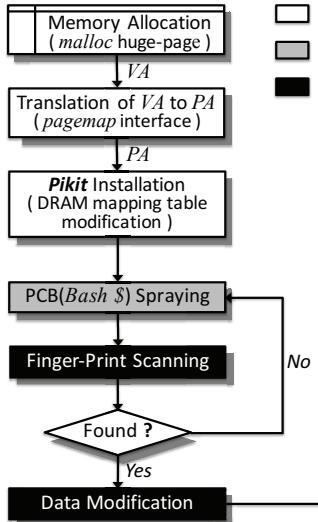

Figure 12: High-level overview of the attack with PIkit for privilege escalation.

lege escalation. One challenge before obtaining privilege escalation is determining the actual address of the PCB (or in particular, the credential data structure) of the bash shell on the victim node. In order to determine the memory location, we use the fingerprint of the credential data structure to identify the proper starting address. As shown in Figure 13, the credential data structure consists of multiple integer variables and pointers which contain 64 bits addresses. Since the bash shell user-level process is owned by the attacker, the attacker knows the user-/group ID of the process and can use the consecutive user and group IDs (e.g., UID, GUID, ..., FSGID), as shown in Figure 13 ① as these variables often have the same values.

To increase the accuracy of the fingerprint, additional pointer information within the credential data structures can also be used. Since most of the x86-64 Linux systems use the specific virtual address ranges for the kernel objects based on the kernel virtual address map [29] (e.g., 0xffff880000000000 – 0xffffc7ffffffffff for the direct mapping), the pointers shown in Figure 13 ② should have virtual addresses that are within this range. This approach is similar to what was used in prior work [46] that used virtual address characteristic to find the process control block used by Window operating system in dumped memory. In addition, some addresses of different variables used in kernel space are publicly available even in the user-level space, including the *Symbol Lookup Table* ('/boot/System.map') [32]. In particular, the virtual address of '*user_ns*', shown in Figure 13 ③, can be found in the *Symbol Lookup Table* which is determined at kernel compile time and can be used as part of the fingerprint.

Based on the three types of information described above, a fingerprint for the credential kernel data struc-

```

struct cred {
    ...
    uid_t      uid;          /* real UID of the task */
    gid_t      gid;          /* real GID of the task */
    uid_t      suid;         /* saved UID of the task */
    gid_t      sgid;         /* saved GID of the task */
    uid_t      euid;         /* effective UID of the task */
    gid_t      egid;         /* effective GID of the task */
    uid_t      fsuid;        /* UID for VFS ops */
    gid_t      fsgid;        /* GID for VFS ops */
};

struct key *thread_keyring; /* keyring private to this thread */
struct key *request_key_auth; /* assumed request_key authority */
struct thread_group_cred *tgcrcd; /* thread-group shared credentials */
...
struct user_namespace *user_ns; /* cached user->user_ns */
...

```

Figure 13: The credential kernel data structure in the Linux kernel 3.6.0 and the fingerprint that we exploit in this work, with the fingerprint highlighted with a rectangle.

ture can be used to determine the location of the credential data structure. The attacker from the attack node can issue read operations for the attack address region – determined by the allocated memory region and the modified DRAM address mapping table on the attack node as described in Section 4 – and begin the fingerprint scanning. The read requests will be routed to the victim node and the data in memory will be returned to the attack node where it will be compared against the fingerprint. If there is a match, the starting address of the credential data structure is found and the attacker can modify the data. If no match is found, the credential data structure of the bash shell is not found on the victim address region – thus, the attacker needs to stop the current bash shell process and restart the bash shell on the victim node, and repeat the fingerprint scanning.

Note that the attacker does not need to know the starting *virtual* address of the kernel data structure on the victim node. In fact, the appropriate *physical* address within the victim address region does not need to be known as well. Only the *corresponding* address on the attack node needs to be determined from the fingerprint scanning and the attack (or the modification of the data) is done based on the physical address of the attack node and the corresponding virtual address within the attack node is used in the actual data modification.

5.1.2 Modifying the Data

Once the corresponding address of the credential data structure is determined from the scanning, the offset within the data structure can be easily determined based on the credential data structure definition (e.g., Figure 13) and the different variables within the data structures can be easily modified with PIkit. Thus, the root privilege can be obtained by modifying either the *euid* (Effective User ID) or the *uid* (User ID) field within the credential data structure to a value of 0 (instead of the original value) as the *uid* of 0 specifies the root user. In order to overwrite this variable, a memory write instruction in assembly language can be used by the attacker to obtain the root privilege – e.g.,

```
movnti $0, (Virtual Address)
```

where the virtual address is the address determined from

```
[smith@server ~]$ id
uid=500(smith) gid=500(smith) groups=500(smith) context=unconfined_u:u
[smith@server ~]$ id
uid=500(smith) gid=500(smith) euid=0(root) egid=0(root) groups=0(root)
ined_t:s0-s0:c0.c1023
```

	<pre>union mhead { bits64_t mh_align; /* 8 */ struct { char mi_alloc; /* ISALLOC or ISFREE */ /* 1 */ ① char mi_index; /* index in nextfl */ /* 1 */ u_bits16_t mi_magic2; /* should be == MAGIC2 */ /* 2 */ ② u_bits32_t mi_nbytes; /* # of bytes allocated */ /* 4 */ ③ } minfo; };</pre>

Figure 15: Keyboard buffer data structure in the bash 4.3 and the fingerprint that we exploit in this work, with the fingerprint highlighted with a rectangle.

scanning and PIkit routes this write instruction to the victim node. However, we used a non-temporal SSE instruction in our evaluation in order to bypass the cache within the processor. If the write occurs to the cache within the attack node, the effect of the root privilege escalation can be delayed until write-back to the memory occurs.

The result from the attack is shown in Figure 14, consisting of the ID information before and after that attack using the `id` command from of the bash shell on the victim node. The EUID of *Bash Shell* in the victim node is modified to root user and thus, root privilege escalation is achieved.

5.1.3 Spraying the Process Control Block

As described earlier, the attack address region is mapped to some victim address region on the victim node through PIkit. As a result, all memory accesses to the attack address region on the attack node are constrained to some victim address region based on the DRAM physical mapping which is not known. As a result, if a user-level application (i.e., bash shell) executing on the victim node is not placed in the victim address region, an attacker can not access the kernel objects of the process. To increase the probability that the credential data structure can be found, the PCB can be sprayed across the victim node by executing multiple bash shells on the victim node. This increases the probability that one of the processes (and the corresponding PCB) is placed within the victim address region and reduces the amount of time it takes to achieve privilege escalation.

5.2 Bash Keyboard Buffer Attack

In this section, we describe how PIkit can be exploited to carry out an information leakage attack on another user’s bash shell and perform a *bash keyboard buffer monitoring* attack. Since no data modification is required, this attack can be classified as a read-only attack. When a

Table 3: Dell PE R620 server using in our evaluation.

user types any word on their own shell prompt, all characters are stored in a bash keyboard buffer in the memory unencrypted.

In the Bash shell (v4.3), the bash keyboard buffer is represented by a data structure referred to as `mhead`, as shown in Figure 15. Similar to the bash shell credential object attack described earlier, a fingerprint is necessary to detect this data structure in memory. For the fingerprint of the bash keyboard buffer, we use three unique values as the fingerprint based on the `mhead` data structure. The character variable (Figure 15①) has a unique 8 bits value (e.g., either 0x7F when allocated or 0x54 when freed). In addition, the 16-bit variable (Figure 15②) is always a predefined magic number (0x5555) and the 32-bit variable (Figure 15③) is always 0x100 that refers to the size of the buffer.

Based on the fingerprint, after PIkit is installed, an attacker can search for the fingerprint to gather information from victim users’ shell prompt, including potentially password information since data in the keyboard buffer is unencrypted. To evaluate this attack, we use the system described in Table 3 and assume a SSH server where multiple users use bash shell prompts from remote connections. Multiple remote SSH connections are made on the victim node and for each shell, different prompt inputs are used to evaluate the bash keyboard buffer attack.

By scanning for the fingerprint on the victim address region, we were able to monitor the bash keyboard buffer of other users. Different examples are shown in Figure 16 – Figure 16① shows a user typing in their password while Figure 16③ show other commands being typed by another user. In comparison, Figure 16② shows a keyboard buffer for another user that does not contain any content. Thus, with the buffer monitoring with PIkit installed, the dynamic information from other users’ keyboard input can be leaked.

5.3 Shared Library Attack

The attack described earlier in this section required both heap spraying and fingerprint scanning to obtain privi-

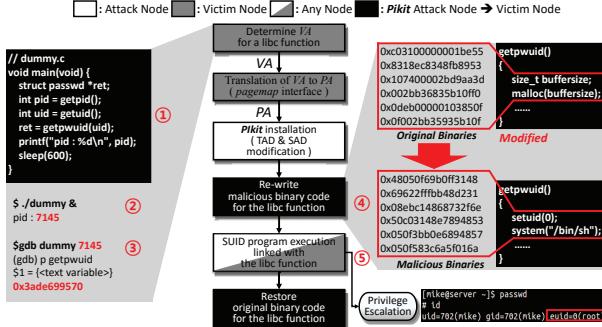

Figure 17: Shared library (libc) Attack with PIkit.

lege escalation. While this approach was successful, the attack can be time consuming because of the amount of time to scan the memory and attack reliability can become an issue since if the heap spraying does not fall within the victim memory region as the attack process needs to be repeated. To increase the attack reliability with PIkit, we take advantage of the target address decoder (TAD) structure available in the Intel Sandybridge architecture that provides the ability to “fix” the victim memory address region based on the attack memory address region. This approach is useful if the victim address region contains information that can be maliciously modified at a fixed physical memory location and does not change over time.

In this section, we take advantage of shared libraries that are often loaded into user memory space at single physical location and shared by different users. Once the shared library is initially loaded, the physical address of the library will likely not change. A commonly used shared library is `libc` and in this section, we exploit PIkit to overwrite existing functions in the `libc` with a malicious code to obtain privilege escalation. No fingerprint scanning or heap spraying is required and results in a highly reliable attack.

An overview of the `libc` attack is shown in Figure 17. To first obtain the virtual address of the `libc` shared library, an attacker can write a simple attack program (Figure 17①) which links `libc` dynamically. By executing a function within `libc` (e.g., `getpwuid()`) in the attack program, the `libc` library is dynamically linked. After obtaining the process ID for the attack program that loaded the shared library (Figure 17②), we use a debugger (e.g., `gdb`) on the running process to determine the virtual address of the `getpwuid()` function in the shared library (Figure 17③). The physical address corresponding to the virtual address of the `libc` library can be determined through the `/proc/pid/pagemap` interface and PIkit can be installed as described earlier in Section 4.5. Since the target victim address (i.e., `libc` function code location) is known, we modify the TAD structure offset accordingly, based on the attack address region obtained with PIkit.

After PIkit is installed, the attacker can re-write the runtime code loaded in the memory with user-level memory operation (Figure 17④). In our example attack, the first 48 bytes of `getpwuid()` function is re-written with malicious binary code that executes shell with root privilege. Even if the shared library is located in non-writable memory regions, PIkit bypasses any OS permission check ($W \oplus X^9$ based implementations [3, 52, 34]) and write the malicious code to the physical DRAM directly. The modified code executes `setuid(0)` to obtain root access but this does not work with user-level privilege and requires root access. However, the `passwd` Linux program has SUID (Set owner User ID) permission and is linked with `getpwuid()` function at runtime, the execution enables the malicious binary code to escalate the user privilege to the root (Figure 17⑤). Once privilege escalation is obtained, the attacker can restore the original binary of `getpwuid()` function to prevent the execution of the malicious code for other users that executes `getpwuid()`. While `getpwuid()` function for the `libc` was used to demonstrate this attack, other seldomly used library functions can be used or the malicious code can be modified to enable root shell only for specific user ID.

6 Discussion

In this section, we provide discussion on how PIkit can be potentially exploited for other types of attack, possible solutions both in software and hardware, as well as some limitations of PIkit.

6.1 VM Escape Attack

VM (virtual machine) escape is defined as enabling a VM to interact with the hypervisor directly and/or access other VMs running on the same host [30, 55]. If PIkit is installed on a multi-socket server that supports VMs, we expect that VM escape attack can be carried out. However, there are two challenges to implement VM escape with PIkit – huge pages and virtual address translation. PIkit exploited the availability of huge pages in modern OS to define the attack address region. Modern virtualization hardware technologies such as Intel VT-d support 1 GB huge pages [43] and hypervisors such as KVM, Xen and VMware also support 1GB huge page for guest VMs. We evaluated the VM escape attack possibility with Xen 4.4 but the hypervisor underneath the guest OS implemented the huge pages as a collection of smaller pages (e.g., 2 MB pages), likely because of implementation complexity. However, there is no fundamental reason why the hypervisor cannot support 1 GB

⁹A memory page must never be writable and executable at the same time.

Algorithm 1: PIkit monitor to detect modification to the DRAM address mapping table.

```

    |   address mapping table
    |   B  $\leftarrow$  Current_address_ranges
    | if A  $\neq$  B then
    |   | PIkit detected
  return

```

huge pages.¹⁰ Another challenge is that address translation needs to be done twice to properly install PIkit – from the guest virtual address (gVA) to the guest physical address (gPA) within the VM and then, another translation to the machine physical address. While */proc/pid/pagemap* interface can be used for the translation from a gVA to a gPA for the VM local OS system, similar to the PIkit implementation described earlier, the hypervisor is responsible for another translation from gPA to machine PA. The hypervisor likely maintains a separate table/data structure for this translation and this needs to be reverse engineered to implement VM escape.

6.2 Possible Solutions

Possible solutions to PIkit can be classified as either a software-based or a hardware-based solution. The actual solution to PIkit is highly dependent upon the manufacturer of the hardware (e.g., Intel, AMD) as well as the system software used.

6.2.1 Exploit Existing Features

While evaluating PIkit on different systems, some of the recent AMD systems were not vulnerable to PIkit. To the best of our knowledge, the vulnerability was not removed for security reasons but removed for power saving implementation. C6 state is an ACPI defined CPU power saving state where the CPU is put in sleep mode and all CPU contexts are saved. In some AMD implementations, when the CPU enters the C6 state, the processor context is saved into a pre-defined region of the main memory. To avoid any possible corruption of the processor contexts that are saved, the AMD systems implement LockDramCfg option where some memory system related configurations cannot be modified, including the DRAM address mapping table [7]. However, the

¹⁰A very recent version of Xen (v 4.6) actually has support for 1 GB huge pages.

Description	Ratio (%)
SPD access period (I/O bound)	99.975 %
DRAM size calc period (CPU bound)	0.003 %
DRAM table access period (I/O bound)	0.019 %
Table Comparison period (CPU bound)	0.003 %

Table 4: Breakdown of CPU cycles ratio for the PIkit monitor. BIOS can disable the C6 state for some of these systems – which would enable PIkit to be installed. A simple solution for PIkit on such AMD systems is to always enable LockDramCfg to prevent PIkit from being installed. For the Intel systems, C6 power state is supported but the processor contexts are saved to the last level cache (and not the memory) to provide faster context switch – thus, to the best of our knowledge, similar LockDramCfg feature is not readily available in Intel x86 CPUs.

6.2.2 Software-based Solutions

Prior rootkit monitors can be extended to detect the presence of PIkit. The monitor continuously compares the value of the current DRAM address mapping table with the “correct” DRAM mapping table value – where the correct value is determined similar to how the DRAM mapping table is initialized by the firmware at boot time. Thus, if we assume the software monitor is protected with a secure platform [8, 9], the solution to detect PIkit can also be protected.

We implemented the PIkit monitor as a Linux kernel thread and we evaluate its performance overhead. High-level description of PIkit monitor is shown in Algorithm 1. We used the PARSEC 3.0 [12] and evaluated workloads with varying MPKI (misses per kilo-instructions), using the system described earlier in Table 2. To measure overall system performance, we run each workload with the number of threads equal to the number of physical cores in the system. Based on Linux kernel 3.6.0, we implemented the rootkit monitor as a loadable kernel module to avoid kernel code modification and re-compilation. The execution time with PIkit monitor is normalized to the baseline without the monitor and the performance overhead from the software is negligible as there is less than 2% impact on overall performance (Figure 18).

The analysis of the PIkit monitor overhead is shown in Table 4. The two CPU computation periods (e.g., DRAM size calculation and comparison) take only 0.006% of the total PIkit monitor execution time. In comparison, the other two I/O bound periods (e.g., SPD and PCI address access) occupy 99% of the monitor execution time since these accesses have long latency – resulting in the kernel thread waiting on the I/O and mostly experience uninterruptible Sleep state. Thus, the PIkit monitor and software solution has minimal impact on performance.

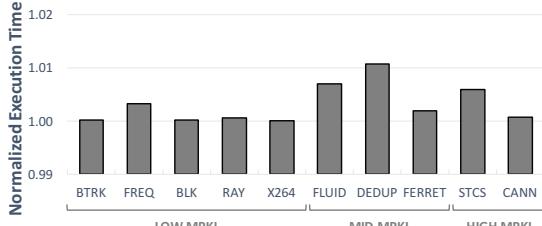

Figure 18: Performance overhead for PIkit monitor

6.2.3 Hardware-based Solutions

PIkit can be prevented with minimal hardware modifications. One hardware solution is to restrict the usage of the DRAM address mapping table entries used in multi-socket servers, based on the number of nodes in the system. If the hardware restricts the number of entries used to equal the number of nodes in the system, PIkit can be minimized. This approach does not completely remove the possibility of the PIkit since the attacker could use the entire local node’s memory as attack address region. However, unless the attacker is the only user on the local node, this can cause non-deterministic behavior. If the number of entries is restricted, the attacker can also modify the DRAM address mapping where only small region is specified as the attack address region but the remaining address range of the local node would not be mapped in the table. As a result, if any memory access occurs to an unmapped address region, the system will likely crash.

Another possible hardware solution is to design the DRAM address mapping table entries as write-once memory-mapped registers such that the DRAM mapping table can not be modified after it is initially written. A block diagram of such write-once register is shown in Figure 19 – after a write is done, the write enable (WE) to the register will be disabled and no further writes can be done to the registers unless system reset is asserted. This approach avoids any possibility of the PIkit attack since the DRAM address mapping table cannot be modified after it is initialized; however, this removes any flexibility in the system if CPU hotplug [38] or memory hotplug [27] is supported. If the system supports hotplug where the DRAM (or CPU) can be added or removed while the system is running, the DRAM address mapping table needs to be modified after it is initialized to reflect the change in the memory capacity. This would require a minor change to the hardware (i.e., OR’ing the RESET signal with another signal that detects a hotplug event). However, this can also open up other attack opportunities if the attacker has physical access to the memory modules – for example, doing a hotplug creates an opportunity to modify the DRAM address mapping table and install the PIkit.

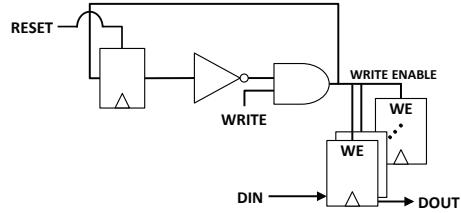

Figure 19: A PIkit hardware solution by creating a write-once register for the DRAM address mapping table.

6.3 Limitations

Memory mapping granularity: As described earlier in Section 4.2, there is a granularity (or the resolution) of the attack memory address region that can be specified with the DRAM address mapping table entries. In the AMD Opteron 6128 system, the smallest amount of memory address range that can be used as the attack address region is 16 MB. For the Intel Xeon E5-2650 (Sandybridge), the lower 26 bits are not specified and the granularity is 64 MBs. Thus, the granularity specifies the lower limit on the smallest attack address region that can be specified. This can be problematic if only normal page size is supported – i.e., with memory page size of 2 MBs, the attacker would require obtaining 8 *physical* pages to cover the 16 MBs attack region. If the entire attack region is not obtained by the attacker, other users (and programs) will access the victim address region and can cause unknown behaviors. However, huge pages that are available in modern OS can overcome this limitation.

DRAM coverage: One challenge of PIkit is the unknown DRAM physical mapping when an attack address is sent to the victim node. The details of how the DRAM physical address is mapped to the DRAM (i.e., row, column, channel, etc.) is vendor-specific. Although these details are often described in the specifications, the PIkit results in an unintended address arriving at the victim node memory system and it is not clear how the physical address bits are interpreted by the DRAM. For example, in the AMD Opteron 6128 system, the memory controller (or MCT) consists of two DRAM controllers (DCT0 and DCT1) where each DCT is responsible for half of the DRAM main memory connected to that particular node. When the attack node ID was *smaller* than the ID of the victim node (i.e., node 1 attacking node 2), only DCT0 address range could be accessed. However, by attacking node 2 from node 3, we discovered that DCT1 range can be accessed. Another limitation was that for some memory accesses, multiple attack addresses can map to the *same* victim address but this is a fundamental limitation of our proposed PIkit on the AMD system. In comparison, for the Intel Xeon E5-2650 (Sandybridge) server, the DRAM coverage issue was significantly minimized as there was an 1:1 memory mapping between the attack and the victim memory address region through the TAD structure. However, it is

not clear if this can be generalized to other Intel-based servers.

7 Conclusion

In this work, we described a new type of rootkit where the vulnerable hardware feature enables malicious activities to be carried out with only user-level code or payload. In particular, we presented PIkit – a processor-interconnect rootkit that enables an attacker to modify a packet’s destination and access victim’s memory region without proper permission. We described the design and challenges in implementing PIkit across both AMD and Intel x86 multi-socket servers. Once PIkit is installed, user-level codes used for malicious activities become very difficult to detect since memory accesses within the attack code appears as “normal” memory accesses to user-allocated memory. We demonstrated different malicious activities with PIkit, including bash shell credential object attack, keyboard buffer attack, and shared library attack.

Abstract

The constant-time programming discipline is an effective countermeasure against timing attacks, which can lead to complete breaks of otherwise secure systems. However, adhering to constant-time programming is hard on its own, and extremely hard under additional efficiency and legacy constraints. This makes automated verification of constant-time code an essential component for building secure software.

We propose a novel approach for verifying constant-time security of real-world code. Our approach is able to validate implementations that locally and intentionally violate the constant-time policy, when such violations are benign and leak no more information than the public outputs of the computation. Such implementations, which are used in cryptographic libraries to obtain important speedups or to comply with legacy APIs, would be declared insecure by all prior solutions.

We implement our approach in a publicly available, cross-platform, and fully automated prototype, *ct-verif*, that leverages the *SMACK* and *Boogie* tools and verifies optimized *LLVM* implementations. We present verification results obtained over a wide range of constant-time components from the *NaCl*, *OpenSSL*, *FourQ* and other off-the-shelf libraries. The diversity and scale of our examples, as well as the fact that we deal with top-level APIs rather than being limited to low-level leaf functions, distinguishes *ct-verif* from prior tools.

Our approach is based on a simple reduction of constant-time security of a program P to safety of a product program Q that simulates two executions of P . We formalize and verify the reduction for a core high-level language using the *Coq* proof assistant.

1 Introduction

Timing attacks pose a serious threat to otherwise secure software systems. Such attacks can be mounted by measuring the execution time of an implementation directly

in the execution platform [23] or by interacting remotely with the implementation through a network. Notable examples of the latter include Brumley and Boneh’s key recovery attacks against *OpenSSL*’s implementation of the RSA decryption operation [15]; and the Canvel et al. [16] and Lucky 13 [4] timing-based padding-oracle attacks, that recover application data from SSL/TLS connections [38]. A different class of timing attacks exploit side-effects of cache-collisions; here the attacker infers memory-access patterns of the target program — which may depend on secret data — from the memory latency correlation created by cache sharing between processes hosted on the same machine [11, 31]. It has been demonstrated in practice that these attacks allow the recovery of secret key material, such as complete AES keys [21].

As a countermeasure, many security practitioners mitigate vulnerability by adopting so-called *constant-time* programming disciplines. A common principle of such disciplines governs programs’ control-flow paths in order to protect against attacks based on measuring execution time and branch-prediction attacks, requiring that paths do not depend on program secrets. On its own, this characterization is roughly equivalent to security in the program counter model [29] in which program counter values do not depend on program secrets. Stronger constant-time policies also govern programs’ memory-access patterns in order to protect against cache-timing attacks, requiring that accessed memory addresses do not depend on program secrets. Further refinements govern the operands of program operations, e.g., requiring that inputs to certain operations do not depend on program secrets, as the execution time of some machine instructions, notably integer division and floating point operations, may depend on the values of their operands.

Although constant-time security policies are the most effective and widely-used software-based countermeasures against timing attacks [11, 25, 20], writing constant-time implementations can be difficult. Indeed, doing so requires the use of low-level programming languages or

compiler knowledge, and forces developers to deviate from conventional programming practices. For instance, the program `if b then x := v1 else x := v2` may be replaced with the less conventional `x := b * v1 + (1 - b) * v2`. Furthermore, the observable properties of a program execution are generally not evident from its source code, e.g., due to optimizations made by compilers or due to platform-specific behaviours.

This raises the question of how to validate constant-time implementations. A recently disclosed timing leak in OpenSSL’s DSA signing [19] procedure demonstrates that writing constant-time code is complex and requires some form of validation. The recent case of Amazon’s s2n library also demonstrates that the deployment of less rigid timing countermeasures is extremely hard to validate: soon after its release, two patches¹ were issued for protection against timing attacks [3, 5], the second of which exploits a timing-related vulnerability introduced when fixing the first. These vulnerabilities eluded both extensive code review and testing, suggesting that standard software validation processes are an inadequate defense against timing vulnerabilities, and that more rigorous analysis techniques are necessary.

In this work, we develop a unifying formal foundation for constant-time programming policies, along with a formal and fully automated verification technique. Our formalism is parameterized by a flexible leakage model that captures the various constant-time policies used in practice, including path-based, address-based, and operand-based characterizations, wherein program paths, accessed memory addresses, and operand sizes, respectively, are independent of program secrets. Importantly, our formalism is precise with respect to the characterization of program secrets, distinguishing not only between public and private input values, but also between private and publicly observable output values. While this distinction poses technical and theoretical challenges, constant-time implementations in cryptographic libraries like OpenSSL include optimizations for which paths, addresses, and operands are contingent not only on public input values, but also on publicly observable output values. Considering only input values as non-secret information would thus incorrectly characterize those implementations as non-constant-time.

We demonstrate the practicality of our verification technique by developing a prototype, `ct-verif`, and evaluating it on a comprehensive set of case studies collected from various off-the-shelf libraries such as OpenSSL [25], NaCl [13], FourQlib [17] and curve25519-donna.² These examples include a diverse set of constant-time algorithms for fixed-point arithmetic, elliptic curve operations, and symmetric and public-key cryptography. Apart from in-

dicating which inputs and outputs should be considered public, the verification of our examples does not require user intervention, can handle existing (complete and non-modified) implementations, and is fully automated.

One strength of our verification technique is that it is agnostic as to the representation of programs and could be performed on source code, intermediate representations, or machine code. From a theoretical point of view, our approach to verifying constant-time policies is a sound and complete reduction of the security of a program P to the assertion-safety of a program Q , meaning that P is constant-time (w.r.t. the chosen policy) if and only if Q is assertion-safe. We formalize and verify the method for a core high-level language using the Coq proof assistant. Our reduction is inspired from prior work on self-composition [10, 37] and product programs [40, 9], and constructs Q as a product of P with itself—each execution of Q encodes two executions of P . However, our approach is unique in that it exploits the key feature of constant-time policies: program paths must be independent of program secrets. This allows a succinct construction for Q since each path of Q need only correspond to a single control path³ of P — path divergence of the two executions of P would violate constant-time. Our method is practical precisely because of this optimization: the product program Q has only as many paths as P itself, and its verification can be fully automated.

Making use of this reduction in practice raises the issue of choosing the programming language over which verification is carried out. On the one hand, to obtain a faithful correspondence with the executable program under attacker scrutiny, one wants to be as close as possible to the machine-executed assembly code. On the other hand, building robust and sustainable tools is made easier by existing robust and sustainable frameworks and infrastructure. Our `ct-verif` prototype performs verification of constant-time properties at the level of optimized LLVM assembly code, which represents a sweet spot in the design space outlined by the above requirements.

Indeed, performing verification after most optimization passes ensures that the program, which may have been written in a higher-level such as C, preserves the constant-time policy even after compiler optimizations. Further, stepping back from machine-specific assembly code to LLVM assembly essentially supports generic reasoning over *all* machine architectures—with the obvious caveat that the leakage model adopted at the LLVM level captures the leakage considered in all the practical lower-level languages and adversary models under study. This is a reasonable assumption, given the small abstraction gap between the two languages. (We further discuss the issues that may arise between LLVM and lower-level assembly

¹See pull requests #147 and #179 at github.com/awslabs/s2n.

²<https://code.google.com/p/curve25519-donna/>

³This is more subtle for programs with publicly observable outputs; see Section 4.

code when describing our prototype implementation.) Finally, our prototype and case studies justify that existing tools for LLVM are in fact sufficient for our purposes. They may also help inform the development of architecture-specific verification tools.

In summary, this work makes the following fundamental contributions, each described above:

- i. a unifying formal foundation for constant-time programming policies used in practice,
- ii. a sound and complete reduction-based approach to verifying constant-time programming policies, verified in Coq, and
- iii. a publicly available, cross-platform, and fully automated prototype implementing this technique on LLVM code, ct-verif, based on SMACK,
- iv. extensive case studies demonstrating the practical effectiveness of our approach on LLVM code, and supporting discussions on the wider applicability of the technique.

We begin in Section 2 by surveying constant-time programming policies. Then in Section 3 we develop a notion of constant-time security parameterized over leakage models, and in Section 4 we describe our reduction from constant-time security to assertion safety on product programs. Section 5 describes our implementation of a verifier for constant-time leveraging this reduction, and in Section 6 we study the verification of actual cryptographic implementations using our method. We discuss related work in Section 7, and conclude in Section 8.

2 Constant-Time Implementations

We now explain the different flavors of constant-time security policies and programming disciplines that enforce them, using small examples of problematic code that arise repeatedly in cryptographic implementations. Consider first the C function of Figure 1, that copies a sub-array of length `sub_len`, starting at index `l_idx`, from array `in` to array `out`. Here, `len` represents the length of array `in`.

```

1 void copy_subarray(uint8 *out, const uint8 *in,
2                    uint32 len, uint32 l_idx, uint32 sub_len) {
3     uint32 i, j;
4     for(i=0; j<0; i<len; i++) {
5         if (i >= l_idx) && (i < l_idx + sub_len) {
6             out[j] = in[i]; j++;
7         }
8     }

```

Figure 1: Sub-array copy: `l_idx` is leaked by PC.

Suppose now that the starting addresses and lengths of both arrays are public. What we mean by this is that, the user/caller of this function is willing to accept a contract expressed over the calling interface, whereby the starting addresses and lengths of both arrays may be leaked to an

attacker, whereas the value of the `l_idx` variable and the array contents must not. Then, although the overall execution time of this function may seem roughly constant because the loop is executed a number of times that can be inferred from a public input, it might still leak sensitive information via the control flow. Indeed, due to the `if` condition in line 4, an attacker that is able to obtain a program-counter trace would be able to infer the value of `l_idx`. This could open the way to timing attacks based on execution time measurements, such as the Canvel et al. [16] and Lucky 13 [4] attacks, or to branch-prediction attacks in which a co-located spy process measures the latency introduced by the branch-prediction unit in order to infer the control flow of the target program [1]. An alternative implementation that fixes this problem is shown in Figure 2.

```

1 uint32 ct_lt(uint32 a, uint32 b) {
2     uint32 c = a ^ ((a ^ b) | ((a - b) ^ b));
3     return (0 - (c >> (sizeof(c) * 8 - 1)));
4 }
5
6 void cp_copy_subarray(uint8 *out, const uint8 *in,
7                       uint32 len, uint32 l_idx, uint32 sub_len) {
8     uint32 i, j, in_range;
9     for(i=0; i<sub_len; i++) out[i]=0;
10    for(i=0, j=0; i<len; i++) {
11        in_range = 0;
12        in_range |= ~ct_lt(i, l_idx);
13        in_range &= ct_lt(i, l_idx+sub_len);
14        out[j] |= in[i] & in_range;
15        j = j + (in_range % 2);
16    }

```

Figure 2: Sub-array copy: constant control flow but `l_idx` is leaked by memory access address trace.

Observe that the control flow of this function is now totally independent of `l_idx`, which means that it is constant for fixed values of all public parameters. However, this implementation allows a different type of leakage that could reveal `l_idx` to a stronger class of timing adversaries. Indeed, the memory accesses in line 13 would allow an attacker with access to the full trace of memory addresses accessed by the program to infer the value of `l_idx`—note that the sequence of `j` values will repeat at 0 until `l_idx` is reached, and then increase. This leakage could be exploited via cache-timing attacks [11, 31], in which an attacker controlling a spy process co-located with this program (and hence sharing the same cache) would measure its own memory access times and try to infer sensitive data leaked to accessed addresses from cache hit/miss patterns.

Finally, the program above also includes an additional potential leakage source in line 14. Here, the value of `j` is updated as a result of a DIV operation whose execution time, in some processors,⁴ may vary depending on the

⁴This is a quotation from the Intel 64 and IA-32 architectures ref-

values of its operands. This line of code might therefore allow an attacker that can take fine-grained measurements of the execution time to infer the value of `l_idx` [25]. There are two possible solutions for this problem: either ensure that the ranges of operands passed to such instructions are consistently within the same range, or use different algorithms or instructions (potentially less efficient) whose execution time does not depend on their operands. We note that, for this class of timing attackers, identifying leakage sources and defining programming disciplines that guarantee adequate mitigation becomes highly platform-specific.

An implementation of the same function that eliminates all the leakage sources we have identified above—assuming that the used native operations have operand-independent execution times—is given in Figure 3.

```

1 uint32 ct_eq(uint32 a, uint32 b) {
2     uint32 c = a ^ b;
3     uint32 d = ~c & (c - 1);
4     return (0 - (d >> (sizeof(d) * 8 - 1)));
5 }
6
7 void ct_copy_subarray(uint8 *out, const uint8 *in,
8     uint32 len, uint32 l_idx, uint32 sub_len) {
9     uint32 i, j;
10    for(i=0;i<sub_len;i++) out[i]=0;
11    for(i=0;i<len;i++) {
12        for(j=0;j<sub_len;j++) {
13            out[j] |= in[i] & ct_eq(l_idx+j, i);
14        }
15    }

```

Figure 3: Constant-time sub-array copy.

It is clear that the trade-off here is one between efficiency and security and, indeed, constant-time implementations often bring with them a performance penalty. It is therefore important to allow for relaxations of the constant-time programming disciplines when these are guaranteed *not* to compromise security. The example of Figure 4, taken from the NaCl cryptographic library [13] illustrates an important class of optimizations that arises from allowing leakage which is known to be *benign*.

This code corresponds to a common sequence of operations in secure communications: first verify that an incoming ciphertext is authentic (line 11) and, if so, recover the enclosed message (line 12) cleaning up some spurious data afterwards (line 13). The typical contract drawn at the function’s interface states that the secret inputs to the function include only the contents of the secret

erence manual: *The throughput of “DIV/IDIV r32” varies with the number of significant digits in the input EDX:EAX and/or of the quotient of the division for a given size of significant bits in the divisor r32. The throughput decreases (increasing numerical value in cycles) with increasing number of significant bits in the input EDX:EAX or the output quotient. The latency of “DIV/IDIV r32” also varies with the significant bits of the input values. For a given set of input values, the latency is about the same as the throughput in cycles.*

```

1 int crypto_secretbox_open(unsigned char *m,
2     const unsigned char *c, unsigned long long clen,
3     const unsigned char *n,
4     const unsigned char *k)
5 {
6     int i;
7     unsigned char subkey[32];
8     if (clen < 32) return -1;
9     crypto_stream_salsa20(subkey, 32, n, k);
10    if (crypto_auth_hmacsha512_verify(c, c+32, clen
11        -32, subkey) != 0) return -1;
12    crypto_stream_salsa20_xor(m, c, clen, n, k);
13    for (i = 0; i < 32; ++i) m[i] = 0;
14    return 0;
15 }

```

Figure 4: Verify-then-decrypt: verification result is publicly observable and can be leaked by control-flow.

key array. Now suppose we ensure that the functions called by this code are constant-time. Even so, this function is *not* constant-time: the result of the verification in line 11 obviously depends on the secret key value, and it is used for a conditional return statement.

The goal of this return statement is to reduce the execution time by preventing a useless decryption operation when the ciphertext is found to be invalid. Indeed, an authenticated decryption failure is typically publicly signaled by cryptographic protocols, in which case this blatant violation of the constant-time security policy would actually *not* constitute an additional security risk. Put differently, the potentially sensitive bit of information revealed by the conditional return is actually benign leakage: it is safe to leak it because it will be revealed anyway when the return value of the function is later made public. Such optimization opportunities arise whenever the target application accepts a contract at the function interface that is enriched with information about publicly observable outputs, and this information is sufficient to classify the extra leakage as benign.

The above examples motivate the remainder of the work in this paper. It is clear that checking the correct enforcement of constant-time policies is difficult. Indeed, the programming styles that need to be adopted are very particular to this domain, and degrade the readability of the code. Furthermore, these are non-functional properties that standard software development processes are not prepared to address. These facts are usually a source of criticism towards constant-time implementations. However, our results show that such criticism is largely unjustified. Indeed, our verification framework stands as proof that the strictness of constant-time policies makes them suitable for automatic verification. This is not the case for more lenient policies that are less intrusive but offer less protection (e.g., guaranteeing that the total execution time varies within a very small interval, or that the same number of calls is guaranteed to be made to a hash compression function).

In the next section we formalize constant-time security following the intuition above, as well as the foundations for a new formal verification tool that is able to automatically verify their correct enforcement over real-world cryptographic code.

3 A Formalization of Constant-Time

In order to reason about the security of the code actually executed after compilation, we develop our constant-time theory and verification approach on a generic unstructured assembly language, in Appendix A. In the present section we mirror that development on a simple high-level structured programming language for presentational clarity. We consider the language of *while programs*, enriched with arrays and assert/assume statements. Its syntax is listed in Figure 5. The metavariables x and e range over program variables and expressions, respectively. We leave the syntax of expressions unspecified, though assume they are deterministic, side-effect free, and that array expressions are non-nested.

$$\begin{aligned} p ::= & \text{skip} \mid x[e_1] := e_2 \mid \text{assert } e \mid \text{assume } e \mid p_1; p_2 \\ & \mid \text{if } e \text{ then } p_1 \text{ else } p_2 \mid \text{while } e \text{ do } p \end{aligned}$$

Figure 5: The syntax of while programs.

Although this language is quite simple, it is sufficient to fully illustrate our theory and verification technique. We include arrays rather than scalar program variables to model constant-time policies which govern indexed memory accesses. We include the assert and assume statements to simplify our reduction from the security of a given program to the assertion-safety of another. Figure 6 lists the semantics of while programs, which is standard.

$$\begin{array}{c} s' = s[\langle x, s(e_1) \rangle \mapsto s(e_2)] \quad s' = s \text{ if } s(e) \text{ else } \perp \\ \frac{}{\langle s, x[e_1] := e_2 \rangle \rightarrow \langle s', \text{skip} \rangle} \quad \frac{}{\langle s, \text{assert } e \rangle \rightarrow \langle s', \text{skip} \rangle} \\ \frac{s(e) = \text{true}}{\langle s, \text{assume } e \rangle \rightarrow \langle s, \text{skip} \rangle} \quad \frac{\langle s, p_1 \rangle \rightarrow \langle s', p'_1 \rangle}{\langle s, p_1; p_2 \rangle \rightarrow \langle s', p'_1; p_2 \rangle} \\ \frac{}{\langle s, \text{skip}; p \rangle \rightarrow \langle s, p \rangle} \quad \frac{}{\langle s, \text{if } e \text{ then } p_1 \text{ else } p_2 \rangle \rightarrow \langle s, p_i \rangle} \\ \frac{p' = (p; \text{while } e \text{ do } p) \text{ if } s(e) \text{ else skip}}{\langle s, \text{while } e \text{ do } p \rangle \rightarrow \langle s, p' \rangle} \end{array}$$

Figure 6: The operational semantics of while programs. All rules are guarded implicitly by the predicate $s \neq \perp$, and we abbreviate the predicate $s(e) = \text{true}$ by $s(e)$.

A *state* s maps variables x and indices $i \in \mathbb{N}$ to values $s(x, i)$, and we write $s(e)$ to denote the value of expression e in state s . The distinguished *error state* \perp represents

a state from which no transition is enabled. A *configuration* $c = \langle s, p \rangle$ is a state s along with a program p to be executed, and an *execution* is a sequence $c_1 c_2 \dots c_n$ of configurations such that $c_i \rightarrow c_{i+1}$ for $0 < i < n$. The execution is *safe* unless $c_n = \langle \perp, _ \rangle$; it is *complete* if $c_n = \langle _, \text{skip} \rangle$; and it is an *execution of program p* if $c_1 = \langle _, p \rangle$. A program p is *safe* if all of its executions are safe.

A *leakage model* L maps program configurations c to *observations* $L(c)$, and extends to executions, mapping $c_1 c_2 \dots c_n$ to the *observation* $L(c_1 c_2 \dots c_n) = L(c_1) \cdot L(c_2) \dots L(c_n)$, where ϵ is the identity observation, and $L(c) \cdot \epsilon = \epsilon \cdot L(c) = L(c)$. Two executions α and β are *indistinguishable* when $L(\alpha) = L(\beta)$.

Example 1. The baseline path-based characterization of constant-time is captured by leakage models which expose the valuations of branch conditions:

$$\begin{aligned} \langle s, \text{if } e \text{ then } p_1 \text{ else } p_2 \rangle &\mapsto s(e) \\ \langle s, \text{while } e \text{ do } p \rangle &\mapsto s(e) \end{aligned}$$

In this work we assume that all leakage models include the mappings above.

Example 2. Notions of constant-time which further include memory access patterns are captured by leakage models which expose addresses accessed in load and store instructions. In our simple language of while programs, this amounts to exposing the indexes to program variables read and written at each statement. For instance, the assignment statement exposes indexes read and written (the base variables need not be leaked as they can be inferred from the control flow):

$$\langle s, x_0[e_0] := e \rangle \mapsto s(e_0) s(e_1) \dots s(e_n)$$

where $x_1[e_1], \dots, x_n[e_n]$ are the indexed variable reads in expression e (if any exist).

Example 3. Notions of constant-time which are sensitive to the size of instruction operands, e.g., the operands of division instructions, are captured by leakage models which expose the relevant leakage:

$$\langle s, x[e_1] := e_2 / e_3 \rangle \mapsto S(e_2, e_3)$$

where S is some function over the operands of the division operation, e.g., the maximum size of the two operands.

In Section 2 we have intuitively described the notion of a contract drawn at a function’s interface; the constant-time security policies are defined relatively to this contract, which somehow defines the acceptable level of (benign) leakage that can be tolerated. Formally, we capture these contracts using a notion of equivalence between initial states (for a set X_i of inputs declared to be public) and

final states (for a set X_o of outputs declared to be publicly observable), as follows.

Given a set X of program variables, two configurations $\langle s_1, _\rangle$ and $\langle s_2, _\rangle$ are *X-equivalent* when $s_1(x, i) = s_2(x, i)$ for all $x \in X$ and $i \in \mathbb{N}$. Executions $c_1 \dots c_n$ and $c'_1 \dots c'_{n'}$ are *initially X-equivalent* when c_1 and c'_1 are *X-equivalent*, and *finally X-equivalent* when c_n and $c'_{n'}$ are *X-equivalent*.

Definition 1 (Constant-Time Security). A program is secure when all of its initially X_i -equivalent and finally X_o -equivalent executions are indistinguishable.

Intuitively, constant-time security means that any two executions whose input and output values differ only with respect to secret information must leak exactly the same observations. Contrasting our definition with other information flow policies, we observe that constant-time security asks that every two complete executions starting with X_i -equivalent states and ending with X_o -equivalent final states must be indistinguishable, while termination-insensitive non-interference asks that every two complete executions starting with X_i -equivalent states must end with X_o -equivalent final states. This makes the constant-time policies we consider distinct from the baseline notions of non-interference studied in language-based security. However, our policies can be understood as a specialized form of delimited release [34], whereby *escape hatches* are used to specify an upper bound on the information that is allowed to be declassified. Our notion of security is indeed a restriction of delimited release where escape hatches—our public output annotations—may occur only in the final state.

4 Reducing Security to Safety

The construction of the output-insensitive product of a program (with itself) is shown in Figure 7. It begins by assuming the equality of each public input $x \in X_i$ with its renamed copy \hat{x} , then recursively applies a guard and instrumentation to each subprogram. Guards assert the equality of leakage functions for each subprogram p and its variable-renaming \hat{p} .

```

product(p)    assume x=ŷ for x ∈ X_i;
               together(p)
together(p)   guard(p);
               instrument[λ p.(p; ũ), together](p)
guard(p)      assert L(p)=L(ũ)

```

Figure 7: Output-insensitive product construction.

Instrumentation preserves the control structure of the original program. Our construction uses the program instrumentation given in Figure 8, which is parameterized by functions α and β transforming assignments and

subprograms, respectively. In our constructions, α is either the identity function or else duplicates assignments over renamed variables, and β applies instrumentation recursively with various additional logics.

	instrument[α, β]($_\right)$
—	
skip	skip
$x[e_1] := e_2$	$\alpha(x[e_1] := e_2)$
assert e	assert e
assume e	assume e
$p_1; p_2$	$\beta(p_1); \beta(p_2)$
if e then p_1 else p_2	if e then $\beta(p_1)$ else $\beta(p_2)$
while e do p	while e do $\beta(p)$

Figure 8: Instrumentation for product construction.

Our first result states that this construction provides a reduction from constant-time security to safety that is sound for all safe input programs (i.e., a security verdict is always correct) and complete for programs where information about public outputs is not taken into consideration in the security analysis (i.e., an insecurity verdict is always correct).

Theorem 1. A safe program with (respectively, without) public outputs is secure if (respectively, iff) its output-insensitive product is safe.

Proof. First, note that program semantics is deterministic, i.e., for any two complete executions of a program p from the same state s_0 to states s_1 and s_2 emitting observations $L(\vec{c}_1)$ and $L(\vec{c}_2)$, respectively, we have $s_1 = s_2$ and $L(\vec{c}_1) = L(\vec{c}_2)$. The product construction dictates that an execution of $\text{product}(p)$ from state $s \uplus \hat{s}$ reaches state $s' \uplus \hat{s}'$ if and only if the two corresponding executions of p leak the same observation sequence, from s to s' and from \hat{s} to \hat{s}' , where \hat{s} is the variable-renaming of s . \square

In order to deal with program paths which depend on public outputs, we modify the product construction, as shown in Figure 9, to record the observations along output-dependent paths in history variables and assert their equality when paths merge. The output-sensitive product begins and ends by assuming the equality of public inputs and outputs, respectively, with their renamed copies, and finally asserts that the observations made across both simulated executions are identical. Besides delaying the assertion of observational indistinguishability until the end of execution, when outputs are known to be publicly observable, this construction allows paths to diverge at branches which depend on these outputs, checking whether both executions alone leak the same recorded observations.

Technically, this construction therefore relies on identifying the branches, i.e., the if and while statements, whose conditions can only be declared benign when public outputs are considered. This has two key implications.

```

product( $p$ )   same_observations := true;
               assume  $x = \hat{x}$  for  $x \in X_i$ ;
               together( $p$ );
               assume  $x = \hat{x}$  for  $x \in X_o$ ;
               assert same_observations

together( $p$ ) if benign( $p$ ) then
                $h := \varepsilon$ ;  $\hat{h} := \varepsilon$ ;
               alone $_h(p)$ ;
               alone $_{\hat{h}}(\hat{p})$ ;
               same_observations &&:=  $h = \hat{h}$ 
            otherwise
               guard( $p$ );
               instrument[ $\lambda p. (p, \hat{p})$ , together]( $p$ )
guard( $p$ )   same_observations &&:=  $L(p) = L(\hat{p})$ 
alone $_h(p)$  record $_h(p)$ ;
               instrument[ $\lambda p. p$ , alone $_h$ ]( $p$ )
record $_h(p)$   $h += L(p)$ 

```

Figure 9: Output-sensitive product construction

First, it either requires a programmer to annotate which branches are benign in a public-sensitive sense, or additional automation in the verifier, e.g., to search over the space of possible annotations; in practice the burden appears quite low since very few branches will need to be annotated as being benign. Second, it requires the verifier to consider separate paths for the two simulated executions, rather than a single synchronized path. While this deteriorates to an expensive full product construction in the worst case, in practice these output-dependent branches are localized to small non-nested regions, and thus asymptotically insignificant.

Theorem 2. *A safe program is secure iff its output-sensitive product is safe with some benign-leakage annotation.*

Proof. Completeness follows from completeness of self-composition, so only soundness is interesting. Soundness follows from the fact that we record history in the variables h and \hat{h} whenever we do not assert the equality of observations on both sides. \square

Coq formalization The formal framework presented in this and the previous section has been formalized in Coq. Our formalization currently includes the output-insensitive reduction from constant-time security to safety of the product program as described in Figures 7 and 8, for the while language in Figure 5. We prove the soundness and completeness of this reduction (Theorem 1) following the intuition described in the sketch presented above. Formalization of the output-sensitive construction and the proof of Theorem 2 should not present any additional difficulty, other than a more intricate case analysis when control flow may diverge. Our Coq formalization serves two purposes: i. it rigorously captures the theoretical foundations of our approach and complements the intu-

itive description we gave above; and ii. it could serve as a template for a future formalization of the machine-level version of these same results, which underlies the implementation of our prototype and is presented in Appendices A and B. A Coq formalization of this low-level transformation could be integrated with CompCert, providing more formal guarantees on the final compiled code.

5 Implementation of a Security Verifier

Using the reduction of Section 4 we have implemented a prototype, ct-verif, which is capable of automatically verifying the compiled and optimized LLVM code resulting from compiling actual C-code implementations of several constant-time algorithms. Before discussing the verification of these codes in Section 6, here we describe our implementation and outline key issues. Our implementation and case studies are publicly available⁵ and cross-platform. ct-verif leverages the SMACK verification tool [32] to compile the annotated C source via Clang⁶ and to optimize the generated assembly code via LLVM⁷ before translating to Boogie⁸ code. We perform our reduction on the Boogie code, and apply the Boogie verifier (which performs verification using an underlying SMT⁹ logic solver) to the resulting program.

5.1 Security Annotations

We provide a simple annotation interface via the following C function declarations:

```

void public_in(smack_value_t);
void public_out(smack_value_t);
void benign_branching();

```

where `smack_value_t` values are handles to program values obtained according to the following interface

```

smack_value_t __SMACK_value();
smack_value_t __SMACK_values(void* ary,
                           unsigned count);
smack_value_t __SMACK_return_value(void);

```

and `__SMACK_value(x)` returns a handle to the value stored in program variable `x`, `__SMACK_values(ary, n)` returns a handle to an `n`-length array `ary`, and `__SMACK_return_value()` provides a handle to the procedure's return value. While our current interface does not provide handles to entire structures, non-recursive structures can still be annotated by annotating the handles to each of their (nested) fields. Figure 10 demonstrates the annotation of a decryption function for the Tiny Encryption Algorithm (TEA). The first argument `v` is a pointer to

a public ciphertext block of two 32-bit words, while the second argument `k` is a pointer to a secret key.

```

1 void decrypt_cpa_wrapper(uint32_t* v, uint32_t* k) {
2     public_in(__SMACK_value(v));
3     public_in(__SMACK_value(k));
4     public_in(__SMACK_values(v, 2));
5     decrypt(v, k);
6 }
```

Figure 10: Annotations for the TEA decryption function.

5.2 Reasoning about Memory Separation

In some cases, verification relies on establishing separation of memory objects. For instance, if the first of two adjacent objects in memory is annotated as public input, while the second is not, then a program whose branch conditions rely on memory accesses from the first object is only secure if we know that those accesses stay within the bounds of the first object. Otherwise, if those accesses might occur within the second object, then the program is insecure since the branch conditions may rely on private information.

Luckily SMACK has builtin support for reasoning about the separation of memory objects, internally leveraging an LLVM-level data-structure analysis [26] (DSA) to partition memory objects into disjoint regions. Accordingly, the generated Boogie code encodes memory as several disjoint map-type global variables rather than a single monolithic map-type global variable, which facilitates scalable verification. This usually provides sufficient separation for verifying security as well. In a few cases, DSA may lack sufficient precision. In those settings, it would be possible to annotate the source code with additional assumptions using SMACK’s `__Verifier_assume()` function. This limitation is not fundamental to our approach, but instead an artifact of design choices¹⁰ and code rot¹¹ in DSA itself.

5.3 Product Construction for Boogie Code

The Boogie intermediate verification language (IVL) is a simple imperative language with well-defined, clean, and mathematically-focused semantics which is a convenient representation for performing our reduction. Conceptually there is little difference between performing our shadow product reduction at the Boogie level as opposed to the LLVM or machine-code level since the Boogie code produced by SMACK corresponds closely to the LLVM code, which is itself similar to machine code. Indeed our machine model of Appendix A is representative. Practically however, Boogie’s minimal syntax greatly facilitates

¹⁰DSA is designed to be extremely scalable at the expense of precision, yet such extreme scalability is not necessary for our use.

¹¹See the discussion thread at <https://groups.google.com/forum/?#!topic/llvm-dev/pnU5ecuvr6c>.

our code-to-code translation. In particular, shadowing the machine state amounts to making duplicate copies of program variables. Since memory accesses are represented by accesses to map-type global variables, accessing a shadowed address space amounts to accessing the duplicate of a given map-type variable.

Our prototype models observations as in Examples 1 and 2 of Section 3, exposing the addresses used in memory accesses and the values used as branch conditions as observations. According to our construction of Section 4, we thus prefix each memory access by an assertion that the address and its shadow are equal, and prefix each branch by an assertion that the condition and its shadow are equal. Finally, for procedures with annotations, our prototype inserts assume statements on the equality of public inputs with their shadows at entry blocks.

When dealing with public outputs, we perform the output-sensitive product construction described in Section 4 adapted to an unstructured assembly language. Intuitively, our prototype delays assertions (simply by keeping track of their conjunction in a special variable) but otherwise produces the standard output-insensitive product program. It then replaces the blocks corresponding to the potentially desynchronized conditional with blocks corresponding to the output-sensitive product construction that mixes control and data product. Finally, it inserts code that saves the current assertions before the region where the control flow may diverge, and restores them afterwards, making sure to also take into account the assertions collected in between.

5.4 Scalability of the Boogie Verifier

Since secure implementations, and cryptographic primitives in particular, do not typically call recursive procedures, we instruct Boogie to inline all procedures during verification. This avoids the need for manually written procedure contracts, or for sophisticated procedure specification inference tools.

Program loops are handled by automatically computing loop invariants. This is fairly direct in our setting, since invariants are simply conjunctions of equalities between some program variables and their shadowed copies. We compute the relevant set of variables by taking the intersection of variables live at loop heads with those on which assertions inserted by our reduction depend.

5.5 Discussion

ct-verif is based on a theoretically sound and complete methodology; however, practical interpretations of its results must be analyzed with care. First, leakage models are constructed, and in our case are based on LLVM rather than machine code. Second, verification tools can

be incomplete, notably because of approximations made by sub-tasks performed during verification (for instance, data-structure analysis or invariant inference).

Therefore, it is important to evaluate ct-verif empirically, both on positive and negative examples. Our positive experimental results in the next section demonstrate that the class of constant-time programs that is validated automatically by ct-verif is significantly larger than those tackled by existing techniques and tools. Our negative examples, available from the public repository,¹² are taken from known buggy libraries (capturing the recent CacheBleed attack,¹³ in particular), and others taken to illustrate particularly tricky patterns. Again, some of these examples illustrate the value of a low-level verification tool by exhibiting compilation-related behaviours. Unsurprisingly, we found that there is little value in running our tool on code that was *not* written to be constant-time. Conversely, we found that our tool can be helpful in detecting subtle breaches in code that was written with constant-time in mind, but was still insecure, either due to subtle programming errors, or to compilation-related issues.

It remains to discuss possible sources of unsoundness that may arise from our choice of LLVM as the target for verification (rather than actual machine code). As highlighted in Section 1, this choice brings us many advantages, but it implies that our prototype does not strictly know what machine instructions will be activated and on which arguments, when the final code is actually executed. For example, our assumptions on the timing of a particular LLVM operation may not hold for the actual processor instruction that is selected to implement this operation in executable code. Nevertheless we argue that the LLVM assembly code produced just before code generation sufficiently similar to *any* target-machine’s assembly code to provide a high level of confidence. Indeed, the majority of compiler optimizations are made prior to code generation. At the point of code generation, the key difference between representations is that in LLVM assembly:

- i. some instruction/operand types may not be available on a given target machine,
- ii. there are arbitrarily-many registers, whereas any given machine would have a limited number, and
- iii. the order of instructions within basic blocks is only partially determined.

First we note that neither of these differences affects programs’ control-flow paths, and the basic-block structure of programs during code generation is generally preserved. Second, while register allocation does generally change memory-access patterns, spilled memory accesses are generally limited to the addresses of scalar stack variables, which are fully determined by control-flow paths. Thus

both path-based and address-based constant-time properties are generally preserved. Operand-based constant-time properties, however, are generally not preserved: it is quite possible that instruction selection changes the types of some instruction’s operands, implying a gap between LLVM and machine assembly regarding whether operand sizes may depend on secrets. Dealing with such sources of leakage requires architecture-specific modeling and tools, which are out of the scope of a research prototype.

6 Experimental Results

We evaluate ct-verif on a large set of examples, mostly taken from off-the-shelf cryptographic libraries, including the pervasively used OpenSSL [25] library, the NaCl [13] library, the FourQlib library [17], and curve25519-donna.¹⁴ The variety and number of cryptographic examples we have considered is unprecedented in the literature. Furthermore, our examples serve to demonstrate that ct-verif outperforms previous solutions in terms of scale (the sizes of some of our examples are orders of magnitude larger than what could be handled before), coverage (we can handle top-level public APIs, rather than low-level or leaf functions) and robustness (ct-verif is based on a technique which is not only sound, but also complete).

All execution times reported in this section were obtained on a 2.7GHz Intel i7 with 16GB of RAM. Size statistics measure the size in lines of code (loc) of the analyzed Boogie code (similar in size to the analyzed LLVM bitcode) before inlining. When presenting time measurements, all in seconds, we separate the time taken to produce the product program (annotating it with the \times symbol) from that taken to verify it: in particular, given a library, the product program can be constructed once and for all before verifying each of its entry points. ct-verif assumes that the leakage trace produced by standard library functions `memcpy` and `memset` depends only on their arguments (that is, the address and length of the objects they work on, rather than their contents). This is a mild assumption that can be easily checked for each platform. For examples that use dynamic memory allocation, such as the OpenSSL implementation of PKCS#1 padding, ct-verif enforces that `malloc` and `free` are called with secret-independent parameters and assumes that the result of `malloc` is always secret-independent in this case. In other words, we assume that the address returned by `malloc` depends only on the trace of calls to `malloc` and `free`, or that the memory allocator observes only the memory layout to make allocation decisions.¹⁵

¹²<https://github.com/imdea-software/verifying-constant-time>

¹³<https://ssrg.nicta.com.au/projects/TS/cachebleed>

¹⁴<https://code.google.com/p/curve25519-donna/>

¹⁵It may be possible to extend this to an allocator that also has access to the trace of memory accesses, since they are made public.

Example	Size	Time (x)	Time
tea	200	2.33	0.47
rlwe_sample	400	5.78	0.65
nacl_salsa20	700	5.60	1.11
nacl_chacha20	10000	8.30	1.92
nacl_sha256_block	20000	27.7	4.17
nacl_sha512_block	20000	39.49	4.29

Table 1: Verification of crypto primitives.

6.1 Cryptographic Primitives

For our first set of examples, we consider a representative set of cryptographic primitives: a standard implementation of TEA [39] (tea), an implementation of sampling in a discrete Gaussian distribution by Bos et al. [14] (rlwe_sample) and several parts of the NaCl library [13] library.

Table 1 gives the details (we include only a subset of the NaCl verification results listed as nacl_xxxx). The verification result for rlwe_sample only excludes its core random byte generator, essentially proving that this core primitive is the only possible source of leakage. In particular, if its leakage and output bytes are independent, then the implementation of the sampling operation is constant-time. Verification of the SHA-256 implementation in NaCl above refers to the compression function; the full implementation of the hash function, which simply iterates this compression function, poses a challenge to our prototype due to the action of DSA: the internal state of the function is initialized as a single memory block, that later stores both secret and public values that are accessed separately. This issue was discussed in Section 5.2, where we outlined a solution using assume statements.

6.2 TLS Record Layer

To further illustrate scalability to large code bases, we now consider problems related to the MAC-then-Encode-then-CBC-Encrypt (MEE-CBC) construction used in the TLS record layer to obtain an authenticated encryption scheme. This construction is well-understood from the perspective of provable security [24, 30], but implementations have been the source of several practical attacks on TLS via timing side-channels [16, 4].

We apply our prototype to two C implementations of the MEE-CBC decryption procedure, treating only the input ciphertext as public information. Table 2 shows the corresponding verification results. We extract the first implementation from the OpenSSL sources (version 0.9.8zg). It includes all the countermeasures against timing attacks currently implemented in the MEE-CBC component in OpenSSL as documented in [25]. We verify the parts of the code that handle MEE-CBC decryption (1K loc of C, or 10K loc in Boogie): i. decryption of the encrypted message using AES128 in CBC

Example	Time (x)	Time
mee-cbc-openssl	10.6	18.73
mee-cbc-nacl	24.64	92.56

Table 2: Verification of MEE-CBC TLS record layer.

mode; ii. removing the padding and checking its well-formedness; iii. computing the HMAC of the unpadded message, even for bad padding, and using the same number of calls to the underlying hash compression function (in this case SHA-1); and iv. comparing the transmitted MAC to the computed MAC in constant-time. Our verification does not include the SHA1 compression function and AES-128 encryption—these are implemented in assembly—and hence our result proves that the only possible leakage comes from these leaf functions. (In OpenSSL the SHA1 implementation is constant-time but AES-128 makes secret-dependent memory accesses.)

As our second example, we consider a full 800 loc (in C, 20K loc in Boogie) implementation of MEE-CBC [5], which includes the implementation of the low level primitives (taken from the NaCl library).

Our prototype is able to verify the constant-time property of both implementations—with only the initial ciphertext and memory layout marked as public. Perhaps surprisingly, our simple heuristic for loop invariants is sufficient to handle complex control-flow structures such as the one shown in Figure 11, taken from OpenSSL.

```

1 k = 0;
2 if /* low cond */ { k = /* low exp */ }
3 if (k > 0)
4 { for (i = 1; i < k / /* low var */; i++)
5   { /* i-dependent memory access */ }
6 }
7 for (i = /* low var */; i <= /* low var */; i++)
8 { /* i-dependent memory access */
9   for (j = 0; j < /* low var */; j++)
10   { if (k < /* low var */)
11     /* k-dependent memory access */
12   else if (k < /* low exp */)
13     /* k-dependent memory access */
14     k++;
15   }
16   for (j = 0; j < /* low var */; j++)
17   { /* j-dependent memory access */ }
18 }
```

Figure 11: Complex control-flow from OpenSSL.

6.3 Fixed-Point Arithmetic

Our third set of examples is taken from the libfixedtimefixedpoint library, developed by Andryesco et al. [7] to mitigate several attacks due to operand-dependent leakage in the timing of floating point operations. In the conclusion of the paper we discuss how our prototype can be extended to deal with the vulnerable code that was attacked in [7]. Here we present

Function	Size	Time
fix_eq	100	1.45
fix_cmp	500	1.44
fix_mul	2300	1.50
fix_div	1000	1.53
fix_ln	11500	2.66
fix_convert_from_int64	100	1.43
fix_sin	800	1.64
fix_exp	2200	1.62
fix_sqrt	1400	1.55
fix_pow	18000	1.42 ¹⁶

Table 3: Verification of `libfixedtimefixedpoint`.

our verification results over the library that provides an alternative secure constant-time solution

The `libfixedtimefixedpoint` library (ca. 4K loc of C or 40K loc in Boogie) implements a large number of fixed-point arithmetic operations, from comparisons and equality tests to exponentials and trigonometric functions. Core primitives are automatically generated parametrically in the size of the integer part: we verify code generated with the default parameters. As far as we know, this is the first application of verification to this floating point library.

Table 3 shows verification statistics for part of the library. We verify all arithmetic functions without any inputs marked as public, but display only some interesting data points here. We discuss the `fix_pow` function, during whose execution the code shown in Figure 12 is executed on a `frac` array that is initialized as a “0” string literal. The function in which this snippet appears is not generally constant-time, but it is always used in contexts where all indices of `frac` that are visited up to and including the particular index that might trigger a sudden loop exit at line 6 contains public (or constant) data. Thanks to our semantic characterization of constant-time policies, ct-verif successfully identifies that the leakage produced by this code is indeed benign, whereas existing type-based or taint-propagation based would mark this program as insecure.

```

1 uint64_t result = 0;
2 uint64_t extra = 0;
3
4 for(int i = 0; i < 20; i++) {
5     uint8_t digit = (frac[i] - (uint8_t)'0');
6     if (frac[i] == '\0') { break; }
7     result += ((uint64_t)digit) * pow10[i];
8     extra += ((uint64_t)digit) * pow10_extra[i];
9 }
```

Figure 12: `fix_pow` code.

¹⁶We manually provide an invariant of the form $\exists i_{\max}. 0 \leq i < i_{\max} \leq 20 \wedge \text{frac}[i_{\max}] == 0 \wedge \forall j. 0 \leq j \leq i_{\max} \Rightarrow \text{public}(\text{frac}[j])$ for the loop shown in Figure 12. Loop unrolling could also be used, since the loop is statically bounded.

Example	Size	Time (x)	Time
curve25519-donna	10000	10.18	456.97
FourQLib	-	7.87	-
eccmadd	2500	-	133.72
eccdouble	3000	-	70.67
eccnorm	3500	-	156.48
point_setup	600	-	0.99
R1_to_R2	2500	-	7.92
R5_to_R1	2000	-	1.26
R1_to_R3	2500	-	2.42
R2_to_R4	1000	-	0.93

Table 4: Verification of elliptic curve arithmetic.

6.4 Elliptic Curve Arithmetic

As a final illustrative example of the capabilities of ct-verif in handling existing source code from different sources, we consider two constant-time implementations of elliptic curve arithmetic: the `curve25519-donna` implementation by Langley,¹⁷ and the `FourQLib` library [17]. The former library provides functions for computing essential elliptic curve operations over the increasingly popular Curve25519 initially proposed by Bernstein [12], whereas the latter uses a recently proposed alternative high-performance curve. Table 4 shows the results.

For `curve25519-donna`, we verify the functional entry point, used to generate public points and shared secrets, assuming only that the initial memory layout is public.

For `FourQLib`, we verify all the core functions for point addition, doubling and normalization, as well as coordinate conversions, all under the only assumption that the addresses of the function parameters are public. ct-verif successfully detects expected dependencies of the execution time on public inputs in the point validation function `ecc_point_validate`.

6.5 Publicly Observable Outputs

We wrap up this experimental section by illustrating the flexibility of the output-sensitive product construction, and how it permits expanding the coverage of real-world crypto implementations in comparison with previous approaches. As a first example we consider an optimized version of the `mee-cbc-nacl` example. Instead of using a constant-time select and zeroing loop to return its result (as shown in Figure 13, where the return code `res` is secret-dependent and marked as public and `in_len` is a public input), the code branches on the return code as shown in Figure 14. (The rest of the code is unmodified, and therefore constant-time.)

This is similar to the motivating example that we presented in Section 2, but here the goal is to avoid the unnecessary cleanup loop at the end of the function in executions where it is not needed. Again, because the return code is made public when it is returned to the caller,

¹⁷<https://code.google.com/p/curve25519-donna/>

```

1 good = ~((res == RC_SUCCESS) - 1);
2 for(i = 0; i < in_len; i++) { out[i] &= good; }
3 *out_len &= good;

```

Figure 13: MEE-CBC decryption: constant-time.

```

1 if (res != RC_SUCCESS) {
2     for(i = 0; i < in_len; i++) { out[i] = 0; }
3     *out_len = 0;
4 }

```

Figure 14: MEE-CBC decryption: constant-time.

this control-flow dependency on secret information can be classified as benign leakage. The output-sensitive product constructed by our prototype for this example, when the displayed conditional is annotated as benign leakage, verifies in slightly less than 2 minutes. The additional computation cost of verifying this version of the program may be acceptable when compared to the performance gains in the program itself—however minor: verification costs are one off, whereas performance issues in the cryptographic library are paid per execution.

```

1 int RSA_padding_check_PKCS1_type_2(uchar *to, int
2 tlen, const uchar *from, int flen, int num)
3 {
4     int i, zero_index = 0, msg_index, mlen = -1;
5     uchar *em = NULL;
6     uint good, found_zero_byte;
7
8     if (tlen < 0 || flen < 0) return -1;
9     if (flen > num) goto err;
10    if (num < 11) goto err;
11
12    em = OPENSSL_zalloc(num);
13    if (em == NULL) return -1;
14    memcpy(em + num - flen, from, flen);
15
16    good = ct_is_zero(em[0]);
17    good &= ct_eq(em[1], 2);
18
19    found_zero_byte = 0;
20    for (i = 2; i < num; i++) {
21        uint equals0 = ct_is_zero(em[i]);
22        zero_index = ct_select_int(~found_zero_byte &
23        equals0, i, zero_index);
24        found_zero_byte |= equals0;
25
26        good &= ct_ge((uint)(zero_index), 2 + 8);
27        msg_index = zero_index + 1;
28        mlen = num - msg_index;
29        good &= ct_ge((uint)(tlen), (uint)(mlen));
30
31        /* We can't continue in constant-time because we
32         * need to copy the result and we cannot fake
33         * its length. This unavoidably leaks timing
34         * information at the API boundary. */
35        if (!good) { mlen = -1; goto err; }
36        memcpy(to, em + msg_index, mlen);
37
38    err:
39        OPENSSL_free(em);
40        return mlen;
41    }

```

Figure 15: RSA PKCS1 padding check from OpenSSL

Finally, we present in Figure 15 an RSA PKCS1.5

padding check routine extracted from OpenSSL (similar code exists in other cryptographic libraries, such as boringssl¹⁸). The developers note the most interesting feature of this code in the comment on line 30: although this function is written in the constant-time style, the higher-level application (here referred to as an API boundary) does not give this implementation enough information to continue without branching on data dependent from secret inputs (here, the contents of `from`). One way in which this could be achieved would be for the function to accept an additional argument indicating some public bound on the expected message length. The constant-time techniques described previously in this paper could then be used to ensure that the leakage depends only on this additional public parameter. However, given the constraint forced upon the implementer by the existing API, the final statements in the function must be as they are, leading to (unavoidable and hence) benign leakage. Using our techniques, this choice can be justified by declaring the message length returned by the function as being (the only) public output that is safe to leak. Note that `flen`, `tlen` and `num` are public, and hence declaring `mlen` as a public output provides sufficient information to verify the control-flow leakage in line 31, and also the accessed addresses in line 32 as being benign. Verifying the output-sensitive product program when `mlen` is marked as a public output takes under a second.¹⁹

This example shows that dealing with relaxations of the constant-time policies enabled by output-sensitive API contracts is important when considering functions that are directly accessible by the adversary, rather than internal functions meant to be wrapped. Dealing with these use cases is an important asset of our approach, and is a problem not considered by previous solutions.

7 Related Work

Product programs Product constructions are a standard tool in the algorithmic analysis of systems. Product programs can be viewed as their syntactic counterpart. Systematic approaches for defining and building product programs are considered in [9]. Three instances of product programs are most relevant to our approach: self-composition [10] and selective self-composition [37], which have been used for proving information flow security of programs, and cross-products [40], which have been used for validating the correctness of compiler optimizations. We review the three constructions below, obliterating their original purpose, and presenting them from the perspective of our work.

¹⁸<https://boringssl.googlesource.com/>

¹⁹With simple implementations of `OPENSSL_zalloc` and `OPENSSL_free` that wrap standard memory functions.

The self-composition of a program P is a program Q which executes P twice, sequentially, over disjoint copies of the state of P . Self-composition is *sound and complete*, in the sense that the set of executions of program Q is in 1-1 bijection with the set of pairs of executions of program P . However, reasoning about self-composed programs may be very difficult, as one must be able to correlate the actions of two parts of program Q which correspond to the same point of execution of the original program P .

The cross-product Q of a program P coerces the two copies of P to execute in lockstep, by inserting assert statements at each branching instruction. Cross-product is not complete for all programs, because pairs of executions of program P whose control-flow diverge result in an unsafe execution of program Q . As a consequence, one must prove that Q is safe in order to transfer verification results from Q to P . However, cross-product has a major advantage over self-composition: reasoning about cross-products is generally easier, because the two parts of program Q which correspond to the same point of execution of the original program P are adjacent.

Selective self-composition is an approach which alternates between cross-product and self-composition, according to user-provided (or inferred for some applications) annotations. Selective self-composition retains the soundness and completeness of self-composition whilst achieving the practicality of cross-product.

Our output-insensitive product construction (Figure 7) is closely related to cross-product. In particular, Theorem 1 implies that cross-products characterize constant-path programs. We emphasize that, for this purpose, the incompleteness of cross-products is not a limitation but a desirable property. On the other hand, our output-sensitive product construction (Figure 9) is closely related to selective self-composition.

Language-based analysis/mitigation of side-channels
Figure 16 summarizes the main characteristics of several tools for verifying constant-time security, according to the level at which they carry out the analysis, the technique they use, their support for public inputs and outputs, their soundness and completeness, and their usability. ct-verif is the only one to support publicly observable outputs, and the only one to be sound, theoretically complete and practical. Moreover, we argue that extending any of these tools to publicly observable outputs is hard; in particular, several of these tools exploit the fact that cryptographic programs exhibit “abnormally straight line code behavior”, and publicly observable outputs are precisely used to relax this behavior. We elaborate on these points below.

FlowTracker [33] implements a precise, flow sensitive, constant-time (static) analysis for LLVM programs. This tool takes as input C or C++ programs with security annotations and returns a positive answer or a counterexample.

Tool	Target	Analysis method	Inputs/Outputs	Sound/Complete	Usability
tis-ct	C	static	X/X	✓/X	✓(a)
ABPV [6]	C	logical	✓/X	✓/✓	X(b)
VirtualCert	x86	static	✓/X	✓/X	X(c)
FlowTracker	LLVM	static	✓/X	✓/X	✓
ctgrind	binary	dynamic	✓/X	X/X	✓
CacheAudit	binary	static	X/X	✓/X	X(d)
This work	LLVM	logical	✓/✓	✓/✓	✓

Figure 16: Comparison of different tools. Target indicates the level at which the analysis is performed. Input/Outputs classifies whether the tool supports public inputs and publicly observable outputs. Usability includes coverage and automation. (a): requires manual interpretation of dependency analysis. (b): requires interactive proofs. (c): requires code rewriting. (d): supports restricted instruction set.

FlowTracker is incomplete (i.e. rejects secure programs), and it does not consider publicly observable outputs.

VirtualCert [8] instruments the CompCert certified compiler [27] with a formally verified, flow insensitive type system for constant-time security. It takes as input a C program with security annotations and compiles it to (an abstraction of) x86 assembly, on which the analysis is performed. VirtualCert imposes a number of restrictions on input programs (so off-the-shelf programs must often be adapted before analysis), is incomplete, and does not support publicly observable outputs.

ctgrind²⁰ is an extension of Valgrind that verifies constant-address security. It takes an input a program with taint annotations and returns a yes or no answer. ctgrind is neither sound nor complete and does not support publicly observable outputs.

tis-ct is an extension of the FramaC platform for analyzing dependencies in C programs and helping towards proving constant-time security.²¹ tis-ct has been used to analyze OpenSSL. Rather than a verification result, tis-ct outputs a list of all input regions that may flow into the leakage trace, as well as the code locations where that flow may occur. Although this does not directly allow the verification of adherence to a particular security policy, we note that checking that the result list is a subset of public inputs could provide, given an appropriate annotation language, a verification method for public input policies. Since it relies on a dependency analysis rather than semantic criteria, tis-ct is incomplete.

Almeida, Barbosa, Pinto and Vieira [6] propose a methodology based on deductive verification and self-composition for verifying constant-address security of C

²⁰<https://github.com/agl/ctgrind/>.

²¹<http://trust-in-soft.com/tis-ct/>

implementations. Their approach extends to constant-address security earlier work by Svenningsson and Sands [36] for constant-path security. This approach does not consider publicly observable outputs and it does not offer a comparable degree of automation to the one we demonstrate in this paper.

CacheAudit [18] is a static analyzer for quantifying cache leakage in a *single run* of a binary program. CacheAudit takes as input a binary program (in a limited subset of 32-bit x86, e.g. no dynamic jump) and a leakage model, but *no* security annotation (there is no notion of public or private, neither for input, nor output). CacheAudit is sound with respect to a simplified machine code semantics, rather than to a security policy. However, it is incomplete.

There are many other works that develop language-based methods for side-channel security (not necessarily in the computational model of this paper). Agat [2] proposes a type-based analysis for detecting timing leaks and a type-directed transformation for closing leaks in an important class of programs. Molnar, Piotrowski, Schultz and Wagner [29] define the program counter security model and a program transformation for making programs secure in this model. Other works include [28, 35, 41].

8 Conclusion

This paper leaves interesting directions for future work. We intend to improve ct-verif in two directions. First, we shall enhance enforcement of more expressive policies, such as those taking into consideration input-dependent instruction execution times. The work of Andryesco et al. [7] shows that variations in the timing of floating point processor operations may lead to serious vulnerabilities in non-cryptographic systems. Dealing with such timing leaks requires reasoning in depth about the semantics of a program, and is beyond the reach of techniques typically used for non-interference analysis. Our theoretical framework inherits this ability from self-composition, and this extension of ct-verif hinges solely on the effort required to embed platform-specific policy specifications into the program instrumentation logics of the prototype. As a second improvement to ct-verif, we will add support for SSE instructions, which are key to reconciling high-speed and security, for example in implementing AES [22].

A Machine-Level Constant-Time Security

In this section we formalize constant-time security policies at the instruction set architecture (ISA) level. Modeling and verification at this low-level captures security of the actual executable code targeted by attacker scrutiny, which can differ significantly from the original source code prior to compilation and optimization. In order to describe our verification approach in a generic setting, independently of the computing platform and the nature of the exploits, we introduce abstract notions of *machines* and *observations*.

A.1 An Abstract Computing Platform

Formally, a *machine* $M = \langle A, B, V, I, O, F, T \rangle$ consists of

- a set A of address-space names,
- a set B of control-block names, determining the set $K = \{\text{fail}, \text{halt}, \text{spin}, \text{next}, \text{jump}(b) : b \in B\}$ of control codes,
- a set V of values — each address space $a \in A$ corresponds to a subset $V_a \subset V$ of values; together, the address spaces and values determine the set $S = A \rightarrow (V_a \rightarrow V)$ of states, each $s \in S$ mapping $a \in A$ to value store $s_a : V_a \rightarrow V$; we write $a:v$ to denote a reference to $s_a(v)$,
- a set I of instructions — operands are references $a:v$, block names $b \in B$, and literal values,
- a set O of observations, including the null observation ϵ ,
- a leakage function $F : S \times I \rightarrow O$ determining the observation at each state-instruction pair, and
- a transition function $T : S \times I \rightarrow S \times K$ from states and instructions to states and control codes.

We assume that the value set V includes the integer value $0 \in \mathbb{N}$, that the control-block names include `entry`, and that the instruction set I includes the following:

$$T(s, \text{assume } a:v) = \begin{cases} \langle s, \text{spin} \rangle & \text{if } s_a(v) = 0 \\ \langle s, \text{next} \rangle & \text{otherwise} \end{cases}$$

$$T(s, \text{assert } a:v) = \begin{cases} \langle s, \text{fail} \rangle & \text{if } s_a(v) = 0 \\ \langle s, \text{next} \rangle & \text{otherwise} \end{cases}$$

$$T(s, \text{goto } b) = \langle s, \text{jump}(b) \rangle$$

$$T(s, \text{halt}) = \langle s, \text{halt} \rangle$$

We write $s[a:v_1 \mapsto v_2]$ to denote the state s' identical to s except that $s'_a(v_1) = v_2$.

Programs are essentially blocks containing instructions. Formally, a *location* $\ell = \langle b, n \rangle$ is a block name $b \in B$ and index $n \in \mathbb{N}$; the location $\langle \text{entry}, 0 \rangle$ is called the *entry location*, and L denotes the set of all locations. The location $\langle b, n \rangle$ is the *next successor* of $\langle b, n - 1 \rangle$ when $n > 0$, and is the *start of block* b when $n = 0$. A *program for machine M* is a function $P : L \rightarrow I$ labeling locations with instructions.

A.2 Semantics of Abstract Machines

A *configuration* $c = \langle s, \ell \rangle$ of machine M consists of a state $s \in S$ along with a location $\ell \in L$, and is called

- *initial* when ℓ is the entry location,

- *failing* when $T(s, P(\ell)) = \langle _, \text{fail} \rangle$,
- *halting* when $T(s, P(\ell)) = \langle _, \text{halt} \rangle$, and
- *spinning* when $T(s, P(\ell)) = \langle _, \text{spin} \rangle$.

The *observation* at c is $F(s, P(\ell))$, and configuration $\langle s_2, \ell_2 \rangle$ is the *successor* of $\langle s_1, \ell_1 \rangle$ when $T(s_1, P(\ell_1)) = \langle s_2, k \rangle$ and

- $k = \text{next}$ and ℓ_2 is the next successor of ℓ_1 ,
- $k = \text{jump}(b_2)$ and ℓ_2 is the start of block b_2 , or
- $k = \text{spin}$ and $\ell_2 = \ell_1$.

We write $c_1 \rightarrow c_2$ when c_2 is the successor of c_1 , and C denotes the set of configurations.

An *execution of program P for machine M* is a configuration sequence $e = c_0 c_1 \dots \in (C^* \cup C^\omega)$ such that $c_{i-1} \rightarrow c_i$ for each $0 < i < |e|$, and $c_{|e|-1}$ is failing or halting if $|e|$ is finite, in which case we say that e is failing or halting, respectively. The *trace* of e is the sequence $o_0 o_1 \dots$ of observations of at $c_0 c_1 \dots$ concatenated, where $o \cdot \epsilon = \epsilon \cdot o = o$. Executions with the same trace are *indistinguishable*.

Definition 2 (Safety). A program P on machine M is safe when no executions fail. Otherwise, P is unsafe.

A.3 Constant-Time Security

To define our security property we must relate program traces to input and output values, since, generally speaking, the observations made along executions should very well depend on, e.g., publicly-known input values. Security thus relies on distinguishing program inputs and outputs as public or private. We make this distinction formally using address spaces, supposing that machines include

- a public input address space $i \in A$, and
- a publicly observable output address space $o \in A$, in addition to, e.g., register and memory address spaces.

Intuitively, the observations made on a machine running a secure program should depend on the initial machine state only in the public input address space; when observations depend on non-public inputs, leakage occurs. More subtly, observations which are independent of public inputs can still be made, so long as each differing observation is eventually justified by differing publicly observable output values. Otherwise we consider that leakage occurs. Formally, we say that that two states $s_1, s_2 \in S$ are *a-equivalent* for $a \in A$ when $s_1(a)(v) = s_2(a)(v)$ for all $v \in V_a$. Executions e_1 from state s_1 and e_2 from state s_2 are *initially a-equivalent* when s_1 and s_2 are *a-equivalent*, and finite executions to s'_1 and s'_2 are *finally a-equivalent* when s'_1 and s'_2 are *a-equivalent*.

Definition 3 (Constant-Time Security). A program is secure when:

1. Initially i-equivalent and finally o-equivalent executions are indistinguishable.
2. Initially i-equivalent infinite executions are indistinguishable.

Otherwise, P is insecure.

The absence of publicly observable outputs simplifies this definition, since the executions of public-output-free programs are finally o-equivalent, trivially.

B Reducing Security to Safety

According to standard notions, security is a property over pairs of executions: a program is secure so long as executions with the same public inputs and public outputs are indistinguishable. In this section we demonstrate a reduction from security to safety, which is a property over single executions. The reduction works by instrumenting the original program with additional instructions which simulate two executions of the same program side-by-side, along the same control locations, over two separate address spaces: the original, along with a *shadow* of the machine state. In order for our reduction to be sound, i.e., to witness all security violations as safety violations, the control paths of the simulated executions must not diverge unless they yield distinct observations — in which case our reduction yields a safety violation. This soundness requirement can be stated via the following machine property, which amounts to saying that control paths can be leaked to an attacker.

Definition 4 (Control Leaking). A machine M is control leaking if for all states $s \in S$ and instructions $i_1, i_2 \in I$ the transitions $T(s, i_1) = \langle _, k_1 \rangle$ and $T(s, i_2) = \langle _, k_2 \rangle$ yield the same control codes $k_1 = k_2$ whenever the observations $F(s, i_1) = F(s, i_2)$ are identical.

For the remainder of this presentation, we suppose that machines are control leaking. This assumption coincides with that of Section 4: all considered leakage models expose the valuations of branch conditions. Besides control leaking, our construction also makes the following modest assumptions:

- address spaces can be separated and renamed, and
- observations are accessible via instructions.

We capture the first requirement by assuming that programs use a limited set $A_1 \subset A$ of the possible address-space names, and fixing a function $\alpha : A_1 \rightarrow A_2$ whose range $A_2 \subset A$ is disjoint from A_1 . We then lift this function from address-space names to instructions, i.e., $\alpha : I \rightarrow I$, by replacing each reference $a:v$ with $\alpha(a):v$. We capture the second requirement by assuming the existence of a function $\beta : I \times A \times V \rightarrow I$ such that

$$T(s, \beta(i, a, v)) = \langle s[a:v \mapsto F(s, i)], \text{next} \rangle.$$

For a given instruction $i \in I$, address space $a \in A$, and value $v \in V$, the instruction $\beta(i, a, v)$ stores the observation $F(s, i)$ in state $s \in S$ at $a:v$.

Following the development of Section 4, we develop an *output-insensitive* reduction which is always sound, but complete only for programs without publicly-annotated outputs. The extension to an *output-sensitive* reduction which is both sound and complete for all programs mirrors that developed in Section 4. This extension is a straightforward adaptation of Section 4’s from high-level structured programs to low-level unstructured programs, thus we omit it here.

Assume machines include a vector-equality instruction

$$T(s, \text{eq } a_x : \vec{x} \ a_y : \vec{y} \ a : z) = \langle s[a : z \mapsto v], \text{next} \rangle$$

where \vec{x} and \vec{y} are equal-length vectors of values, and $v = 0$ iff $s(a_x)(x_n) \neq s(a_y)(y_n)$ for some $0 \leq n < |\vec{x}|$. This requirement is for convenience only; technically only a simple scalar-equality instruction is necessary.

To facilitate the checking of initial/final range equivalences for security annotations we assume that a given program P has only a single `halt` instruction, and

$$\begin{aligned} P(\text{entry}, 0) &= \text{goto } b_0 \\ P(\text{exit}, 0) &= \text{halt}. \end{aligned}$$

This is without loss of generality since any program can easily be rewritten in this form. Given the above functions α and β , and a fresh address space a , the *shadow product* of a program P is the program P_\times defined by an entry block which spins unless the public input values in both i and $\alpha(i)$ address spaces are equal,

$$P_\times(\text{entry}, n) = \begin{cases} \text{eq } i : V_i \ \alpha(i) : V_i \ a : x & n = 0 \\ \text{assume } a : x & n = 1 \\ \text{goto } b_0 & n > 1 \end{cases}$$

an exit block identical to the original program,

$$P_\times(\text{exit}, n) = P(\text{exit}, n)$$

and finally a rewriting of every other block $b \notin \{\text{entry}, \text{exit}\}$ of P to run each instruction on two separate address spaces,

$$P_\times(b, n) = \begin{cases} \beta(i, a, x) & n = 0 \pmod{6} \\ \beta(\alpha(i), a, y) & n = 1 \pmod{6} \\ \text{eq } a : x \ a : y \ a : z & n = 2 \pmod{6} \\ \text{assert } a : z & n = 3 \pmod{6} \\ i & n = 4 \pmod{6} \\ \alpha(i) & n = 5 \pmod{6} \end{cases}$$

where $i = P(b, n/6)$

while asserting that the observations of each instruction are the same along both simulations.

Theorem 3. A safe program P with (respectively, without) public outputs is secure if (respectively, iff) P_\times is safe.

Secure, Precise, and Fast Floating-Point Operations on x86 Processors

Abstract

Floating-point computations introduce several side channels. This paper describes the first solution that closes these side channels while preserving the precision of non-secure executions. Our solution exploits microarchitectural features of the x86 architecture along with novel compilation techniques to provide low overhead.

Because of the details of x86 execution, the evaluation of floating-point side channel defenses is quite involved, but we show that our solution is secure, precise, and fast. Our solution closes more side channels than any prior solution. Despite the added security, our solution does not compromise on the precision of the floating-point operations. Finally, for a set of microkernels, our solution is an order of magnitude more efficient than the previous solution.

1 Introduction

To secure our computer systems, considerable effort has been devoted to techniques such as encryption, access control, and information flow analysis. Unfortunately, these mechanisms can often be subverted through the use of side channels, in which an adversary, with the knowledge of the program, monitors the program’s execution to infer secret values. These side channels are significant because they have been used to discover encryption keys in AES [26], RSA [27], and the Diffie-Hellman key exchange protocol [14], thereby rendering these sophisticated schemes useless.

Numerous side channels exist, including instruction and data caches [27, 26], branch predictors [2], memory usage [12, 35], execution time [31, 4], heat [22], power [15], and electromagnetic radiation [9], but one particularly insidious side channel arises from the execution of variable-latency floating-point instructions [3, 10], in which an instruction’s latency varies widely depending on its operands, as shown in Table 1.

Zero	Normal	Subnormal	Infinity	NaN
7	11	153	7	7

Table 1: Latency (in cycles) of the SQRTSS instruction for various operands.

Both x86¹ and ARM² provide variable-latency floating-point instructions. This variable latency stems from the desire to have graceful floating-point arithmetic behavior, which, as we explain in Section 3, requires the use of so-called *subnormal* values [8], which are processed using special algorithms. Since subnormal values are rare, hardware vendors typically support such values in microcode, so as not to slow down the common case. The resulting difference in instruction latency creates a timing side channel, which has been used to infer cross-origin data in browsers and to break differential privacy guarantees of a remote database [3].

However, variable latency floating-point instructions represent only a part of the problem, since higher level floating-point operations, such as sine and cosine, are typically implemented in software. Thus, the implementation of these floating-point operations can leak secret information through other side channels as well. Depending on the secret values, programs can throw exceptions, thereby leaking the presence of abnormal inputs through termination. Programs can also contain conditional branches, which can leak secrets through the instruction pointer, branch predictor, or memory access count. Finally, programs that index into lookup tables can leak secrets through the memory address trace.

To prevent information leaks in both floating-point instructions and floating-point software, a strong solution should ensure at least four key properties, which correspond to the side channels that we discussed above:

¹http://www.agner.org/optimize/instruction_tables.pdf

²<http://infocenter.arm.com/help/index.jsp?topic=/com.arm.doc.ddi0344k/ch16s07s01.html>

(1) fixed-time operations that are independent of secret values, (2) disabled exceptions, (3) sequential control flow, and (4) uniform data accesses that are independent of the value of secret variables. Previous solutions [3, 5] are inadequate because they do not ensure all four properties, are slow, are orders of magnitude less precise, or are difficult to implement.

This paper presents a novel solution that closes side channels arising from both hardware and software implementations of floating point operations, providing all four properties mentioned above. Our compiler-based solution has two components.

The first component creates building blocks of elementary floating-point operations for instructions that are natively supported by the hardware (addition, subtraction, multiplication, division, square root, and type conversion). Our solution leverages unused SIMD lanes so that fast operations on normal operands are accompanied by slower dummy computations on subnormal operands, yielding a consistent yet low instruction latency for all types of operands.

The second component is a software library of higher-level floating-point operations like sine and cosine. The key to creating this second component is a new code transformation that produces fixed-latency functions through normalized control flows and data access patterns. Code generated by our compiler closes *digital side-channels*, which have been defined to be those side channels that carry information over discrete bits [28]. Whereas previous work in closing digital side channels employs a runtime system [28], our solution shifts much of the work to compile time, yielding a significantly smaller runtime overhead.

This paper makes the following contributions:

1. We present a novel compiler-based system, called *Escort*, for closing digital side channels that arise from the processing of floating-point instructions.
2. **Secure:** We demonstrate that our solution is secure not just against timing but also against digital side channels. We demonstrate *Escort*'s capabilities by defeating a machine-learning side-channel attack, by defending against a timing attack on the Firefox web browser, by conducting extensive performance measurements on an x86 processor, and by verifying our solution's code using typing rules.
3. **Precise:** We show that *Escort* provides precision that is *identical* to that of the standard C math library. By contrast, the previous solution's precision is off by several million floating-point values.
4. **Fast:** We show that our solution is fast. On a set of micro-benchmarks that exercise elementary

floating-point operations, *Escort* is 16× faster than the previous solution [3].

5. As an ancillary contribution, we introduce a methodology for evaluating the precision and security of floating-point operations, which is fraught with subtleties.

The rest of this paper is organized as follows. Section 2 describes our threat model, related work, and system guarantees. We provide background in Section 3 before presenting our solution in Section 4. We evaluate our solution in Sections 5–7. Finally, we conclude in Section 8.

2 Threat Model and Related Work

This section begins by describing our threat model, which shapes our subsequent discussion of related work and of *Escort*'s security guarantees.

Threat Model. Our goal is to prevent secret floating-point operands from leaking to untrusted principals that either read digital signals from the processor's pins or that are co-resident processes.

We assume that the adversary is either an external entity that monitors *observation-based* side channels (*e.g.* time [14], memory address trace [11], or the /proc pseudo-filesystem [12]) or a co-resident process/VM that monitors *contention-based* side channels (*e.g.* cache [27] or branch predictor state [2]).

For off-chip observation-based channels, we assume that the processor resides in a sealed and tamper-proof chip that prevents the adversary from measuring physical side channels like heat, power, electromagnetic radiation, etc. We assume that the CPU encrypts data transferred to and from DRAM. All components other than the processor are untrusted, and we assume that the adversary can observe and tamper with any digital signal. For on-chip contention-based channels, we assume that the OS is trusted and does not leak the victim process's secret information. We also assume that the adversary cannot observe or change the victim process's register contents. Our trusted computing base includes the compilation toolchain.

Side-Channel Defenses. Decades of prior research have produced numerous defenses against side channels, the vast majority of which close only a limited number of side channels with a single solution. For instance, numerous solutions exist that close only the cache side channel [6, 36, 39, 37, 16] or only the address-trace side channel [33, 20, 32, 29]. Raccoon [28] is the first solution that closes a broad class of side channels—in

particular, the set of digital side channels—with a single solution. Similar to Raccoon, Escort also closes digital side channels with a single solution, but unlike Raccoon, Escort focuses on closing floating-point digital side channels, which can arise from variable latency floating-point instructions and from software implementations of floating-point libraries, in which points-to set sizes are typically small. Given Escort’s narrower focus on floating-point computations, Escort is faster than Raccoon by an order of magnitude.

Timing Side-Channel Defenses. Prior defenses against timing side-channel attacks utilize new algorithms [30], compilers [23], runtime systems [21], or secure processors [18]. However, these solutions only address one source of timing variations—either those stem from the choice of the algorithm [31] or those that stem from the microarchitectural design [10]. By contrast, Escort closes timing variations from both sources.

Floating-Point Side-Channel Defenses. Andryscy et al. [3] present *libfixedtimefixedpoint* (FTFP), the first software solution for closing the floating-point timing channel. FTFP has some weaknesses, as we now discuss, but the main contribution of their paper is the demonstration of the significance of this side channel, as they use variable-latency floating-point operations to break a browser’s same-origin policy and to break differential privacy guarantees of remote databases. FTFP is a *fixed-point* library that consists of 19 hand-written functions that each operates in fixed time, independent of its inputs. FTFP is slow, it is imprecise, and it exposes secrets through other side channels, such as the cache side channel or the address trace side channel. Cleempot et al. [5] introduce compiler transformations that convert variable-timing code into fixed-timing code. Their technique requires extensive manual intervention, applies only to the division operation, and provides weak security guarantees. Both solutions require manual construction of fixed-time code—a cumbersome process that makes it difficult to support a large number of operations. By contrast, Escort implements a fixed-time floating-point library, while preventing information leaks through timing as well as digital side channels. Escort includes a compiler that we have used to automate the transformation of 112 floating-point functions in the Musl standard C library, a POSIX-compliant C library. Escort also provides precision identical to the standard C library.

Escort’s Guarantees. Escort rejects programs that contain unsupported features—I/O operations and recursive function calls. Unlike prior work [18, 28], Escort

does transform loops that leak information through trip counts. Escort is unable to handle programs containing irreducible control flow graphs (CFGs), but standard compiler transformations [24] can transform irreducible CFGs into reducible CFGs. Escort assumes that the input program does not use vector instructions, does not exhibit undefined behavior, does not terminate abnormally through exceptions, and is free of race conditions. Given a program that abides by these limitations, Escort guarantees that the transformed code produces identical results as the original program, does not leak secrets through timing or digital side channels, and that the transformed code does not terminate abnormally.

3 Background

The variable latency of floating-point instructions creates security vulnerabilities. In this section, we explain subnormal numbers, which are the cause of the variable latency, and we explain the difficulty of fixing the resulting vulnerability. We also explain how the Unit of Least Precision (ULP) can be used to quantify the precision of our and competing solutions.

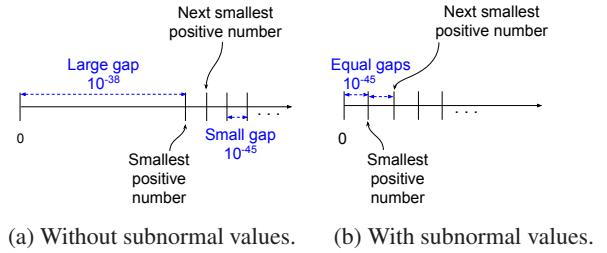

Figure 1: Impact of allowing subnormal numbers. Without subnormal values, there exists a much larger gap between zero and the smallest positive number than between the first two smallest positive numbers. With subnormal numbers, the values are more equally spaced. (The figure is not drawn to scale.)

3.1 Subnormal Numbers

Subnormal numbers have tiny exponents, which result in floating-point values that are extremely close to zero: $10^{-45} < |x| < 10^{-38}$ for single-precision numbers and $10^{-324} < |x| < 10^{-308}$ for double-precision numbers. Subnormal values extend the range of floating-point numbers that can be represented, but more importantly, they enable *gradual underflow*—the property that as floating-point numbers approach zero along the number scale, the difference between successive floating-point numbers does not increase³. Figures 1a and 1b show the

³https://www.cs.berkeley.edu/~wkahan/ARITH_17U.pdf

differences between zero and the two smallest positive floating-point numbers. With subnormal numbers, the gap between any two consecutive floating-point values is never larger than the values themselves, thus exhibiting Gradual Underflow. Subnormal numbers are indispensable because gradual underflow is required for reliable equation solving and convergence acceleration [8, 13].

To avoid the added hardware complexity of supporting subnormal numbers, which occur infrequently, vendors typically process subnormal values in microcode, which is orders of magnitude slower than hardwired logic.

The resulting difference in latencies creates a security vulnerability. An adversary that can measure the latency of a floating-point instruction can make reasonable estimates about the operand type, potentially inferring secret values using the timing channel. While subnormal values occur infrequently in typical program execution, an adversary can deliberately induce subnormal values in the application’s inputs to enable subnormal operand timing attacks.

3.2 Floating-Point Error Measurement

Unlike real (infinite precision) numbers, floating-point numbers use a limited number of bits to store values, thus making them prone to rounding errors. Rounding errors in floating-point numbers are typically measured in terms of the Unit of Least Precision (ULP) [25]. The ULP distance between two floating-point numbers is the number of distinct representable floating-point numbers between them, which is simply the result of subtracting their integer representations. If the result of the subtraction is zero, the floating-point numbers must be exactly the same.

4 Our Solution: Escort

Escort offers secure counterparts of ordinary non-secure floating-point operations, including both elementary operations and higher-level math operations. The elementary operations include the six basic floating-point operations that are natively supported by the ISA—type conversion, addition, subtraction, multiplication, division, and square root—and a conditional data copy operation. The 112 higher-level math operations are those that are implemented using a combination of native instructions. Examples of higher-level functions include sine, cosine, tangent, power, logarithm, exponentiation, absolute value, floor, and ceiling.

The next subsections describe Escort’s design in three parts. First, we describe the design of Escort’s secure elementary operations. These operations collectively form the foundation of Escort’s security guarantees. Second, we describe Escort’s compiler, which accepts non-secure

code for higher-level operations and converts it into secure code. This compiler combines a code transformation technique with Escort’s secure elementary operations. Third, we present an example that shows the synergy among Escort’s components.

4.1 Elementary Operations

The key insight behind Escort’s secure elementary operations is that the latencies of SIMD instructions are determined by the slowest operation among the SIMD lanes (see Figure 2), so the Escort compiler ensures that each elementary instruction runs along side a dummy instruction whose operand will produce the longest possible latency. Our analysis of 94 x86 SSE and SSE2 instructions (which includes single- and double-precision arithmetic, comparison, logical, and conversion instructions) reveals: (1) that only the multiplication, division, square root, and single-precision to double-precision conversion (upcast) instructions exhibit latencies that depend on their operands and (2) that subnormal operands induce the longest latency.

In particular, Escort’s fixed-time floating-point operations utilize SIMD lanes in x86 SSE and SSE2 instructions. Our solution (1) loads genuine and dummy (subnormal) inputs in spare SIMD lanes of the same input register, (2) invokes the desired SIMD instruction, and (3) retains only the result of the operation on the genuine inputs. Our tests confirm that the resulting SIMD instruction exhibits the worst-case latency, with negligible variation in running time (standard deviation is at most 1.5% of the mean). Figure 3 shows Escort’s implementation of one such operation.

Escort includes Raccoon’s conditional data copy operation (see Figure 4) which does not leak information through digital side channels. This operation copies the contents of one register to another register if the given condition is true. However, regardless of the condition, this operation consumes a fixed amount of time, executes the same set of instructions, and does not access application memory.

4.2 Compiling Higher-Level Operations

Escort’s compiler converts existing non-secure code into secure code that prevents information leakage through digital side channels. First, our compiler replaces all elementary floating-point operations with their secure counterparts. Next, our compiler produces straight-line code that preserves control dependences among basic blocks while preventing instruction side effects from leaking secrets. Our compiler then transforms array access statements so that they do not leak information through memory address traces. Finally, our compiler transforms

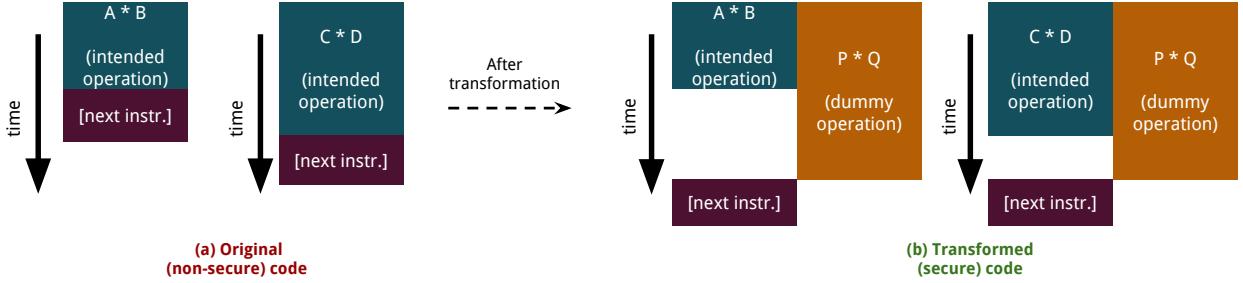

Figure 2: The key idea behind Escort’s secure elementary operations. The operation is forced to exhibit a fixed latency by executing a fixed-latency long-running operation in a spare SIMD lane.

```
double escort_mul_dp(double x, double y) {
    const double k_normal_dp = 1.4;
    const double k_subnormal_dp = 2.225e-322;

    double result;
    __asm__ volatile(
        "movdqa    %1, %%xmm14;"          // Load x
        "movdqa    %2, %%xmm15;"          // Load y
        "pslldq   $8, %1;"              // Shift x left by 8
        "pslldq   $8, %2;"              // Shift y left by 8
        "por      %3, %1;"              // Compute sign of result
        "por      %4, %2;"              // Compute sign of result
        "movdqa   %2, %0;"              // Load k_subnormal_dp
        "mulpd   %1, %0;"              // Compute result
        "psrldq   $8, %0;"              // Shift result right by 8
        "movdqa   %%xmm14, %1;"         // Store result
        "movdqa   %%xmm15, %2;"         // Store y
        : "=x" (result), "+x" (x), "+x" (y)
        : "x" (k_subnormal_dp), "x" (k_normal_dp)
        : "xmm15", "xmm14");
    return result;
}
```

Figure 3: Escort’s implementation of double-precision multiplication, using the AT&T syntax.

loops whose trip count reveals secrets over digital side channels. We now describe each step in turn.

4.2.1 Step 1: Using Secure Elementary Operations

The Escort compiler replaces x86 floating-point type-conversion, multiplication, division, and square root assembly instructions with their Escort counterparts. However, Escort’s secure elementary operations can be up to two orders of magnitude slower than their non-secure counterparts. Hence, our compiler minimizes their usage by using taint tracking and by employing the quantifier-free bit-vector logic in the Z3 SMT solver [7], which is equipped with floating-point number theory. If the solver can prove that the operands can never be subnormal values, then Escort refrains from replacing that instruction.

In effect, the Escort compiler constructs path-sensitive Z3 expressions for each arithmetic statement in the

```
01: copy(uint8_t pred, uint32_t t_val, uint32_t f_val) {
02:     uint32_t result;
03:     __asm__ volatile (
04:         "mov    %2, %0;"           // Move t_val to result
05:         "test   %1, %1;"          // Test pred
06:         "cmovz %3, %0;"          // If pred is true, move f_val to result
07:         "test   %2, %2;"          // Test pred again
08:         : "=r" (result)
09:         : "r" (pred), "r" (t_val), "r" (f_val)
10:         : "cc"
11:     );
12:     return result;
13: }
```

Figure 4: Code for conditional data copy operation that does not leak information over digital side channels. This function returns `t_val` if `pred` is `true`; otherwise it returns `f_val`. The assembly code uses AT&T syntax.

LLVM IR. For every Φ -node that produces an operand for an arithmetic expression, Escort creates one copy of the expression for each input to the Φ -node. If the solver reports that no operand can have a subnormal value, then Escort skips instrumentation of that floating-point operation.

We set a timeout of 40 seconds for each invocation of the SMT solver. If the solver can prove that the instruction never uses subnormal operands, then Escort skips replacing that floating-point instruction with its secure counterpart. Figure 5 shows the percentage of floating-point instructions in commonly used math functions that are left untransformed by Escort.

This optimization is conservative because it assumes that all floating-point instructions in the program have subnormal operands unless proven otherwise. The correctness of the optimization is independent of the code’s use of pointers, library calls, system calls, or dynamic values. The static analysis used in this optimization is flow-sensitive, path-sensitive, and intra-procedural.

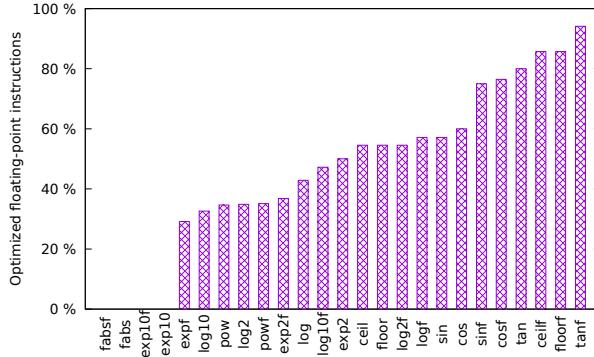

Figure 5: Percentage of instructions that are left uninstrumented (without sacrificing security) after consulting the SMT solver.

4.2.2 Step 2: Predicating Basic Blocks

Basic block predicates represent the conditions that dictate whether an instruction should execute. These predicates are derived by analyzing conditional branch instructions. For each conditional branch instruction that evaluates a predicate p , the Escort compiler associates the predicate p with all basic blocks that execute if the predicate is true, and it associates the predicate $\neg p$ with all basic blocks that execute if the predicate is false. For unconditional branches, the compiler copies the predicate of the previous block into the next block. Finally, if the Escort compiler comes across a block that already has a predicate, then the compiler sets the block’s new predicate to the logical OR of the input predicates. At each step, the Escort compiler uses Z3 as a SAT solver to simplify predicates by eliminating unnecessary variables in predicate formulas. Figure 6 shows the algorithm for basic block predication.

4.2.3 Step 3: Linearizing Basic Blocks

The Escort compiler converts the given code into straight-line code so that every invocation of the code executes the same instructions. To preserve control dependences, the basic blocks are topologically sorted, and then the code is assembled into a single basic block with branch instructions removed.

4.2.4 Step 4: Controlling Side Effects

We now explain how Escort prevents side effects from leaking secrets. Here, *side effects* are modifications to the program state or any observable interaction, including memory accesses, exceptions, function calls, or I/O. Escort controls all side effects except for I/O statements.

```

1: for each basic block  $bb$  in function do
2:   if  $entry\_block(bb)$  then
3:      $pred[bb] \leftarrow \text{true}$ 
4:   else
5:      $pred[bb] \leftarrow \text{false}$ 
6:   end if
7: end for
8:
9: for each basic block  $bb$  in function do
10:   $br \leftarrow branch(bb)$ 
11:  if  $unconditional\_branch(br)$  then
12:     $\{s\} \leftarrow successors(bb)$ 
13:     $pred[s] \leftarrow pred[s] \vee pred[bb]$ 
14:     $pred[s] \leftarrow simplify(pred[s])$ 
15:  else                                 $\triangleright$  Conditional Branch.
16:     $\{s_1, s_2\} \leftarrow successors(bb)$ 
17:    if  $loop\_condition\_branch(br)$  then
18:       $\triangleright$  Skip branches that represent loops.
19:       $pred[s_1] \leftarrow pred[s_1] \vee pred[bb]$ 
20:       $pred[s_2] \leftarrow pred[s_2] \vee pred[bb]$ 
21:    else
22:       $p \leftarrow condition(br)$ 
23:       $pred[s_1] \leftarrow pred[s_1] \vee (pred[bb] \wedge p)$ 
24:       $pred[s_2] \leftarrow pred[s_2] \vee (pred[bb] \wedge \neg p)$ 
25:    end if
26:     $pred[s_1] \leftarrow simplify(pred[s_1])$ 
27:     $pred[s_2] \leftarrow simplify(pred[s_2])$ 
28:  end if
29: end for

```

Figure 6: Algorithm for predication basic blocks.

Memory Access Side Effects. To ensure proper memory access side effects, the Escort compiler replaces store instructions with conditional data-copy operations that are guarded by the basic block’s predicate, so memory is only updated by instructions whose predicate is true.

Unfortunately, this naïve approach can leak secret information when the program uses pointers. Figure 7 illustrates the problem: If store instructions are not allowed to update a pointer variable when the basic block predicate is false, then the address trace from subsequent load instructions on the pointer variable will expose the fact that the pointer variable was not updated.

The Escort compiler prevents such information leaks by statically replacing pointer dereferences with loads or stores to each element of the points-to set⁴. Thus Escort replaces the statement in line 8 (Figure 7) with a store operation on b . When the points-to set is larger than a

⁴Escort uses a flow-sensitive, context-insensitive pointer analysis: <https://github.com/grievejia/tpa>. Replacing a pointer dereference with a store operation on all elements of the points-to set is feasible for Escort because points-to set sizes in the Musl C library are very small.

```

1:  $p \leftarrow \&a$ 
2:  $secret \leftarrow input()$      $\triangleright$  Assume  $input()$  returns true.
3: if  $secret = \text{true}$  then
4:   ...
5: else
6:   ...
7:      $p \leftarrow \&b$   $\triangleright$  Instruction does not update pointer  $p$ ,
       since basic block's execution-time predicate is false.
8:      $*p \leftarrow 10$             $\triangleright$  Accesses  $a$  instead of  $b$ !
9: end if

```

Figure 7: The use of pointers can leak information. If store instructions are not allowed to access memory when the basic block’s predicate is false, then pointer p will dereference the address for a instead of b , thus revealing that $secret$ is true.

singleton set, Escort uses the conditional data copy operation on all potential *pointees* *i.e.* the elements of the points-to set. The predicate of the conditional copy operation checks whether the pointer points to the candidate pointee. If the predicate is false, the pointee’s existing value is overwritten, whereas if the predicate is true, the new value is written to the pointee.

Function Call Side Effects. Adversaries can observe the invocation of functions (or lack thereof) using side channels like the Instruction Pointer. Thus, a solution incapable of handling function calls will leak information to the adversary. While inlining functions is a potential solution, inlining is impractical for large applications.

Escort handles side effects from function calls by propagating the predicate from the calling function to the callee. Thus, each user-defined function is given an additional argument that represents the predicate of the call site’s basic block. The callee ensures correct handling of side effects by ANDing its own predicates with the caller’s predicate.

Side Effects from Exceptions. Program termination caused by exceptions will leak the presence or absence of abnormal operands. To prevent such information leakage, Escort requires that exceptions not occur during program execution⁵.

Escort manages floating-point and integer exceptions differently. Escort requires that the programmer disable floating-point exceptions (*e.g.* using `feclearexcept()`). For integer exceptions, Escort borrows ideas from Raccoon by replacing abnormal operands with benign operands (*e.g.* Escort prevents integer division-by-zero by replacing a zero divisor with a non-zero divisor).

⁵Escort assumes that the input program does not throw exceptions, so masking exceptions does not change the semantics of the program.

4.2.5 Step 5: Transforming Array Accesses

Array index values reveal secrets as well. For instance, if the adversary observes that accesses to $array[0]$ and $array[secret_index]$ result in accesses to locations 10 and 50, then the adversary knows that $secret_index = 40$. To eliminate such information leaks, the Escort compiler transforms each array access into a linear sweep over the entire array, which hides from the adversary the address of the program’s actual array index.

Of course, the transformed code is expensive, but this approach is feasible because (1) math library functions typically use only a few small lookup tables, thus requiring relatively few memory accesses and (2) the processor’s caches and prefetchers dramatically reduce the cost of sweeping over the arrays.

4.2.6 Step 6: Transforming Loops

Some loops introduce timing channels because their trip counts depend on secret values. The Escort compiler transforms such loops using predictive mitigation [38]. The loop body executes as many times as the smallest power of 2 that is greater than or equal to the loop trip count. For instance, if the actual loop trip count is 10, then the loop body is executed 16 times. The basic block predicate ensures that dummy iterations do not cause side effects. With this transformed code, an adversary that observes a loop trip count of l can infer that the actual loop trip count l' is between l and $0.5 \times l$. However, the exact value of l' is not revealed to the adversary.

Unfortunately, this naive approach can still leak information. For instance, if two distinct inputs cause the loop to iterate 10 and 1000 times respectively, the transformed codes will iterate 16 and 1024 times respectively—a large difference that may create timing variations. To mitigate this problem, Escort allows the programmer to manually specify the minimum and maximum loop trip counts using programmer annotations. These annotations override the default settings used by the Escort compiler.

4.3 Example Transformation: `exp10f`

We now explain how Escort transforms an example non-secure function (Figure 8a) into a secure function (Figure 8c). To simplify subsequent analyses and transformations, the Escort compiler applies LLVM’s `mergereturn` transformation pass, which unifies all exit nodes in the input function (see Figure 8b).

First, the Escort compiler replaces elementary floating-point operations in lines 8 and 10 with their secure counterpart function shown in lines 21 and 22 of the transformed code. Second, using the algorithm shown in Figure 6, the Escort compiler associates predicates with

```

float e10(float x) {
    float n, y = mf(x, &n);
    if (int(n) >> 23 & 0xff < 0x82) {
        float p = p10[(int) n + 7];
        if (y == 0.0f) {
            return p;
        }
        return exp2f(3.322f * y) * p;
    }
    return exp2(3.322 * x);
}

```

(a) Original code for `exp10f()`.

```

01: float e10(float x) {
02:     float n, y = mf(x, &n);
03:     if (int(n) >> 23 & 0xff < 0x82) {
04:         float p = p10[(int) n + 7];
05:         if (y == 0.0f)
06:             result = p;
07:         else
08:             result =
09:                 exp2f(3.322f * y) * p;
10:     } else
11:         result = exp2(3.322 * x);
12:     return result;
}

```

(b) Result after applying LLVM's `mergereturn` pass. This code becomes the input for the Escort compiler.

```

12: float e10(float x) {
13:     return e10_cloned(x, true);
14: }
15:
16: float e10_cloned(float x, uint pred) {
17:     float n, y = mf_cloned(x, &n, pred);
18:     float p = write(int(n) >> 23 & 0xff
19:                     < 0x82, stream_load(p10, (int) n + 7));
20:     bool p2 = y == 0.0f;
21:     write(pred & p1 & p2, p, &result);
22:     write(pred & p1 & !p2,
23:           escort_mul(
24:             escort_mul(
25:               exp2f_cloned(3.322f,
26:                             pred & p1 & !p2),
27:               y),
28:               p),
29:             &result);
30:
31:     write(!p1,
32:           escort_mul(
33:             exp2_cloned(3.322, pred & !p1),
34:             escort_upcast(x))),
35:             result);
36:
37:     return result;
38: }

```

(c) Result of the Escort compiler's transformation.

Figure 8: Escort's transformation of `exp10f()`.

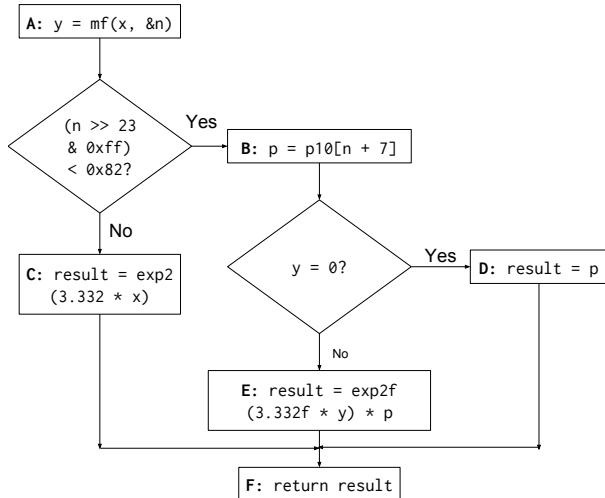

Figure 9: Control flow graph with labeled statements for the code in Figure 8b. **A, B, D, E, C, F** is one possible sequence of basic blocks when linearized by the Escort compiler.

Line #	Predicate
2, 3, 11	TRUE
4, 5	(n >> 23 & 0xff) < 0x82
6	(n >> 23 & 0xff) < 0x82 \wedge y = 0
8	(n >> 23 & 0xff) < 0x82 \wedge y \neq 0
10	$\neg((n >> 23 & 0xff) < 0x82)$

Table 2: Predicates per line for function in Figure 8b.

each basic block, which we list in Table 2. Third, the Escort compiler linearizes basic blocks by applying a topological sort on the control flow graph (see Figure 9) and fuses the basic blocks together. Finally, the Escort compiler replaces the array access statement in line 4 with a function that sweeps over the entire array. The resulting code, shown in Figure 8c, eliminates control flows and data flows that depend on secret values. In addition to closing digital side channels, the code also uses secure floating-point operations.

5 Security Evaluation

This section demonstrates that Escort’s floating-point operations run in fixed time and do not leak information through digital side channels. Since precise timing measurement on x86 processors is tricky due to complex processor and OS design, we take special measures to ensure that our measurements are accurate. In addition to Escort’s timing and digital side channel defense, we also demonstrate Escort’s defense against a floating-point timing channel attack on the Firefox web browser.

5.1 Experimental Setup

We run all experiments on a 4-core Intel Core i7-2600 (Sandy Bridge) processor. The processor is clocked at 3.4 GHz. Each core on this processor has a 32 KB private L1 instruction cache, a 32 KB private L1 data cache, and a 256 KB private L2 cache. A single 8 MB L3 cache is shared among all four cores. The host operating system is Ubuntu 14.04 running kernel version 3.13. We implement compiler transformations using the LLVM compiler framework [17] version 3.8.

We measure instruction latencies using the RDTSC instruction that returns the number of elapsed cycles since resetting the processor. Since the latency of executing the RDTSC instruction is usually higher than the latency of executing operations, our setup measures the latency of executing 1024 consecutive operations and divides the measured latency by 1024. Our setup uses the CPUID instruction and volatile variables for preventing the processor and the compiler from reordering critical instructions. Finally, our setup measures overhead by executing an empty loop body—a loop body that contains no instructions other than those in the test harness. By placing an empty volatile `__asm__` block in the empty loop body, our setup prevents the compiler from deleting the empty loop body.

5.1.1 Outlier Elimination

Many factors outside of the experiment’s control, like interrupts, scheduling policies, etc., may result in outliers in performance measurements. We now explain our procedure for eliminating outliers, before demonstrating that the elimination of these outliers does not bias the conclusions.

We use Tukey’s method [34] for identifying outliers, but we adapt it to conservatively classify fewer values as outliers (thus including more values as valid data points). The original Tukey’s method first finds the minimum (M_n), median (M_d), and maximum (M_x) of a set of values. The first quartile, Q_1 , is the median of values between M_n and M_d . The third quartile, Q_3 , is the median of values

between M_x and M_d . The difference between the first and the third quartiles ($Q_3 - Q_1$) is called the Inter-Quartile Range, R_{IQ} . Tukey’s method states that any value v , such that $v > Q_3 + 3 \times R_{IQ}$ or $v < Q_1 - 3 \times R_{IQ}$ is a probable outlier. In our evaluation, we weaken our outlier elimination process (*i.e.* we count fewer values as outliers), by (1) setting the R_{IQ} to be at least equal to 1.0, and (2) classifying v as an outlier when $v > Q_3 + 20 \times R_{IQ}$ or $v < Q_1 - 20 \times R_{IQ}$. Results presented in the following sections use the relaxed Tukey method described above.

	Mean	Median	Std. Dev.
Different Operands	847,323 (0.81%)	1,066,270 (1.02%)	381,467
Same Operands	929,703 (0.89%)	1,139,961 (1.09%)	364,192

Table 3: Number of discarded outliers from 100 million double-precision square-root operations. The results indicate that our outlier elimination process is statistically independent of the input operand values.

To demonstrate that our outlier elimination process does not bias conclusions, we compare the distribution of outliers between (a) 100 million operations using randomly-generated operands, and (b) 100 million operations using one fixed operand. The two experiments do not differ in any way other than the difference in their input operands. Table 3 shows the mean, median, and standard deviation of outliers for the double-precision square-root operation. Results for other floating-point operations are similar and are elided for space reasons. Since the difference in mean values as well as the difference in median values is within a quarter of the standard deviation from the mean, we conclude that the discarded outlier count is statistically independent of the input operand values.

5.2 Timing Assurance of Elementary Operations

Since exhaustively testing all possible inputs for each operation is infeasible, we instead take the following three-step approach for demonstrating the timing channel defense for Escort’s elementary operations: (1) We characterize the performance of Escort’s elementary operations using a specific, fixed floating-point value (*e.g.* 1.0), (2) using one value from each of the six different types of values (zero, normal, subnormal, $+\infty$, $-\infty$, and not-a-number), we show that our solution exhibits negligible variance in running time, and (3) to demonstrate that each of the six values in the previous experiment is representative of the class to which it belongs, we generate 10 million normal, subnormal, and not-a-number (NaN)

values, and show that the variance in running time among each set of 10 million values is negligible. Our key findings are that Escort’s operations run in fixed time, are fast, and that their performance is closely tied to the performance of the hardware’s subnormal operations.

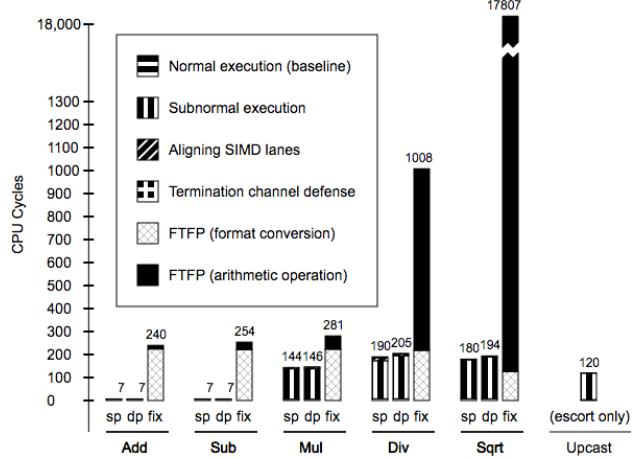

Figure 10: Comparison of running times of elementary operations. **sp** identifies Escort’s single-precision operations, **dp** identifies Escort’s double-precision operations, and **fix** identifies FTFP’s fixed-point operations. Numbers at the top of the bars show the total cycle count. We see that Escort’s execution times are dominated by the cost of subnormal operations, and we see that FTFP’s overheads are significantly greater than Escort’s.

Figure 10 compares the running times of elementary operations of Escort and of previous solutions (FTFP). First, we observe that the running times of Escort’s single- and double-precision operations are an order-of-magnitude lower than those of FTFP’s fixed-precision operations. Second, Escort’s running time is almost entirely dominated by the processor’s operation on subnormal numbers. Third, conversion between fixed-point and floating-point takes a non-trivial amount of time, further increasing the overhead of FTFP’s operations. Overall, Escort elementary operations are about 16× faster than FTFP’s.

Table 4 shows the variation in running time of elementary operations across six different types of inputs (zero, normal value, subnormal value, $+\infty$, $-\infty$, and not-a-number value) and compares it with the variation of SSE (native) operations. While SSE operations exhibit high variation (the maximum observed standard deviation is 176% of the mean), Escort’s operations show negligible variation across different input types.

Finally, we measure Escort’s running time for 10 million random normal, subnormal, and not-a-number values. We observe that the standard deviation of these measurements, shown in Table 5, is extremely low (at most

Function	Escort	Native (SSE)
add-sp	0	0
add-dp	0	0
sub-sp	0	0
sub-dp	0	0
mul-sp	0	49.2 (175%)
mul-dp	0	49.2 (175%)
div-sp	0.66 (0.4%)	65.67 (163%)
div-dp	1.66 (0.8%)	69.08 (164%)
sqrt-sp	1.49 (0.8%)	62.7 (170%)
sqrt-dp	2.98 (1.5%)	66.87 (169%)
upcast	0	40.99 (178%)

Table 4: Comparison of standard deviation of running times of elementary operations across six types of values (zero, normal, subnormal, $+\infty$, $-\infty$, and not-a-number). Numbers in parenthesis show the standard deviation as a percentage of the mean. The **-sp** suffix identifies single-precision operations while the **-dp** suffix identifies double-precision operations. Compared to SSE operations, Escort exhibits negligible variation in running times.

3.1% of the mean). We thus conclude that our chosen values for each of the six classes faithfully represent their class.

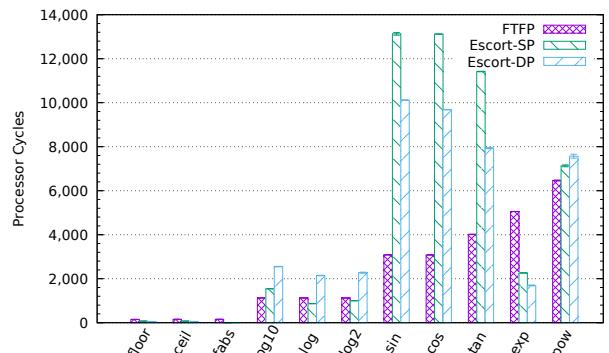

Figure 11: Comparison of running times of commonly used higher-level functions. Error bars (visible for only a few functions) show the maximum variation in running time for different kinds of input values.

5.3 Timing Assurance of Higher-Level Operations

Using different types of floating-point values (zero, normal, subnormal, $+\infty$, $-\infty$, and not-a-number), Figure 11 compares the performance of most of the commonly used

Fn.	NaN	Normal	Subnormal
add-sp	0.21 (3.1%)	0.21 (2.9%)	0.19 (2.7%)
add-dp	0.21 (3.0%)	0.20 (2.9%)	0.21 (3.0%)
sub-sp	0.18 (2.6%)	0.19 (2.7%)	0.20 (2.9%)
sub-dp	0.19 (2.7%)	0.19 (2.7%)	0.19 (2.7%)
mul-sp	0.98 (0.7%)	0.94 (0.7%)	1.05 (0.7%)
mul-dp	0.90 (0.6%)	1.04 (0.7%)	1.02 (0.7%)

Table 5: Standard deviation of 10 million measurements for each type of value (normal, subnormal, and not-a-number). All standard deviation values are within 3.1% of the mean. Furthermore, the mean of these 10,000,000 measurements is always within 2.7% of the representative measurement.

single- and double-precision higher-level operations⁶. Overall Escort’s higher-level operations are about $2\times$ slower than their corresponding FTFP operation, which is the price for closing side channels that FTFP does not close.

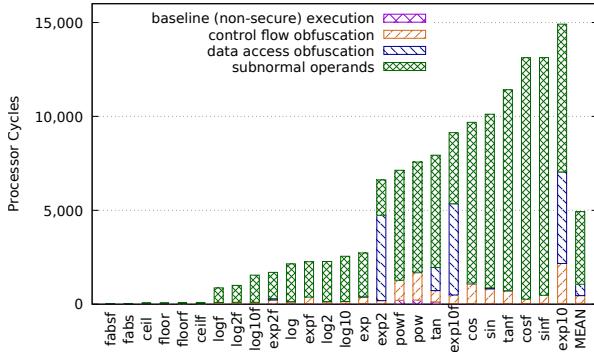

Figure 12: Performance breakdown of Escort’s commonly used higher-level functions. The baseline (non-secure) execution and exception handling together cost less than 250 cycles for each function, making them too small to be clearly visible in the above plot.

Figure 12 shows the breakdown of the performance of commonly used higher-level functions. We observe that the performance of most higher-level functions is dominated by the latency of operations on subnormal operands, which is closely tied to the performance of the underlying hardware. A handful of routines ($\text{exp10}()$,

⁶We exclude the $\text{exp2}()$ (6,617 cycles), $\text{exp10}()$ (14,910 cycles), $\text{exp2f}()$ (1,693 cycles), and $\text{exp10f}()$ (9,134 cycles) from Figure 11 because FTFP does not implement these operations.

$\text{exp10f}()$, $\text{exp2f}()$, and $\text{exp2f}()$ use lookup tables that are susceptible to address-trace-based side-channel information leaks, so the code transformed by Escort sweeps over these lookup tables for each access to the table. Finally, we see that the cost of control flow obfuscation (*i.e.* the cost of executing all instructions in the program) contributes the least to the total overhead.

5.4 Side-Channel Defense in Firefox

We now evaluate Escort’s defense against the timing channel attack by Andryesco et al. [3] on the Firefox web browser. The attack reconstructs a two-color image inside a victim web page using only the timing side channel in floating-point operations. The attack convolves the given secret image with a matrix of subnormal values. The convolution step for each pixel is timed using high resolution Javascript timers. By comparing the measured time to a threshold, each pixel is classified as either black or white, effectively reconstructing the secret image.

We integrate Escort into Firefox’s convolution code⁷ and re-run the timing attack. The results (see Figure 13c) show that Escort successfully disables the timing attack.

5.5 Control- and Data-Flow Assurance

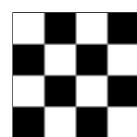

We now show that Escort’s operations do not leak information through control flow or data flow. We first use inference rules over the LLVM IR to demonstrate non-interference between secret inputs and digital side channels. We run a machine-learning attack on Escort and demonstrate that Escort successfully disables the attack.

5.5.1 Non-Interference Using Inference Rules

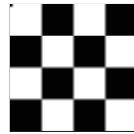

Since Escort’s elementary operations are small and simple—they are implemented using fewer than 15 lines of assembly code, they do not access memory, and they do not contain branch instructions—they are easily verified for non-interference between secret inputs and digital side channels. Using an LLVM pass that applies the inference rules from Table 6, tracking labels that can be either **L** (for low-context *i.e.* public information) or **H** (for high-context *i.e.* private information), we verify that Escort’s higher-level operations close digital side channels. This compiler pass initializes all function arguments with the label **H**, since arguments represent secret inputs.

Inference rules for various instructions dictate updates to the labels. The environment Γ tracks the label of each pointer and each address. The Escort compiler tags load

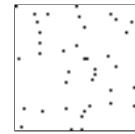

⁷Specifically, we replace three single-precision multiplication operations with invocations to the equivalent Escort function. All source code changes are limited to the code in the `ConvolvePixel()` function in `SVGFEConvolveMatrixElement.cpp`.

(a) Original image.

(b) Reconstructed image using timing attack.

(c) Reconstructed images in 3 independent, consecutive experiments after patching Firefox with Escort.

Figure 13: Results of attack and defense on a vulnerable Firefox browser using timing-channel information leaks arising from the use of subnormal floating-point numbers.

and store instructions as secret if the pointer is tainted, or public otherwise. Unlike a public load or store instruction, a secret load or store instruction is allowed to use a tainted pointer since Escort generates corresponding loads and stores to *all* statically-determined candidate values in the points-to set. The sanitization rule resets the value’s label to L and is required to suppress false alarms from Escort’s loop condition transformation. Escort’s transformed code includes instructions with special LLVM metadata that trigger the sanitization rule.

During verification, the compiler pass iterates over each instruction and checks whether a rule is applicable using the rule’s antecedents (the statement above the horizontal line); if so, it updates its local state as per the rule’s consequent (the statement below the horizontal line). If no applicable rule is found, then the compiler pass throws an error. The compiler pass processes the code for Escort’s 112 higher-level operations without throwing errors.

5.5.2 Defense Against Machine-Learning Attack

We use the TensorFlow [1] library to design a machine-learning classifier, which we use to launch a side-channel attack on the execution of the `expf()` function, where the input to the `expf()` function is assumed to be secret. Using three distinct inputs, we run this attack on the implementations in the (non-secure) Musl C library and in the (secure) Escort library. We first use the Pin dynamic binary instrumentation tool [19] to gather the full instruction address traces of both `expf()` implementations⁸. We train the TensorFlow machine-learning classifier by feeding the instruction address traces to the classifier, associating each trace with the secret input to `expf()`. We use cross entropy as the cost function for TensorFlow’s training phase. In the subsequent testing phase, we randomly select one of the collected address traces and ask the classifier to predict the secret input value.

We find that for the Musl implementation, the classifier is accurately able to predict the correct secret value from the address trace. On the other hand, for the Escort

implementation, the classifier’s accuracy drops to 33%, which is no better than randomly guessing one of the three secret input values.

6 Precision Evaluation

We examine the precision of Escort and FTFP by comparing Escort’s and FTFP’s results with those produced by a standard C library.

6.1 Comparison Using Unit of Least Precision

Methodology. We adopt an empirical approach to estimate precision in terms of Unit of Least Precision (ULP), since formal derivation of maximum ULP difference requires an intricate understanding of theorem provers and floating-point algorithms. We run various floating-point operations on 10,000 randomly generated pairs (using `drand48()`) of floating-point numbers between zero and one. For elementary operations, we compare the outputs of Escort and FTFP with the outputs of native x86 instructions. For all other operations, we compare the outputs of Escort and FTFP with the outputs produced by corresponding function from the Musl C library.

Results. We observe that Escort’s results are identical to the results produced by the reference implementations, *i.e.* the native (x86) instructions and the Musl C library. More precisely, the ULP difference between Escort’s results and reference implementation’s results is zero. On the other hand, FTFP, which computes arithmetic in fixed-point precision, produces output that differs substantially from the output of Musl’s double-precision functions (see Table 7). The IEEE 754 standard requires that addition, subtraction, multiplication, division, and square root operations are computed with ULP difference of at most 0.5. Well-known libraries compute results for most higher-level operations within 1 ULP.

⁸Using the `md5sum` program, we observe that Escort’s address traces for all three inputs are identical.

T-PUBLIC-LOAD	$P = ptset(\text{ptr})$
	$\Gamma(\text{ptr}) = \mathbf{L}$
	$m = \max_{\text{addr} \in P} \Gamma(\text{addr})$
	$\Gamma' = \Gamma[\text{val} \mapsto m]$
	$\frac{}{\Gamma \vdash \text{val} := \text{public-load } \text{ptr} : \Gamma'}$
T-PUBLIC-STORE	$\forall \text{addr} \in ptset(p)$
	$\Gamma(\text{ptr}) = \mathbf{L}$
	$m = \max(\Gamma(\text{val}), \Gamma(\text{addr}))$
	$\Gamma' = \Gamma[\text{addr} \mapsto m]$
	$\frac{}{\Gamma \vdash \text{public-store } \text{ptr}, \text{val} : \Gamma'}$
T-SECRET-LOAD	$\Gamma' = \Gamma[\text{val} \mapsto H]$
	$\frac{}{\Gamma \vdash \text{val} := \text{secret-load } \text{ptr} : \Gamma'}$

	$\frac{}{\Gamma \vdash S(x) : \Gamma'}$

Table 6: Inference rules for verifying the security of Escort’s higher-level operations.

6.2 Comparison of Program Output

Methodology. Since differences in program outputs provide an intuitive understanding of the error introduced by approximate arithmetic operations, we compare the output of the test suite of Minpack⁹, a library for solving non-linear equations and non-linear least squares problems. We generate three variants of Minpack: MINPACK-C uses the standard GNU C library, MINPACK-ESCORT uses the Escort library, and MINPACK-FTFP uses the FTFP library. We run the 29 programs in Minpack’s test suite and compare the outputs produced by the three program variants.

Results. We observe that MINPACK-ESCORT produces output that is identical to MINPACK-C’s output. We also observe that all outputs of MINPACK-FTFP differ from MINPACK-C. Specifically, 321 values differ between the outputs of MINPACK-FTFP and MINPACK-C. We ana-

Table 7: Floating-point difference for 10,000 operations on random inputs in terms of Unit of Least Precision (ULP) in **FTFP** versus **Musl C library**. Since we observe zero ULP distance between Escort’s results and Musl’s results, this table omits Escort’s results.

< 10 ⁻⁵	10 ⁻⁵ to 10 ⁻³	10 ⁻³ to 10 ⁰	10 ⁰ to 10 ³	> 10 ³
49%	9%	21%	10%	11%

Table 8: Distribution of differences in answers produced by MINPACK-FTFP and MINPACK-C. In all, 321 values differ between the outputs of the two programs.

lyze all 321 differences between MINPACK-FTFP and MINPACK-C by classifying them into the following five categories: (1) smaller than 10^{-5} , (2) between 10^{-5} and 10^{-3} , (3) between 10^{-3} and 10^0 , (4) between 10^0 and 10^3 , and (5) larger than 10^3 . As seen in Table 8, almost half of the differences (49%) are extremely small (less than 10^{-5}), possibly arising from relatively small differences between fixed-point and floating-point calculations. However, we hypothesize that differences amplify from propagation, since nearly 42% of the differences are larger than 10^{-3} .

7 Performance Evaluation

We now evaluate the end-to-end application performance impact of Escort’s floating-point library and Escort’s control flow obfuscation.

Application	Escort Overhead	Static (LLVM) Floating-Point Instruction Count
433.milc	29.33×	2,791

480.sphinx3	52.46×	629
MEAN	32.63× (geo. mean)	9,370 (arith. mean)

Table 9: Overhead of SPEC-ESCORT (SPECfp2006 using Escort operations) relative to SPEC-LIBC (SPECfp2006 using libc).

7.1 Impact of Floating-Point Library

This section evaluates the performance impact of Escort on the SPEC floating point benchmarks, as well as on a security-sensitive program $\text{SVM}^{\text{light}}$, a machine-learning classifier.

Evaluation Using SPEC Benchmarks. We use the C and C++ floating-point applications in the SPEC CPU 2006 benchmark suite with reference inputs. We generate two versions of each program—the first version (SPEC-LIBC) uses the standard C library functions, and the second version (SPEC-ESCORT) uses functions from the Escort library¹⁰. We compile the SPEC-LIBC program using the Clang/LLVM 3.8 compiler with the -O3 flag, and we disable auto-vectorization while compiling the SPEC-ESCORT program. The following results demonstrate the *worst* case performance overhead of Escort for these programs, since we transform *all* floating-point operations in SPEC-ESCORT to use the Escort library. More precisely, we do not reduce the number of transformations either using taint tracking or using SMT solvers.

Table 9 shows that Escort’s overhead is substantial, with a geometric mean of 32.6×. We expect a lower average overhead for applications that use secret data, since taint tracking would reduce the number of floating-point operations that would need to be transformed.

Evaluation Using $\text{SVM}^{\text{light}}$. To evaluate Escort’s overhead on a security-sensitive benchmark, we measure Escort’s performance on $\text{SVM}^{\text{light}}$, an implemen-

¹⁰We also ran the same programs using the FTFP library, but the programs either crashed due to errors or ran for longer than two hours, after which they were manually terminated.

Test Case	Overhead for Training	Overhead for Classification
#1	8.66×	1.34×
#2	30.24×	0.96×
#3	1.41×	1.11×
#4	12.75×	0.92×
GEO MEAN	8.28×	1.07×

Table 10: Overhead of Escort on $\text{SVM}^{\text{light}}$ program.

tation of Support Vector Machines in C, using the four example test cases documented on the $\text{SVM}^{\text{light}}$ website¹¹. We mark the training data and the classification data as secret. Before replacing floating-point computations, Escort’s taint analysis discovers all floating-point computations that depend on the secret data, thus reducing the list of replacements. We also instruct Escort to query the Z3 SMT solver to determine whether candidate floating-point computations could use subnormal operands. Escort then replaces these computations with secure operations from its library. We compile the baseline (non-secure) program using the Clang/LLVM 3.8 compiler with the -O3 flag, and we disable auto-vectorization while compiling $\text{SVM}^{\text{light}}$ with Escort. We measure the total execution time using the RDTSC instruction. Table 10 shows that Escort’s overhead on $\text{SVM}^{\text{light}}$. We observe that Escort’s overhead on $\text{SVM}^{\text{light}}$ is substantially lower than that on SPEC benchmarks. Using the md5sum program, we verify that the output files before and after transformation of $\text{SVM}^{\text{light}}$ are identical.

7.2 Impact of Control Flow Obfuscation

To compare the performance impact of Escort’s control flow obfuscation technique with that of Raccoon, we use the same benchmarks that were used to evaluate Raccoon [28], while compiling the baseline (non-transformed) application with the -O3 optimization flag. Although both Escort and Raccoon obfuscate control flow *and* data accesses, we compare the cost of control flow obfuscation only, since both Escort and Raccoon obfuscate data accesses using the identical technique. Table 11 shows the results.

We find that programs compiled with Escort have a significantly lower overhead than those compiled with Raccoon. Escort’s geometric mean overhead is 32%, while that of Raccoon is 5.32×. The worst-case overhead for Escort is 2.4× (for ip-tree).

The main reason for the vast difference in overhead is that Raccoon obfuscates branch instructions at *execution* time, which requires the copying and restoring of

¹¹<http://svmlight.joachims.org/>

Benchmark	Raccoon Overhead	Escort Overhead

dijkstra	859.65×	1.10×
GEO MEAN	5.32×	1.32×

Table 11: Performance comparison of benchmarks compiled using Raccoon and Escort. We only compare the control flow obfuscation overhead, since both Raccoon and Escort use the same technique for data access obfuscation.

the stack for each branch instruction. Since the stack can be arbitrarily large, such copying and restoring adds substantial overhead to the running time of the program. On the other hand, Escort’s code rewriting technique obfuscates code at *compile* time using basic block predicates, which enables significant performance boosts on the above benchmarks.

8 Conclusions

In this paper, we have presented Escort, a compiler-based tool that closes side channels that stem from floating-point operations. Escort prevents an attacker from inferring secret floating-point operands through the timing channel, though micro-architectural state, and also through off-chip digital side channels, such as memory address trace.

Escort uses native SSE instructions to provide speed and precision. Escort’s compiler-based approach enables it to support a significantly larger number of floating-point operations (112) than FTFP (19).

Escort’s design motivates further research into hardware support for side-channel resistant systems. For example, by allowing software to control the timing of integer instruction latencies and their pipelined execution, Escort’s guarantees could be extended to instructions beyond floating-point instructions.

Acknowledgments. We thank our shepherd Stephen McCamant and the anonymous reviewers for their helpful feedback. We also thank David Kohlbrenner for giving us the Firefox timing attack code. We are grateful to Jia Chen for providing us the pointer analysis library, and to Joshua Eversmann for help with code and discussions. This research was funded in part by NSF Grants DRL-1441009, CNS-1314709, and CCF-1453806, CFAR (one of the six SRC STARnet Centers sponsored by MARCO and DARPA), and a gift from Qualcomm.

Abstract—We present überSpark (üSpark), an innovative architecture for compositional verification of security properties of extensible hypervisors written in C and Assembly. üSpark comprises two key ideas: (i) endowing low-level system software with abstractions found in higher-level languages (e.g., objects, interfaces, function-call semantics for implementations of interfaces, access control on interfaces, concurrency and serialization), enforced using a combination of commodity hardware mechanisms and lightweight static analysis; and (ii) interfacing with platform hardware by programming in Assembly using an idiomatic style (called CASM) that is verifiable via tools aimed at C, while retaining its performance and low-level access to hardware. After verification, the C code is compiled using a certified compiler while the CASM code is translated into its corresponding Assembly instructions. Collectively, these innovations enable compositional verification of security invariants without sacrificing performance. We validate üSpark by building and verifying security invariants of an existing open-source commodity x86 micro-hypervisor and several of its extensions, and demonstrating only minor performance overhead with low verification costs.

1. INTRODUCTION

The modern hypervisor stack is, by necessity, extensible. Hypervisors not only enable the old-hat style of customization, such as modularity for device drivers, but are further extended with convenient functionality for security services such as attestation, debugging, tracing, application-level integrity and confidentiality, trustworthy resource accounting, on-demand I/O isolation, trusted path, and authorization [14], [18], [22], [49], [53], [57], [62], [64], [65], [71], [74], [75], [77], [80], [83]–[86]. Further, the overwhelming majority of the deployed hypervisor codebase is written in low-level C and Assembly, due to hardware accesses, developer familiarity, and performance requirements.

1.1. Problem – The unbridled growth of these extensible hypervisors, while enabling useful functionality,

raises significant security concerns. As the size and complexity of these systems increase – not to mention the number of extensions, which may be active in arbitrary combinations – so has the incidence of security-related bugs. Indeed exploitable bugs in extension interfaces have led to compromises in various hypervisors ranging from complex VMMs to micro-hypervisors [2], [3], [26], [27], [44]. Thus, higher assurance in the security properties offered by hypervisors is critically important.

1.2. Solution – We address this challenge by developing überSpark (üSpark), an architecture for building extensible hypervisors that: (a) is *compatible with commodity systems*; (b) enables *automated compositional verification of security properties*; and (c) produces *performant systems*. Compatibility with commodity systems is crucial to impacting developers and deployment ecosystems. üSpark supports development and verification directly at the C and Assembly source and enables access to more commodity hardware features. It is thus distinct from prior approaches that sacrifice commodity compatibility by employing new programming languages or hardware models [33], [36], [81]. Compositionality means that extensible systems can be verified modularly, rapidly, and independently as they are implemented. Specifically, when an extension is added, üSpark does not require complete system re-verification to re-establish properties. While this goal guides much work in high-level languages, achieving it for low-level languages is a significant challenge. Furthermore, it distinguishes us from verification of full functional correctness [31], [33], [43]. We focus only on security invariants – memory separation, control-flow integrity, information flow – and other extension properties that can be formulated as invariants. We verify such properties directly, compositionally, and automatically on the C and Assembly implementation. This helps bring to commodity-compatible hypervisors those on-going approaches, which offer full functional correctness, but we also enable precise reasoning on untrusted and unverified system code. Finally, the üSpark hypervisor’s performance is close to that of a commodity unverified system.

[†]In the fictional Transformers universe, the AllSpark is a powerful object capable of creating a new Transformer by bestowing ordinary machinery with sparks – the building blocks of a Transformer. In a similar vein, ÜBERSPARK bestows ordinary hypervisors with verifiable objects (ÜOBJECT) for automated compositional security analysis.

Key to the power of üSpark is the enforcement of verifiable-object abstractions to hypervisors. The basic building block is a *üobject*, which encapsulates specific system resources and provides an interface for accessing them – with a well-defined behavioral contract comprising a use manifest along with formal behavior specifications. A üobject may represent core components of a hypervisor or an extension and may be concurrent or sequential. Public methods of concurrent üobjects are invoked in parallel by multiple cores whereas sequential üobjects are implemented as monitors, guarding all method invocations via a per-üobject lock. üObjects communicate with each other via function calls.

There are two special üobjects: *prime* sets up a sane initial state, while *sentinel* ensures control-flow semantics even when üobjects with different levels of privilege and trust invoke each other. Together, they enable compositional inductive proofs of security properties expressed as invariants over sequential üobjects via source code analysis and hardware assumptions [8]. A third group of special üAPI üobjects allow access to shared resources enabling state-of-the-art tools for automatic verification of sequential C code to be soundly applied to verifying security properties, while still allowing multi-threaded high-performance applications.

In keeping with our first and second design goals, üSpark enforces verifiable-object abstractions using a combination of commodity hardware mechanisms (page-tables and de-privileging) and light-weight static analysis, leveraging off-the-shelf C99 source-code analysis and certified-compilation tools. üObjects, including prime and sentinel, are automatically and modularly verified using Frama-C [41], an industrial-strength software analysis and verification framework. We use standard and custom Frama-C plug-ins to perform static verification checks that include: per-üobject behavioral contracts (via a standard weakest-precondition plug-in); abstract variable assertions that enable behavioral asserts as well as üobject control-flow integrity (via a standard abstract-interpretation plug-in on stack frames and other variables); syntactic checks that ensure conformance with a restricted C99 syntax and logical de-privileging of üobjects (via a standard abstract syntax tree analysis plug-in); and, composition checks that enable client üobjects that share a common server üobject to compose soundly (via a custom composition-check plug-in).

üSpark also provides an idiomatic use of Assembly, called CASM, to separate it from C code during system construction. During analysis with Frama-C, the CASM code is replaced by a C99 hardware model which models key commodity hardware features. Our custom Frama-C plug-in checks that the syntactic restrictions imposed by CASM are respected by every üobject. The verified üobjects are then compiled into executable binaries. Dur-

ing üobject compilation, all C99 code is processed using the certified CompCert compiler [12] while each CASM instruction is replaced by the corresponding Assembly instruction by our custom Frama-C plugin. The CASM language is designed to ensure that the C and Assembly code operate on disjoint state. Our longer-term goal is to guarantee that the verified source code properties carry over to the binary by leveraging the C-Assembly separation and cleanly extending the bisimulation proof of the CompCert compiler to encompass hardware state and Assembly code. In addition, we aim to ensure the semantic equivalence between the hardware model and the corresponding Assembly instructions. Proving these guarantees formally appears straightforward, and need only be done once for the üSpark framework, but we leave it to future work.

The üSpark object abstraction is distinguished from other systems in that it allows many fine-grained objects in privileged mode. Static analysis enforces logical deprivileging of those objects – e.g., a hypervisor module running in host-mode ring 0 is precluded from accessing page-table structures, thereby being “logically” deprivileged – while control transfer between them does not involve a context switch, thereby significantly helping with system performance, our third design goal.

1.3. Contributions – (a) We present üSpark, an innovative architecture providing verifiable object abstractions for automated compositional verification of hypervisor security properties while targeting commodity compatibility and performance (§4,§5). (b) We use üSpark to incrementally develop and verify security properties of an existing open-source commodity x86 micro-hypervisor with multiple independent security extensions (hypervisor and extensions realized as 11 üobjects with 7001 SLoC; 5544 and 2079 lines of annotations and hardware model; §6,§7). (c) We carry out a comprehensive evaluation showcasing verification metrics, development effort and performance, and report on our experience (1 person yr; üobject verification times from 1–23 minutes with a cumulative time \approx 1hr; 2% average runtime overhead over native micro-hypervisor applications with guest performance unaffected; §8,§9).

2. A MOTIVATING EXAMPLE

To motivate and explain üSpark, we use as a running example, a hypervisor that closely corresponds to our case study. Imagine the hypervisor managing a multi-CPU guest, and supporting optional security extensions that implement various guest-specific and system-wide security properties. The hypervisor manages system devices used by itself, by extensions, and by the guest. System devices execute device firmware in parallel with the CPUs and perform DMA. The hypervisor and extensions are written in C and Assembly.

The hypervisor leverages CPU capabilities, such as memory-mapped I/O (MMIO) and legacy I/O, for system-to-device interaction; it initializes boot CPU (BSP) state; it sets up memory page tables, as well as device allocations and DMA protections (e.g., via an IOMMU); it initializes multi-CPU support via the Local Advanced Programmable Interrupt Controller (LAPIC) and activates other CPUs and sets up their memory page tables and appropriate protections. Constructing a verified hypervisor of this sort, the developers must not only build it and test it well, but also verify its code against a set of general safety properties (e.g., memory integrity) as well as functional invariants on hardware and software state (e.g., IOMMU, LAPIC, CPU states).

Consider now adding two new *verified* extensions to the hypervisor: **hyperdep**, which ensures that guest VM data pages are non-executable; and (b) **sysclog**, which ensures that every system call issued by the guest is logged via a dedicated network card to an external trusted entity on the network. In order to preserve the verified status of the system, the developers must prove that: (a) memory integrity is not violated by the extensions; (b) each extension provides its claimed property to guests configured to use it; and (c) the extensions are used in tandem by a guest if and only if they provide a well-defined compositional property (e.g., separability). This is non-trivial, since it requires the construction and verification of inductive invariants that imply the core security properties of the hypervisor, and those of enabled extensions. Also, since extensions are optional, verification must account for all possible configurations – e.g., enabling either **hyperdep**, or **sysclog**, or both – while avoiding the combinatorial blowup.

Of course, history tells us that two extensions are never enough for any extensible system. What is more, not all extensions come from the same developers or with the same pedigree. Consider, for instance, an *unverified*, strictly optional extension to the hypervisor; this might be an extension that provides essential functionality, but has not been verified, and is taken as an acceptable risk. For our example, let us use **aprveexec**, an extension that ensures that guest code pages contain only read-only, whitelisted content. As with **hyperdep** and **sysclog**, core hypervisor properties, and the properties of other extensions should not be violated by running **aprveexec**, and the risk of running **aprveexec** should only be suffered by a guest that explicitly enables it and relies on its presumed properties. Note that the guest itself, unless it is verified as rigorously as the rest of the hypervisor, is such an unverified component in the system.

3. GOALS AND ASSUMPTIONS

3.1. Goals – Our overarching goal is to enable development of performant extensible hypervisors offering pro-

ofs of wide-ranging properties on their code, including low-level memory safety, control-flow guarantees, and information flow, as well as higher-level properties such as trusted network logging (**sysclog**) and data execution prevention (**hyperdep**), going all the way up to security properties spanning both hardware and software states (IOMMU, LAPIC, network-card and CPU). Also, verification must support properties over shared system states: e.g., both **hyperdep** and **sysclog** manipulate guest memory protections via the same guest page-tables. Our design goals fall broadly in three categories.

3.1.1. Compositionality: When new components are added, or existing components changed, human re-verification effort should be limited to the changed codebase, yet it should provide guarantees about the entire system under all possible configurations.

3.1.2. Legacy Compatibility & Usability: Our development and verification approach must integrate into the existing hypervisor C and Assembly language programming ecosystem, and cover the entire source code base including commodity hardware and guest OS. We must support extensions that are unverified in order to preserve the legacy ecosystem. However, unverified code (e.g., the guest) must not violate system properties established by verified code. Our development and verification techniques must foster wider adoption by hypervisor developers. We envision that entry-level developers will rely on basic building blocks to provide simple properties while seasoned developers will harness the full verification power to provide stronger guarantees.

3.1.3. Performance: Verification must not preclude aggressive code optimizations for individual components, including extensions, and must not adversely affect runtime performance. Further, commodity guest OS on multi-core hardware must be supported.

3.2. Non-goals – We do not aim for full functional correctness (i.e., verifying that the implementation behaves exactly as specified in a high-level abstraction). This separates the concerns of showing how a complex low-level system achieves low-level formal properties from how those low-level properties refine a high-level abstract model; we focus on the former, since it is a hard and as yet open problem, whereas much on-going work tackles the latter [31], [42].

3.3. Attacker Model and Assumptions – We assume that the attacker does not have physical access to the CPU, memory, chipset or other verified extension-specific system devices (our hardware TCB). Other system devices, the guest OS, and unverified extensions are under the attacker’s control. This is reasonable since a majority of today’s attacks are mounted by malicious software or untrusted system devices. We assume that our hardware TCB is functionally correct, and we have load-time integrity, i.e., the verified hypervisor is the one

securely loaded onto the hardware at boot time. Finally, we assume that the verification tools we use are sound.

4. ÜSPARK ARCHITECTURE

We next describe our architecture, and how it addresses our goals (§3.1) via verifiable object abstractions (Fig 1)

4.1. üObjects – The basic building block in üSpark– the “üobject” – is used to contain any system component including verified and unverified hypervisor and guest blobs and system devices. Logically, a üobject is a singleton object guarding some otherwise indivisible resources (e.g., registers, memory, devices) and implementing public methods to access them. Public methods are essentially regular function signatures but can be restricted to specific callers (§4.2.1). Every üobject also has a special public method, *init*, to set up the üobject in a known-good initial state. A üobject may be concurrent or sequential. The public methods of a concurrent üobject can be invoked in parallel on multiple cores. In contrast, at most one core can invoke the methods of a sequential üobject at a time, as with a traditional monitor. When multiple cores are active, sequential execution is enforced via per-üobject locks.

Each üobject defines its functionality using C and Assembly. Assembly language for a verified üobject is written using CASM, a dialect of C in which Assembly instructions are encoded within regular C functions (CASM functions) via C-like pseudo-function calls (CASM instructions¹). For example, for the x86 instruction `movcr3` involving register `eax` there is a corresponding CASM pseudo-function called `ci_movl_eax_cr3`. Each CASM instruction pseudo-function is defined in the üSpark hardware model (§7.1.2) and bridges the shift between the reference C semantics and the hardware instructions (e.g. access to memory and to registers). During verification, each CASM instruction is replaced by the C source code from the hardware model. The resulting C-only program is verified for required properties. CASM functions are verified to respect the C application binary interface (ABI), which is crucial for the soundness of verification. During compilation, all C functions are processed via a certified compiler while each CASM instruction is replaced by the corresponding Assembly instruction. In contrast to prior code-level verification approaches (§10), CASM supports two-way nested C to Assembly calling with full device modeling. This allows using various verification techniques to prove (higher-level) properties on device states other than just memory and numeric

safety (§7.2). CASM also allows aggressive compiler optimizations of the callee C functions including inlining as per compiler specifications, resulting in optimal runtime performance (§8.3). We envision further optimizations including inlining of hand-written CASM code as part of our future work (§11.2).

Beyond defining its own functionality, a üobject is also accompanied by a behavior *contract*. This consists of a *use manifest* (§4.3) and a formal *behavior specification* of its own public interface, which guarantee that if a certain assumption is satisfied in how a public method is invoked, then a property on the return values is guaranteed to hold upon return of that method, without mention of internal üobject state.

Every üobject is held to a number of invariants, which together guarantee its adherence to the verifiable-object abstraction. These invariants include memory and (internal) control-flow integrity, so that the code can be reasoned about; and satisfaction of the formal contract, so that the contract alone may overapproximate the üobject, thereby enabling compositional verification; as well as correct initialization. The invariants are discharged via assumptions on the hardware and proofs on the source code of the üobject, and on the contract of üobjects it interacts with (§5, §7.2).

While our use of object encapsulation is similar to existing micro-kernel architectures [42] and prior capability systems [32], [63], üSpark is distinguished by privileged disaggregation, i.e., multiple verified privileged üobjects can be logically deprivileged. This enables us to achieve the sweet spot with both high performance (there is no hardware de-privileging overhead; §8.3.1) and compositional verification (privileged üobjects can be verified separately; §7.2).

4.1.1. Prime: is the first üobject to execute in a üSpark enabled hypervisor. Prime is verified to satisfy its contract which is: to set up the required system interfaces and associated policies, establish operating stacks, prepare the platform CPU cores, invoke the *init* methods of other üobjects to initialize their state, and kick-start üobject interactions.

4.2. üObject Interaction – A üobject interacts with another by invoking a public method in its interface with appropriate parameters. All verified üobjects operate on a single stack (one per CPU core) that is set up initially by the prime. Each unverified üobject uses its own, separate stack. The verifiable-object abstraction requires üobject-to-üobject control-flow integrity (otherwise returns could land at arbitrary üobject program sites, access controls would be violated, etc.). Therefore, üobjects must also be verified to use their stack correctly (another invariant). For unverified üobjects, that also means that stacks must be switched to/from the unverified üobject stack and a separate shadow stack must be maintained for storing

¹CASM syntax is similar to existing “asm” keywords supported by traditional C compilers for integrating Assembly language instructions. However, CASM provides a more principled way to integrate Assembly instructions tailored for verification while retaining performance.

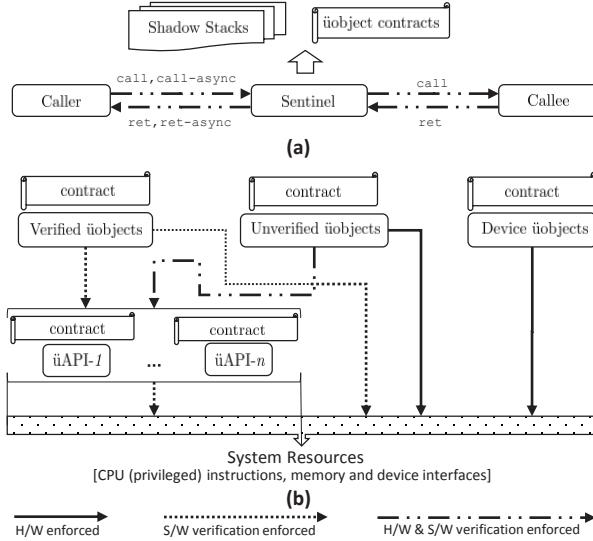

Fig. 1: überSpark: enforces verifiable object abstractions using a combination of commodity hardware and software verification mechanisms to: (a) translate synchronous (call) and asynchronous (e.g., exceptions, intercepts) inter-üobject control transfers, to establish pure function call-return semantics; and (b) establish üobject resource confinement.

return addresses during control transfers. The special *sentinel* üobject performs (verifiably) this functionality.

4.2.1. Sentinel: is a special üobject that mediates interactions among other üobjects. Thus, an invocation of a public method of a callee üobject by a caller üobject is intercepted by the sentinel and dispatched only after a number of optional runtime checks have succeeded.

These runtime checks logically ensure that the caller may invoke a given public method on the callee according to the üobject manifest (§4.3). For example, an extension can be split between a top half and a bottom half as with traditional device drivers (in our case study, **sysclog** could shed its networking code into a separate üobject, **sysclognw**, that only takes transmission requests from **sysclog**, and is the only authorized user of a separate NIC dedicated to logging), ensuring that only the top half may invoke the bottom half at runtime, while still keeping the two isolated from each other and independently verifiable. If caller and callee are both verified, then no runtime check is required, since static analysis enforces the call policy (§4.3). If one is unverified, the sentinel consults the policy dynamically and allows or rejects the call accordingly.

Besides the runtime checks, the sentinel is responsible for transferring control among üobjects. If both are verified, the control transfer is just a function call. But if either is unverified, the sentinel must employ the appropriate control-transfer method for the isolation mechanism imposed on the unverified üobject (e.g., if using ring-based isolation, switch privilege levels and stacks, marshal arguments, etc.). The sentinel may implement control transfers according to a number of concrete

ways (hardware virtual machines, software fault isolation, etc.), while still adhering to the high-level invariant for isolation. For example, in our micro-hypervisor implementation, the sentinel traverses both ring-based isolated üobjects, and hardware virtual machines (§6).

The sentinel is an üobject, so it adheres to the same invariants as regular üobjects, but it is also verified to implement its function correctly (perform the checks, properly transfer control, etc.).

4.3. üObject Resource Confinement – üSpark implements *iobject resource confinement* in which distinct system resources are: (a) managed by designated üobjects, (b) protected from access by unauthorized üobjects, and (c) regulated in their use by authorized client üobjects. Such resources include üobject local memory (code, data, stack), system memory (e.g., BIOS data, free memory), CPU state and privileged instructions, system devices and I/O regions. Every üobject includes a *use manifest* in its contract that describes which resources it may access. It is held to the property that it can only use the resources declared in its manifest.

For verified üobjects, üSpark employs a hardware model identifying CPU interfaces to system resources (e.g., I/O and designated memory instructions interface to system devices, instructions that can modify CPU model specific register states, etc.) and static analysis to ensure that access to those interfaces respects the üobject's manifest (§7). For example, **sysclog**'s manifest shows that it may access the dedicated NIC for its remote logging, and static analysis ensures that the code for **sysclog** may access only that NIC, nor can any other üobject access **sysclog**'s NIC.

In contrast, unverified üobjects are held to their use manifests via more direct enforcement mechanisms, such as hardware MMU and privilege protections (virtualization, de-privileging) and software manipulations (e.g., SFI). Unverified üobjects can also be granted direct access to exclusively held system devices so they can perform I/O without any performance overhead (e.g., a guest OS üobject is allocated all the devices except the LAPIC and **sysclog**'s network card). Device üobjects use DMA as their interface to other üobjects. üSpark uses hardware IOMMU capabilities to ensure that device üobjects are restricted to perform DMA only to designated üobject DMA memory regions.

4.3.1. üAPI üobjects: are a special set of üobjects that encapsulate shared resources over which system properties are established (§6.4). For example, guest OS üobject memory and CPU state are manipulated by multiple extensions (**hyperdep** and **sysclog**). üSpark enforces a composition check (§7.2.1), which for a given set of üAPI üobjects checks if a set of “client” üobjects are composable. Note that every üAPI üobject also performs compositability checks at runtime for invocations from

unverified üobjects. Such composability checks reason about the use-manifest portion of a client üobject’s contract, which constrains how that üobject invokes the üAPI’s public methods, ensuring some system-specific and üAPI-specific composability guarantee, such as separability. Client üobjects must satisfy the property that whenever they invoke a üAPI call, they obey their own use manifest, and üSpark discharges this property via static analysis on verified üobjects or runtime sentinel checks for unverified üobjects.

4.4. üSpark Blueprint – üSpark also defines a hypervisor *blueprint* (üBP), which a hypervisor implementation is held to. The üBP is a high-level control-flow graph that divides hypervisor execution into three phases: startup, intercept, and exception handling which can in turn be customized based on the actual number of system üobjects and their interactions (Figure 2; §6). The üBP along with our high-level proofs (§5) enables us to abstract the hypervisor, running on multi-core platform hardware with system devices and DMA, as a non-deterministic sequential program. This, in turn, allows us to prove invariant properties of üobjects, and the hypervisor as a whole, via sequential source-code verification. Further, the üBP also enforces that fragile bits of the hardware state (e.g., CPU and IOMMU) are only touched within a monitor. This, allows us to prove invariant properties encompassing hardware states and keeps our hardware model simple by precluding modeling of concurrent hardware accesses (§7.1.2).

5. ÜSPARK FORMALISM

We present a formalization of üSpark that justifies the soundness of our analysis. For brevity, we first give an overview of the formal reasoning followed by our high-level verification approach and related theorems. Full proof details can be found in our technical report [73].

5.1. üSpark Formalism Overview – üSpark reasoning relies foundationally on a set of invariants – properties that must hold throughout the execution of a üSpark hypervisor (Appendix A). The invariants are divided into üSpark system invariants and üSpark general programming invariants (those that pertain specifically to üobject C and CASM functions). Each invariant is proved by reducing it further to a set of *proof-assumptions on hardware* (PAHs) and *proof-obligations on code* (POCs) using the üSpark blueprint (üBP; Fig. 2). POCs are then discharged on all üSpark verified üobjects including the prime and sentinel using specific verification tools and techniques (§7). A hypervisor implementation is compliant with üSpark– and therefore amenable to compositional reasoning – if it satisfies all the üSpark invariants. Full details of invariant-to-PAH/POC mappings, a one-time effort, is described in [73]. At a high level, üSpark invariants ensure the hypervisor implementation follows

the üBP and that prime is correct, and the first to start in the system, and that it sets up memory protections, stacks, and CPUs, before starting other execution contexts in a well-defined state. The remaining invariants guarantee that üobjects have memory and control-flow integrity, and the sentinel properly transfers control among them, respecting the concurrent or sequential designation.

5.2. Verification Approach and Theorems – There are two tasks in verifying properties of a üSpark hypervisor: (a) showing that it obeys the üSpark invariants; and (b) showing that it obeys any hypervisor/extension-specific invariant properties. The benefit of (a) is that developers can express system-specific properties in terms of üobjects and their interactions with each other, yet verify those properties separately on each individual üobject in isolation, and on the ensemble of the behavior contracts of all üobjects, without having to perform slow verification of the combined source code for the whole code base.

Crucial to the model of üobject are CASM programs, defined below. First, we define a *CASM function* as a CompCert-C99 (CC99) function whose body consists only of a block of Assembly instructions that respect the CC99 ABI. A üobject CASM program is a CC99 program such that: (i) all Assembly code appears only in CASM functions; and (ii) these CASM functions preserve the caller C functions’ CPU register state.

Given a üobject CASM program, we are interested in verifying two kinds of properties: (1) invariant properties: whether φ holds at every state (after every instruction), and (2) individual state assertions: whether φ holds at specific program points. We can also specify assumptions (i.e., preconditions), stating that we assume φ holds when a function is called. Verification tools such as Frama-C (§7) take programs annotated with properties to be checked and decide whether the properties hold on all execution traces of the program.

We begin by stating two üSpark theorems essential for the correctness of our approach, which follow directly from the üSpark programming invariants (Appendix A).

Theorem 1 (DISJOINTCASM). *The union of üobject CASM and C functions preserve the existing semantic preservation property of the certified compiler.*

Theorem 2 (EXITSENTINEL). *üobject execution can only exit via the sentinel.*

The next theorem states that each üSpark execution is an interleaving of properly nested executions of üobjects, one on each core (a more formal definition can be found in [73]). Intuitively, it means that üobject calls and returns are properly nested except that the return of an unverified üobject can be an exception, as an unverified

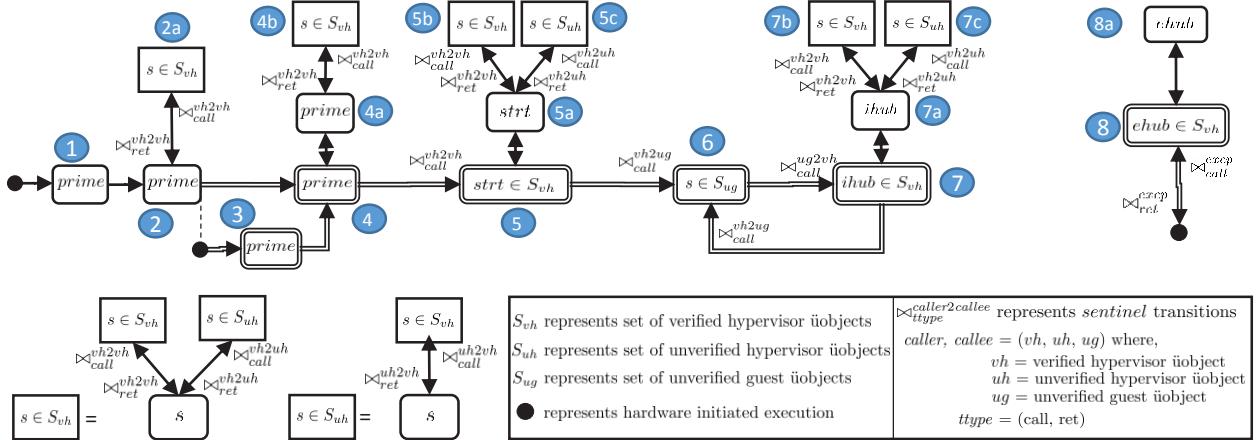

Fig. 2: üSpark Hypervisor Blueprint: startup, intercept and exception handling execution phases. Rounded boxes = üobjects; Square boxes = nested üobject calls; Arrows = intra- and inter-üobject transitions; Single-lines = serialized execution; Double-lines = concurrent execution.

üobject can lie about its return address, but will be caught by the hardware if it steps out of the üobject memory. This theorem enables us to view üSpark semantically as a concurrent object-oriented program, which is then abstracted as a non-deterministic sequential program for verification.

Theorem 3 (NESTEDCALL). Consider a legal execution π of üSpark and a sequential üobject s . The projection of π on executions of s consists of a sequence of properly nested executions of s , each on a specific core.

5.2.1. Hardware Model and Converting Assembly to C: We use C verification tools to verify CASM functions in üobjects by converting Assembly to C. In addition to general-purpose registers (which are preserved to respect the CC99 ABI) these Assembly instructions access special hardware registers (e.g., LAPIC). Let us denote the set of registers accessed by CASM functions in üSpark by \mathcal{R}_{hw} . We introduce a set of fresh C variables (denoted \mathcal{V}_{hw}), one for each register; replace each Assembly instruction accessing \mathcal{R}_{hw} by one or more CC99 statements that operate in a semantically equivalent way over \mathcal{V}_{hw} ; replace each $r \in \mathcal{V}_{hw}$ with v_r in assertions used for specifying hardware state during verification. We refer to the mapping between \mathcal{R}_{hw} and \mathcal{V}_{hw} , and the induced mapping from Assembly instructions to CC99 statements, as our *hardware model*. We assume that this mapping is correct. We refer to the CC99 function obtained by transforming a CASM function f in this manner as \tilde{f} .

5.2.2. Abstract üSpark: We abstract üobjects as a non-deterministic CC99 (NDCC99) program, i.e., a CC99 program with non-deterministic selection of values from finite sets. In particular, the abstract üSpark üBP consists of a set of abstract üobjects, where each abstract üobject \tilde{s} is obtained from the corresponding concrete üobject s by converting each function $g \in p(s)$ to an

abstract function \tilde{g} ; more concretely: by replacing all CASM functions as described above, replacing accesses to data that other cores and devices can modify by non-deterministic values, replacing a call to an unverified üobject by a call to the intercept handler üobject with non-deterministic arguments. The next theorem states that each function g in a sequential üobject refines its abstract version \tilde{g} in that for each properly nested execution of g , there is a corresponding execution of \tilde{g} . This is crucial to the soundness of our verification.

Theorem 4 (EXECREFINE). If g is a function belonging to a sequential üobject such that all Assembly code in g is in a CASM function satisfying all üSpark programming invariants, and c is any core, then for each properly nested execution τ of g on c there is a corresponding execution $\tilde{\tau} \in \llbracket \tilde{g} \rrbracket$ such that: $\tau \equiv \tilde{\tau}$, where $\tau \equiv \tilde{\tau}$ lifts the per-state equivalence to the trace.

We use C verification tools to verify POCs directly on üBP (NDCC99 programs) of üSpark. Theorem 4 allows us to lift the verification results to üobject source-code, formally stated in the following theorem (we only show the statement for invariant properties; the statement for individual state assertions is similar).

Theorem 5 (INVCOMPOSE). Given any sequential üobject s , let \tilde{s} be the üBP abstraction of s . If an invariant property φ holds on every execution of $g(\tilde{s})$, then φ is an invariant property of every execution of s .

6. ÜSPARK HYPERVISOR IMPLEMENTATION

We applied üSpark to XMHF, an open-source micro-hypervisor for the x86 32-bit hardware-virtualized platform [72]. Originally, XMHF consists of a core hypervisor and a single extension (called *hypapp*), that together implement security-specific functionality. The latest version (0.2.2) runs a Ubuntu 12.04 32-bit multi-core guest OS with the core and hypapp at the highest

privilege level and has been used to develop a wide variety of security applications [53], [74], [83], [85], [86]. Our goal is üXMHF – an incrementally developed and verified version with deprivileged components, and multiple hypapps. As a first step, we refactor XMHF into: (a) verified hypervisor (*vh*) üobjects for prime, sentinel, core, üAPIs, and verified hypapps; (b) unverified hypervisor (*uh*) üobjects for unverified hypapps; and (c) unverified guest (*ug*) üobjects for the OS (Figure 2); §8 quantifies this refactoring effort.

6.1. Core, Hypapp and Guest üObjects – We instantiate üXMHF core using three *vh* üobjects: *xcstrt* (startup), *xcihub* (handling *ug* üobject intercepts), and *xcehub* (runtime hardware exception and watchdog handling). We instantiate extensions described in §2 as separate *vh* and *uh* üobjects and add support for multiple hypapps within *xcihub*. Finally, we instantiate a *ug* üobject, *guest* for the guest OS. The *xcstrt* üobject gets control from the prime üobject (§6.2), invokes all registered hypapp üobjects for initialization, and then transfers control to *guest*. The *xcihub* üobject gets control from the sentinel upon any intercept (§6.3) and in turn invokes the hypapp üobjects for *guest* event processing. Upon intercept handling, *xcihub* resumes execution of *guest ug* üobject (Figure 2).

6.2. Prime üObject – The üXMHF boot-loader uses the GETSEC[SENTER] instruction to setup a dynamic root-of-trust and invokes the prime üobject in a hardware protected execution environment with the CPUs in a known good state and interrupts and DMA disabled.

Prime first enumerates devices and uses VT-d IOMMU to restrict their DMA to designated memory regions. It then initializes the *vh* and *uh* PAE page tables and the *ug* 2D EPT page tables for memory protections such that: (i) *vh* page tables map *vh* üobject memory regions, including MMIO, with supervisor privileges, and all *uh* and *ug* üobject memory regions as user with read-write permissions; (ii) each *uh* and *ug* page tables marks only its own region, including MMIO, as user and present; (iii) for *uh* üobjects, all *vh* üobject memory regions are marked supervisor; and (iv) for *ug* üobjects all *vh* and *uh* memory regions including MMIO are marked not-present. Prime uses disjoint CPU I/O bitmaps (which are marked supervisor within *uh* and *ug* üobject page tables) for *uh* and *ug* üobjects’ legacy I/O isolation.

Finally, for each CPU in the system, prime: (a) activates protected-mode with paging and hypervisor-mode via control registers CR0 and CR4 and the VMXON instruction; (b) sets up SYSENTER MSRs, interrupt descriptor table and VM control structure (VMCS) to transfer control to the sentinel; and (c) loads *vh* page tables in CR3 and transfers control to *xcstrt* core startup üobject.

6.3. Sentinel üObject – For *vh* to *vh* üobject control transfers, the sentinel uses an indirect JMP instruction.

The SYSEXIT and SYSENTER fast system call instructions are used *vh* to *uh* control transfers and vice-versa. In such cases, the sentinel loads the *uh* page tables into the CR3 register and transfers control to the *uh* üobject entry point (or return address via the SYEXIT instruction) at the de-privileged level. The sentinel uses the VMLAUNCH instruction for a call from a *vh* to *ug* üobject. It handles intercepts by transferring control to the *vh* *xcihub* üobject and upon return from *xcihub* resumes the *ug* üobject via the VMRESUME instruction. In both cases, it loads the *ug* üobject EPTs prior to the launch. The sentinel handles exceptions by transferring control to the *vh* *xcehub* üobject. Upon return from *xcehub* execution is resumed via the IRET instruction.

6.4. üAPI üObjects – Both the core and hypapp üobjects use üAPI üobjects to influence the *ug* üobject state. This state includes the *ug* üobject EPTs and VMCS. We implement üAPI üobjects *ugmpgtbl* and *ugcpust* which present interfaces to the *ug* üobject EPTs and VMCS respectively. We also implement an additional üAPI üobject *uhcpust* as an interface to shared CPU state between *vh* and *uh* üobjects (e.g., MSRs).

6.5. üObject Runtime Library – üObjects rely on a set of common functionality implemented in the following libraries: (a) *libuc* with memory and string functions; (b) *libucrypt* with SHA-1 functionality; (c) *libustub* with üobject entry and sentinel CASM stubs; and (d) *libuhw* for platform hardware access.

7. ÜSPARK HYPERVISOR VERIFICATION

7.1. Verification and Development Tools – We first describe the verification and development tools we use.

7.1.1. Static Analysis with Frama-C: Frama-C [41] is an industrial-strength C99 static analysis and verification toolkit, written in type-safe OCaml. It has a modular architecture and offers different plugins for distinct styles of analysis. We use the following Frama-C plugins: *Deductive verification* via Frama-C’s Weakest-Precondition (WP) plugin enables the verification of assume-guarantee behavior specifications on C functions. Those specifications are expressed in the Annotated ANSI C Specification Language (ACSL) [25] in terms of the C source variables and operations. The WP plugin verifies such ACSL specifications statically on the body of the function by discharging verification conditions via an ensemble of external SMT solvers. *Abstract interpretation* via Frama-C’s Value plugin analyzes a program using a sound abstraction of its concrete semantics. It is used to prove ACSL assertions placed in the body of the program that express partial specifications about program variables, and can be combined with deductive verification. *Abstract syntax tree (AST) analysis* via Frama-C’s AST plugin performs syntactic analysis on control-flow

graphs and ASTs to enforce syntactic restrictions, e.g., the absence of primitives like function pointers.

7.1.2. Hardware Model: We have implemented a C99 hardware model for the commodity x86 hardware-virtualized platform, by representing platform features such as CPU registers and system-device states as C variables and describing formally how the hardware (should) behave. The hardware model is a re-usable but trusted component. Our hardware model allows for iterative development, modeling only portions of the device used in proving security invariants. This design principle, coupled with serialization enforced by the üSpark architecture blueprint (§4.4), enables us to keep the hardware model simple and amenable to formal validations. Various techniques exist to validate such a hardware model [50], [58] which we plan on exploring as future work (§11).

7.1.3. üSpark Frama-C Plugins: We built üSpark-specific plugins on top of Frama-C as follows: (a) übp – enforces üSpark blueprint; (b) ühwm – embeds hardware model during verification; (c) ücasm – substitutes Assembly mnemonics corresponding to CASM instructions after verification; (d) ücc – enforces general üSpark coding rules; (e) ümf – parses üobject manifest; and (f) ücvf – performs composition check (§7.2.1). These üSpark-specific plugins do not impact the robustness of the Frama-C toolset as we do not modify the kernel or standard plugins. Further, Frama-C’s modular architecture helps us keep üSpark-specific Frama-C plugins small, simple, and amenable to manual audits to ensure correctness (§8.1).

7.1.4. Frama-C and CompCert: In keeping with our longer term goal of guaranteeing that the verified source code properties carry over to the binary, we employ the CompCert [11], [12], [46] certified C99 compiler to compile üobjects. CompCert over-specifies C99 implementation-defined and unspecified behaviors and is formally verified to produce semantically equivalent Assembly from a C99 program. Our choice of Frama-C and CompCert is further justified by their semantic compatibility. We empirically tested Frama-C against CompCert’s C99 specifications and found that both tools had the same treatment of C99 implementation-defined and unspecified behaviors. Further, both tools employ an identical byte-addressable memory model with base addresses and offsets. Therefore, they combine naturally into a powerful analysis and development workflow towards producing verified system binaries.

7.1.5. Soundness Via Weakening: We weaken our execution model in two cases to enable sound reasoning. First, since current state-of-the-art static analyzers including Frama-C largely assume sequential execution, we treat all reads to DMA memory and all memory reads by a concurrent üobject as non-deterministic, for verification

```

1 void ugmpgtbl_setentry(u32 gsid, u32 addr, u64 v) {
2 /*sysclog*/ {v=v&7; v&=~_X; v|= _R; v|=_W;}
3 /*hyperdep*/ {v=v&7; v&=~_X; v|= _R; v|=_W;}
4 /*@assert sysclog: (! (v&_X) && (v&_R) && (v&_W));*/
5 /*@assert hyperdep: (! (v&_X) && (v&_R) && (v&_W));*/
6 }

(a)
7 void ugmpgtbl_setentry(u32 gsid, u32 addr, u64 v) {
8 /* sysclog */ {v=v&7; v&=~_X; v|= _R; v|=_W;}
9 /* aprvexec */ {v=v&7; v&=~_W; v|= _R; v|=_X;}
10 /*@assert sysclog: (! (v&_X) && (v&_R) && (v&_W));*/
11 /*@assert aprvexec: (! (v&_W) && (v&_R) && (v&_X));*/
12 }

```

(b)

Fig. 3: Composition check: (a) **hyperdep** and **sysclog** üobjects both use ugmpgtbl üAPI setentry interface to set guest memory page protections in a composable manner. (b) **sysclog** and **aprveexec** both use setentry in a non-composable manner.

to soundly model interference from devices and other cores. Second, we preclude use of C function pointers and CASM indirect jump instructions, which remain challenging for current state-of-the-art static analyzers [21]. In practice (§7.2), this weakening does not stop us from verifying important security properties, since such properties are implemented via sequential üobjects using non-DMA memory.

7.2. üXMHF Verification – Verification of üXMHF consists of: (a) üobject composition check, and (b) verifying üSpark invariants (§5) and üobject local properties. Throughout this section we use *vh*, *uh* and *ug* as acronyms for verified and unverified hypervisor and unverified guest üobjects respectively.

7.2.1. üObject Composition Check: Resources accessed by multiple üobjects are guarded by üAPI üobjects (§4.3.1). Here we check that all üobjects are composable over the set of üAPIs they use. At a high level, this is checked by constructing an assertion that captures the conjunction of the possible values that the two üobjects write to a shared resource, and then verifying that this assertion is not violated. More specifically, for every üAPI üobject, an interface stub function is first created using its manifest. Next, the stub is populated with invariant definitions and assertions (if any) listed in the manifest of every *vh* and *uh* non-üAPI üobject that invokes it. Figure 3a shows an example stub for ugmpgtbl üobject setentry interface with **hyperdep** and **sysclog** hypapps enabled. Lines 2–6 are populated using the corresponding hypapp üobject manifests. Figure 3b shows the same stub with **sysclog** and **aprveexec** hypapps enabled. Finally, the assertions in the stub are verified under *non-deterministic* inputs. For example, **hyperdep** and **sysclog** both set the read, write and clear the execute bits for the memory protections of the provided guest memory-page (lines 2–3) and are therefore composable; the assertions (lines 4–6) in Figure 3a are valid. However, **sysclog** and **aprveexec** are not composable (Figure 3b) since **aprveexec** sets the execute bit while **sysclog** clears the execute bit in the protections for the provided memory-page (lines 9–

10). Note, such composition check assertions are also performed at runtime for üAPI invocations from *uh* üobjects (§4.3.1). This composition check procedure is üXMHF-specific, and a more general check is an interesting direction for future work.

7.2.2. *iObject Compositional Verification:* As we discussed in §5, we first verify üSpark invariants via a set of PAHs and specific POCs on all *vh* üobjects including the prime and sentinel. §7.2.3 describes POC verification in further detail. We then verify each of the üXMHF core, hypapp and üAPI üobjects for their local invariants. For brevity we summarize the **hyperdep** üobject verification approach here. Appendix B lists the invariants and verification approach for other üXMHF üobjects. **hyperdep** preserves the following invariant over the `ugmpgtbl` setentry üAPI: guest OS provided memory pages are marked read-write and not executable. We use deductive verification to verify the `hyperdep` üobject `activate` method to ensure that the guest page address that is passed is used as the parameter to the `ugmpgtbl` üobject `setentry` method with read, write and no-execute protections. Finally, we verify the üobject runtime library (§6.5) for memory safety including behavior specifications for the memory and string functions within `libuc`. Note, *uh* üobjects are not verified since their properties follow from üAPI invariants, ensured by our composition check (§7.2.1).

7.2.3. *POC Verification:* For brevity, we choose a sampling of POCs from a few üSpark invariants ($\text{Inv}_{\bar{u}}^4$, $\text{Inv}_{\bar{u}}^6$, $\text{Inv}_{\bar{u} \text{prog}}^6$, $\text{Inv}_{\bar{u} \text{prog}}^7$, and $\text{Inv}_{\bar{u}}^{10}$; see Appendix A and [73]) that showcase the importance of all the verification techniques described in §7.1.1. All the üSpark invariant POCs are verified using a combination of these techniques. Note that examples described below are necessary (but not sufficient since they are a sample) for the high-level proofs; for example the NESTEDCALL theorem (§5) cannot be proved if there is no non-overlapping, unity-mapped memory ($\text{Inv}_{\bar{u}}^4$) or DMA protection ($\text{Inv}_{\bar{u}}^6$).

Figure 4 shows a POC code snippet – from the *vh* üobject page-table setup function within prime – for $\text{Inv}_{\bar{u}}^4$ verified using deductive verification. ACSL *requires-assign-ensure* clause triples (lines 4–11) are used to specify function behavior. In this case they specify that every memory address in the page tables is disjoint with virtual-to-physical unity mapping. ACSL *loop invariant* clause allows specification of loops with data structure invariants (lines 17–25). Finally, ACSL *ghost variables* – C statements and variables only visible in specifications – are most notably used for modular reasoning of nested function calls. For example, line 28 invokes a support function for obtaining the memory protection of the specified memory address. This is aliased into a ghost variable which can then be used within the specification (line 29). In summary, the requires-

```

1 // @ ghost u64 gflags[SZ_PDPT*SZ_PDT*SZ_PT];

19 ...
```

Fig. 5: üSpark hardware model and proving IOMMU DMA protection.

assigns-ensures clause triplet is sufficient to represent the function behavior, and the loop invariants and ghost variables within the function are used to prove the clause triplet. ACSL is highly expressive with global and type invariants, including first-order, polymorphic, recursive and higher-order specifications [25].

Fig 5 shows a POC code snippet for $\text{Inv}_{\bar{u}}^6$ verified using abstract interpretation and the hardware model. The snippet is part of the DMA protection setup function within prime. Line 2 in Fig 5 shows üobject using a designated CASM instruction to perform device I/O to the IOMMU. The hardware model hooks this CASM instruction to the IOMMU device model if the specified I/O range falls within the IOMMU device space (lines 6–7). The IOMMU modeling then simulates the required logic based on the register accessed and value written (line 12). The hardware model also invokes the appro-

priate verification driver callbacks whenever such device registers are written to (line 12). This ensures required device state invariants. For example, assertions in lines 16–17 of the IOMMU control register callback ensure that DMA page-table protections when enabled always point to the populated DMA page tables (which are populated by the prime in a separate function not shown). This ensures that devices can only perform DMA to üobject DMA memory region. Similar techniques are used to: (a) hook designated CASM instructions for üobject access to system memory including *ug* üobject memory regions; and (b) proving intra-üobject CFI in the presence of both C and CASM functions by ensuring that CASM functions respect the C ABI and preserve callee registers and stack frames (via corresponding hardware model callbacks, assertions, and ACSL annotations).

POCs for $\text{Inv}_{\text{iprog}}^6$ and $\text{Inv}_{\text{iprog}}^7$ are verified by analysing the abstract syntax trees (AST) to preclude statements involving function pointers in C functions and to ensure CASM functions always end with a CASM `ret` instruction respectively. The POC for Inv_i^{10} is verified via CFG analysis to enforce üSpark blueprint conformance. Similar AST-based techniques are employed to: (a) embed hardware model statements, (b) substitute Assembly mnemonics, and (c) ensure soundness of the hardware model by precluding C functions from touching hardware model functions and variables and vice-versa.

8. EVALUATION

8.1. System size and Verification TCB – üXMHF is implemented in 7001 SLoC *verified* privileged code split

Fig. 7: Frama-C üSpark specific plugins are written in OCaml and build atop existing Frama-C kernel and standard plugins.

into 11 üobjects with 5544 lines of ACSL annotations and 2079 lines of hardware model (Figure 6). We also implemented an unverified hypervisor extension (**aprexec**; 199 SLoC) to illustrate how unverified and verified hypervisor üobjects interact. Depending on the properties, üobject verification takes 48 seconds to 23 minutes, and up to 1.1 GB of memory. Cumulative verification time is just over an hour, comparing favorably to related verification efforts [34]. Compositional verification enables each üobject to be (re-)verified separately. The prime üobject takes the longest to verify, but typically does not change as often as other üobjects. Decomposing prime into multiple üobjects can further reduce its (re-)verification time significantly.

Our verification TCB comprises the ACSL annotations, the hardware model (§7.1.2), and Frama-C with associated plugins. Modularity of üobject programs helps keep annotations small and feasible for manual review. Various orthogonal techniques exist to validate our hardware model [50], [58] that we plan to explore as future work. Frama-C is an industrial-strength tool used in many critical systems today [41]; we did not encounter any soundness bugs in these tools (§9). Frama-C üSpark specific plugins (totaling 1021 SLoC of OCaml; Figure 7) are modular, simple, and built upon the existing Frama-C kernel and plugins making them amenable to manual audits. Overall, our TCB compares favorably with other prior approaches (Figure 8).

8.2. Developer Effort – üXMHF was developed and verified in a year by a single system developer who was new to Frama-C/ACSL. A fraction of the time was spent adding implementation support for multiple hypapps with a greater part spent on porting to the üSpark hypervisor architecture by creating required üobjects and adding verification related harnesses and annotations. Annotation-to-code ratio (ACR) ranges from 0.2:1 to 1.6:1 (Figure 6). For üobjects whose properties rely solely on üAPI’s the ACR is small (e.g., **hyperdep**). üObjects with properties requiring functional correctness (e.g., **sysclog** and **xcihub**) have relatively larger ACR. The prime and sentinel üobjects have the highest ACR since they discharge most of the üSpark invariants.

8.3. Performance Measurements – All performance benchmarks were carried out on a Dell Optiplex 9020 with an Intel Core-i5 4590 quad-core processor with 4GB of memory. All üobjects were compiled with full compiler optimizations turned on.

8.3.1. üSpark Microbenchmarks: The cost of a CASM NULL function call is only 12 clock cycles. Sentinel

call overhead for verified-to-verified üobject transitions is 2x w.r.t NULL function call (Figure 9). This is due to control transfers to the sentinel and üobject entry points and return addresses via JMP instructions. For transitions involving unverified üobjects the sentinel overhead is broken up into: (a) software overhead such as register saving, parameter marshalling, and call-policy enforcement; and (b) hardware deprivileging overhead. As seen, segmentation and CR3-based page tables provide the lowest overheads (37x and 48x), but are still an order of magnitude larger than the verified-to-verified sentinel call overhead. Hardware deprivileging adds a significant portion (upward of 60%) to the sentinel call in this case. These overheads are comparable to existing unverified disaggregated systems and micro kernels (§10).

8.3.2. üXMHF Microbenchmarks: For purposes of micro benchmarking we measure the üXMHF `xcihub` üobject, which handles several intercepts required for guest execution. üXMHF delivers near native XMHF performance in all cases (Figure 10). We attribute the small overhead for certain intercepts to the code refactoring using üobjects.

8.3.3. üXMHF Guest Benchmarks: We execute both compute-bound and I/O-bound applications for guest benchmarking purposes. For compute-bound applications, we use the SPEC-INT 2006 suite. For

I/O-bound applications, we use the iozone (disk reads and writes with 4K block size and 2GB file size), compilebench (project compilation benchmark), and Apache web server performance (ab tool with 200,000 transactions with 20 concurrent connections). üXMHF does not affect native XMHF’s guest performance in all cases (Figure 12).

8.3.4. üXMHF Application Benchmarks: We use the hypapps described in §6.1 along with another unverified hypapp `ropdet` (which captures guest branch information for ROP detection) for hypapp performance benchmarking. We wrote a guest üobject that interacts with the hypapps to leverage their services as follows. For `sysclog`, activate syscall logging by setting the syscall code page to no-execute and perform sample syscalls. For `hyperdep`, set a data page to no-execute and perform data read and write operations on that page. For `aprveexec`, setup a code page for approved execution, and invoke the hypapp to approve and lock the page against writes, before executing a sort function on that code page. Finally, for `ropdet`, register a test function over which ROP detection is to be performed, and invoke the test function to collect branch information. Figure 11 shows the performance overhead for these hypapps compared to native XMHF without üSpark. Verified `sysclog` and `hyperdep` run close to native XMHF speeds (2% avg. overhead). Unverified `aprveexec` and `ropdet` incur higher overheads (9% and 11% respectively). The overhead is due to üAPI invariant checks (<10%) and the sentinel cost of deprivileging, shadow stack and parameter marshalling (§8.3.1).

For I/O performance benchmarks, we wrote a mix of DMA I/O (usb and net) and programmed I/O operations (disk and serial) within a hypervisor üobject. The I/O performance overhead (Figure 11) is anywhere from 1-5% with the DMA-based I/O incurring more overhead. We attribute the higher DMA-based I/O overhead to the IOMMU page tables for DMA access. Note that üSpark does not actively interpose on any I/O operations, which results in a much lower overhead. These I/O overheads also match up to existing micro hypervisor I/O architecture overheads [67], [72], [86].

9. EXPERIENCE AND LESSONS LEARNED

9.1. Frama-C – The WP plugin’s limited casting support helped detect erroneous esoteric casts, e.g., pointer

to int/u8. While the Value plugin cannot propagate states to arbitrarily large loops, the semantic unrolling option helped propagate states only for desired functions so memory/time resources can be well spent. WP loop invariants are versatile in supporting unbounded loops with nesting. WP discharges proofs more effectively when operating over single-dimensional array accesses for mutating assignments and invariants and simple statements using shift and bit-wise operators. WP also caused proof failures in certain cases with local variable aliasing of function parameters; using parameter variables directly ameliorated the issue. We did not encounter any soundness bugs in Frama-C and its plugins.

9.2. Verification Theories – Automated verification results vary by theory, e.g., Alt-Ergo and Z3 failed to discharge a few verification conditions (VC) that CVC3 handled. Frama-C’s ability to combine provers was very useful; CVC3, Z3 and Alt-Ergo together solved all the VCs generated during verification.

9.3. Annotations – ACSL is versatile in its support for writing partial specifications (e.g., memory safety of SHA-1) and assertions as well as complete specifications (e.g., page-table setup). Further, ACSL annotations use actual C variables and operations. This expressivity spectrum thus allows system programmers to easily transition into the verification domain by initially using simple assertions and function contracts (partial specifications) and iteratively mastering complete specifications.

9.4. CompCert – The C99 subset handled by CompCert suffices to implement most systems-level software constructs. However, struct bit fields with packing and alignment within struct fields are currently unsupported. We added methods with bitwise operators to pack, unpack, deconstruct, and align such variables in the sources.

10. RELATED WORK

10.1. Unverified monolithic – SELinux [66], AppArmor [1] and FBAC [59] are some examples of OS kernel modifications that add features to an existing (privileged) kernel to enforce various access control policies. Such approaches suffer from the lack of assurance and separation: a bug in an extension or the core can exist, and then affect other parts of the system arbitrarily.

10.2. Unverified disaggregation – Xen/Xoar [17] converts Xen into depriveleged partitions. NOVA [67] depriveleges everything (including VMM modules), except for a small privileged micro kernel. Safe composition of OS kernel extensions include extensible operating systems [10], [15], [20], [23], [39], [61], kernel driver isolation [13], [28], [47], [48], [69], [70], [78], interposition mechanisms [29], [35], [37], [40] and API compatibility libraries [5], [7], [9], [30], [56], [79]. Xax [19] confines untrusted application code to an ABI for accessing OS services. SGX [4] protects application code from (buggy)

privileged code. Disaggregation brings mere isolation but no formal guarantees on its own.

10.3. Verified sandboxing – SFI [52], [54], [60], [76], [82] is a software-based approach for application-level memory isolation but lacks support for low-level privileged instructions and hardware device access, which are necessary for hypervisor and its extensions. Also, SFI employs unverified binary rewriting which can change the semantics of the program and break invariants necessary for compositional verification. Singularity [36] sacrifices legacy compatibility with a complete redesign of a OS written in type-safe languages (MSIL/TAL) and uses software mechanisms to isolate processes (SIP) and supports only memory and type-safety properties.

10.4. Verified kernels – seL4 [43] verifies full functional correctness of the C implementation (7500 LOC) of the micro kernel by showing that it refines an abstract specification. Their specifications don’t support abstractions among the kernel or the different kernel modules. These interdependencies often lead to more complex invariants which are difficult to prove (20 person years). Further, seL4 does not allow adding properties using untrusted services; such additions require direct integration into the kernel and lengthy re-verification. Furthermore, there is no support for Assembly (ASM) or device states, which precludes verification of low-level code interacting with devices; (1200 C and 500 ASM SLoC remain unverified). mCertiKOS [31] follows a similar approach to seL4 but makes the abstract specification layered to reduce the interdependencies among the kernel and various extensions and makes the verification process more tractable for an admittedly stripped down version of the original CertiKOS kernel (single-core, non-preemptible custom guest OS, basic process and syscall handling). There is no hardware model and support for ASM is limited to only general-purpose registers. Adding extra system instruction support and device models does not seem trivial; even the stripped down version of the kernel has 300 C and 170 ASM SLoC unverified. This is attributed to memory model limitations of their methodology [31]. Lastly, both mCertiKOS and seL4 require the developer to write line-for-line specifications for C/ASM code in a different abstract language (Isabelle/HOL or Coq/Ocaml/Lasm) with a very steep learning curve.

The VCC project [16], [45] verifies the functional correctness of a fixed Hyper-V hypervisor codebase running a multi-CPU guest, via automated theorem proving. However, the code annotations do not support abstractions among the core hypervisor or drivers. This leads to complex invariants due to interdependencies; only 20% of the hypervisor code-base has been verified [16]. Further, their ASM verification methodology and lack of a full hardware model only allows proving memory safety and arithmetic properties for ASM functions while

precluding compiler optimizations for the corresponding C callee functions [51]. XMHF [72] employs the CBMC model checker with assertions on the C code of a micro-hypervisor to verify memory integrity. However, multiple extensions or composing other properties on top of memory integrity are unsupported. Further, that effort *assumes* interface confinement and leaves out 422 C and 388 ASM SLoC due to limitations of CBMC with large-loops and lack of a hardware model.

10.5. Verified System Stack – In Verve [81], a simplified OS and applications are verified for type and memory safety using a Hoare-style verification condition (VC) generator and automated theorem proving. Ironclad [33] extends Verve with support for higher-level application properties. High-level specifications (written in Dafny) are translated to corresponding code with VCs discharged via an automated theorem prover; the verification took 3 person-years. Verisoft [6] integrates hardware and software, with high-level specifications written in C0 (a tiny subset of C semantics) and refined down to a custom CPU semantics. The verification took 20 person-years on a simple OS with only a disk driver. System stack verification approaches, while powerful, sacrifice compositionality, legacy compatibility and performance. Any changes to kernel code and/or extension configuration requires lengthy re-verification (in person years). Further, the entire system software stack has to be re-implemented in type-safe languages such as C# and TAL (in Verve) or in high-level Dafny specifications (in Ironclad) or on a non-commodity CPU abstraction (in Verisoft). Furthermore, these approaches lack support for co-existence with unverified programs or a guest OS.

11. LIMITATIONS AND FUTURE WORK

We now discuss current limitations of our approach with pointers to future work towards bridging these gaps.

11.1. Hardware Model – Our hardware model is currently a trusted component. However, orthogonal techniques such as path-exploration lifting [50] and mechanized x86-multiprocessor semantics [58] provide a solid foundation on which we plan to build upon and validate our hardware model in the future.

11.2. CASM and Certified Compilation – Our high-level proofs depend on CompCert’s specification of the C memory and register semantics and CASM’s adherence to those semantics (discharged as invariants on the source-code and our hardware model) to ensure that the C and Assembly code operate on disjoint state. In the future, we plan on leveraging recent developments with CompCert such as the ability to compile and link multi-module source programs [68] to cleanly extend the bi-simulation proof of the CompCert compiler to encompass hardware state and Assembly code. Future work also involves proving (e.g., via bi-simulation) the

semantic equivalence between the hardware model and the corresponding Assembly instructions and demonstrating the semantic synergy between CompCert, CASM and the Frama-C kernel more rigorously for proved properties to translate to the binary.

11.3. Functional Verification – Our focus in this paper is on security invariants and trace properties and functional correctness to support such properties. We are optimistic that liveness properties and full-functional correctness are achievable future goals and not any more harder than existing approaches [31], [33], [43].

11.4. Concurrency – We have shown that a practical multi-threaded system with interesting security properties can be built by dealing with a serialized execution model and sequential verification in lieu of complex concurrent verification. However, we do realize the importance of relaxing our serialized execution model especially in high-performance computing environments and plan on leveraging source-level multi-threaded verification (e.g., Frama-C mthread plugin [24]) to address concurrency in the future.

11.5. Soundness of Tools – Similar to existing approaches, we assume that the verification tools such as Frama-C with associated plugins and back-end theorem provers such as Z3, CVC3 and Alt-Ergo are sound (§8.1,§3.3). Discharging this assumption, while a desirable goal, is currently an open and hard problem in the face of formal methods. However, seminal breakthroughs such as certified software model-checking [55] and formal verification of C static analyzers [38] give us hope that proving soundness of our verification tools will indeed be possible in the future.

11.6. Applicability – Our future work involves generalizing überSpark to a more broadly applicable framework for building compositionally verifiable systems. We are exploring the applicability of überSpark to general-purpose hypervisors (e.g., Xen and KVM), BIOS, device firmware, operating-system kernel and drivers, user-space applications and browser extensions including vertical integration among these stacked subsystems. The immediate challenges we envision there include unraveling complex data structures, supporting dynamic memory allocations and use of indirect function calls in addition to supporting some form of concurrency.

12. CONCLUSION

We presented überSpark, an innovative architecture enforcing verifiable object abstractions in low-level C and Assembly languages and leveraging them in combination with off-the-shelf C software verifiers and certifying compilers to produce high assurance hypervisors for commodity platforms. We incrementally developed and verified a commodity x86 micro-hypervisor using überSpark, and performed a comprehensive evaluation which

shows automated compositional verification with modest development effort and minimal runtime overhead.

APPENDIX A ÜSPARK INVARIANTS

ÜSpark reasoning relies foundationally on a set of invariants – properties that must hold throughout the execution of a üSpark hypervisor. The invariants are divided into üSpark system invariants (Figure 13) and üSpark general programming invariants (those that pertain specifically to üSpark üobject C and CASM functions; Figure 14). Each invariant is proved by reducing it further to a set of *proof-assumptions on hardware* (PAHs) and *proof-obligations on code* (POCs) using the üSpark blueprint (üBP; §4–Figure 2). POCs are then discharged on all üSpark verified üobjects including the prime and sentinel using specific verification tools and techniques (§7). A hypervisor implementation is compliant with üSpark– and therefore amenable to compositional reasoning – if it satisfies all the üSpark invariants. Full details including a formal model of the üSpark architecture, semantics, verification approach, associated theorem proofs and invariant-to-PAH/POC mappings can be found in our technical report [73].

$\text{Inv}_\text{ü}^1$	üSpark begins execution with the entry point of a distinguished initial “prime” üobject s_1 in single-core mode with just core 1 activated
$\text{Inv}_\text{ü}^2$	A special “asynchronous” function $\text{startcores}(s)$ activates all cores $i > 1$ and begins executing a designated üobject s immediately thereafter; all cores remain active thereafter for the system lifetime.
$\text{Inv}_\text{ü}^3$	Asynchronous control transfers (hardware interrupts, exceptions and intercepts) respect the blueprint state execution threading and transitions
$\text{Inv}_\text{ü}^4$	üObject memory regions are unity-mapped and non-overlapping
$\text{Inv}_\text{ü}^5$	üObject s accesses only its own memory
$\text{Inv}_\text{ü}^6$	üObject code, data and stack regions are DMA protected
$\text{Inv}_\text{ü}^7$	üObject code is write-protected
$\text{Inv}_\text{ü}^8$	Inter-üobject synchronous control-flow respect blueprint transitions
$\text{Inv}_\text{ü}^9$	Each core has its own stack at all times and stays within the stack limits.
$\text{Inv}_\text{ü}^{10}$	Blueprint state has state appropriate execution threading (multi-core or single-core)
$\text{Inv}_\text{ü}^{11}$	Locks behave like “memory fences”; any write preceding a call to unlock is observed by any read following the next call to lock

Fig. 13: üSpark System Invariants

$\text{Inv}_{\text{üprog}}^1$	CASM functions preserve caller registers
$\text{Inv}_{\text{üprog}}^2$	CASM functions establish local stack frame non-overlapping with incoming caller stack frame
$\text{Inv}_{\text{üprog}}^3$	CASM functions have conditional and unconditional branches local to the function
$\text{Inv}_{\text{üprog}}^4$	CASM functions establish callee incoming stack frame for calls to other C or CASM functions
$\text{Inv}_{\text{üprog}}^5$	CASM functions tear down local stack frame before returning
$\text{Inv}_{\text{üprog}}^6$	CASM functions end with return instruction
$\text{Inv}_{\text{üprog}}^7$	No function pointers in C functions
$\text{Inv}_{\text{üprog}}^8$	C and CASM functions do not write to caller stack frame params and return-address
$\text{Inv}_{\text{üprog}}^9$	CASM functions can only encode instructions within the domain of CASM instruction set
$\text{Inv}_{\text{üprog}}^{10}$	CASM non-local control transfer instructions can only be to fixed function entry points

Fig. 14: üSpark Programming Invariants

APPENDIX B VERIFICATION OF ÜXMHF ÜOBJECTS LOCAL INVARIANT PROPERTIES

We now describe our verification approach in detail for verifying the invariant properties of the üXMHF üobjects shown in Figure 15. For all the üobjects we verify via deductive verification that the üobject entry point function transfers control to the appropriate method handler for a given public method.

We verify the üAPI üobjects via abstract interpretation. For the `uhcpust` üobject we verify that the `write` method, in case of a write to MSR EFER, always preserves the EFER bits required for üSpark functionality.

üObject	Type	Invariant Property
<code>xcihub</code>	<i>vh</i>	On intercept invoke corresponding hypapp handler
<code>ugcpust</code>	<i>vh</i>	Writes to host state only by prime or sentinel
<code>uhcpust</code>	<i>vh</i>	No writes to host MSR EFER
<code>ugmpgtbl</code>	<i>vh</i>	No mapping of hypervisor memory regions
<code>hyperdep</code>	<i>vh</i>	Guest OS provided memory-pages are marked read-write and not executable
<code>sysclog</code>	<i>vh</i>	On system call trap intercept, log syscall information to network log buffer
<code>sysclognw</code>	<i>vh</i>	Log info in network log buffer and transmit buffer when full
<code>aprvexec</code>	<i>uh</i>	Guest OS approved code pages are always marked read-only and executable

Fig. 15: üXMHF Core, üAPI and Hypapp üobject invariants; *vh* = verified hypervisor üobject, *uh* = unverified hypervisor üobject

For the `ugmpgtbl` üobject we verify that the `setentry` method’s entry parameter does not fall within hypervisor memory regions. Finally, for the `ugcpust` üobject we verify that the `write` method disallows writes to any host-specific state in the guest VMCS.

For the `xcihub` üobject we employ deductive verification to verify the `main` method such that, for any given intercept a special function `hcbinvoke` is called with the intercept type and associated parameters. `hcbinvoke` is then verified to ensure that it calls all the registered hypapp üobjects for that intercept.

For the `sysclog` üobject we employ deductive verification to first verify that the `init` method invokes the `ugmpgtbl` üobject `setentry` method with the syscall page address with read and no-execute protections. We then verify that the syscall trap handler obtains syscall information via a call to the `ugcpust` üobject `read` method and stores this information to the network log buffer via a call to the `sysclognw` üobject `log` method.

We verify the `sysclognw` üobject via deductive verification and abstract interpretation. We use deductive verification to verify the `log` method to ensure that: (a) the buffer passed in as parameters is stored in the network buffer data structure, and (b) when the buffer is full, its contents are copied into the üobject `dmadata` region, buffer is reset, and the network send function is invoked. We then verify the `send` function via abstract interpretation to ensure that it programs the network card hardware to read from the `dmadata` region, transmit the buffer, and wait for end of transmission signal.

We use deductive verification to verify the `hyperdep` üobject `activate` method to ensure that the guest page address that is passed is used as the parameter to the `ugmpgtbl` üobject `setentry` method with read, write and no-execute protections.

Note, `aprvexec` (unverified) üobject is not verified since its properties follow from the `ugmpgtbl` üAPI invariants ensured by our composition check as described in §7.2.1.

Undermining Information Hiding (And What to do About it)

Abstract

In the absence of hardware-supported segmentation, many state-of-the-art defenses resort to “hiding” sensitive information at a random location in a very large address space. This paper argues that information hiding is a weak isolation model and shows that attackers can find hidden information, such as CPI’s SafeStacks, in seconds—by means of *thread spraying*. Thread spraying is a novel attack technique which forces the victim program to allocate many hidden areas. As a result, the attacker has a much better chance to locate these areas and compromise the defense. We demonstrate the technique by means of attacks on Firefox, Chrome, and MySQL. In addition, we found that it is hard to remove all sensitive information (such as pointers to the hidden region) from a program and show how residual sensitive information allows attackers to bypass defenses completely.

We also show how we can harden information hiding techniques by means of an Authenticating Page Mapper (APM) which builds on a user-level page-fault handler to authenticate arbitrary memory reads/writes in the virtual address space. APM bootstraps protected applications with a minimum-sized safe area. Every time the program accesses this area, APM authenticates the access operation, and, if legitimate, expands the area on demand. We demonstrate that APM hardens information hiding significantly while increasing the overhead, on average, 0.3% on baseline SPEC CPU 2006, 0.0% on SPEC with SafeStack and 1.4% on SPEC with CPI.

1 Introduction

Despite years of study, memory corruption vulnerabilities still lead to control-flow hijacking attacks today. Modern attacks employ code-reuse techniques [9, 34] to overcome broadly deployed defenses, like data-execution prevention (DEP) [5] and address-space layout randomization (ASLR) [30]. Such attacks are still possible primarily because of address leaks, which are used

to discover the location of useful instruction sequences, called gadgets, that can be chained together to perform arbitrary computations [34].

In response, researchers have been exploring various directions to put an end to such attacks. A promising solution is code-pointer integrity (CPI) [24] that aims to prevent the hijacking of code pointers, and therefore taking control of the program. The separation of code pointers from everything else can be done by employing hardware or software-enforced isolation [39, 42], or by *hiding* the region where pointers are stored, which is a faster alternative, than software-based isolation, when hardware-based isolation is not available. This *information hiding (IH)* is achieved by placing the area where code pointers are stored at a random offset in memory and ensuring that the pointer to that area cannot be leaked (e.g., by storing it in a register). For example, safe versions of the stack, referred to as safe stacks, that only include return addresses are protected this way both by CPI and ASLR-guard [26]. This type of IH is also adopted by other defenses [7, 15] that aim to prevent attacks by eliminating data leaks, which would enable the location of gadgets, while it has also been adopted in shadow stack [13, 41] and CFI [27, 43] research.

Reliance on information hiding is, however, problematic. Recently published work [18] developed a memory scanning technique for client applications that can survive crashes. It exploits the fact that browsers, including Internet Explorer 11 and Mozilla Firefox, tolerate faults that are otherwise critical, hence, enabling memory scanning to locate “hidden” memory areas. Before that researchers demonstrated that it was possible to locate CPI’s safe region, where pointers are stored [17], if IH is used instead of isolation.

In this paper, we reveal two new ways for defeating information hiding, which can be used to expose the “hidden” critical areas used by various defenses and subvert them. The first is technique caters to multithreaded applications, which an attacker can cause a process to spawn

multiple threads. Such applications include browsers that now support threads in Javascript and server applications that use them to handle client connections. By causing an application to spawn multiple threads, the attacker “sprays” memory with an equal number of stacks and safe stacks. As the address space fills with these stacks, the probability of “striking gold” when scanning memory increases dramatically. We incorporate this technique, which we coin *thread spraying*, in the memory scanning attack described above [18] and show that we can locate safe regions, such as the safe stacks used by CPI and ASLR-guard and parallel shadow stacks [14], in *seconds* instead of tens of minutes. The second approach utilizes bookkeeping data of various standard libraries in Linux such as the POSIX threads library and glibc. Our investigation reveals several pointers that can lead to safe regions in information kept to manage thread local storage (TLS) and thread-control blocks (TCB). Isolating these leftover pointers with a better implementation might be possible. However, at the time of writing, there is no algorithm for assessing if *all sensitive* pointers are properly removed. We therefore argue that a sound implementation which excludes all pointers that can lead to a safe region from the rest of the process is challenging.

These two new attack vectors demonstrate that it is surprisingly hard to use information hiding to replace strong isolation. Nevertheless, it is possible to further harden IH and mitigate these attacks. We propose and develop a technique that aims to shift the odds back in favor of the defender. Our solution is based on two observations: first, only a small part of the memory allocated to safe areas is actually used, and, second, safe areas are usually accessed using well-defined instrumentation-induced instruction patterns that are distinguishable from application code. For example, under CPI only a small part of the safe region and stacks allocated by CPU is actually used, and, on x86-64 architectures, the `gs` segment register and the `RSP` register are used to access the safe region and safe stacks, respectively.

Building on these observations, we introduce APM (Authenticating Page Mapper), an IH hardening strategy that verifies that all the first accesses to inactive pages in safe areas follow legitimate and unforgeable execution patterns, increasing in this fashion the entropy of IH. APM is implemented as a user-level page-fault handler, exploiting the same page “trapping” technique used by mechanisms like checkpoint/restart [31], hot patching [4], and ATL+DEP [1]. To further improve security, APM artificially inflates the virtual memory region reserved for safe areas. In particular, it decreases the number of accessible pages on a shadow stack to the minimum, but reserves many (initially inaccessible) additional pages that serve as tripwire. All illegitimate accesses to non-accessible pages trigger an alarm. Like-

wise, we offset the stack pointer by a random number of bytes.

In summary, we make the following contributions:

1. We introduce a new attack vector, called thread spraying, that reduces the entropy of information hiding techniques by creating many threads and filling up the memory space with safe areas such as safe stacks. We demonstrate the practicality of thread spraying for browsers (Firefox and Chrome) and the MySQL server, all protected with CPI’s SafeStack, and show that we can find the hidden stacks in seconds.
2. We analyze in detail the strength of information hiding techniques used in state-of-the-art defenses and show that existing solutions are not free of pointers to safe areas. Our results enable an adversary to utilize these pointers to compromise the safe area.
3. We propose a new IH hardening strategy to improve information hiding by means of a user-level page fault handler that increases the entropy significantly, makes pages accessible on demand, and vets all first-time accesses to pages—greatly increasing the probability of detecting an attack. We evaluate the solution using a variety of applications as well as the SPEC benchmarks and show that the performance impact is very low (on average 0.3% on baseline SPEC, 0.0% on SPEC with SafeStack, 1.4% on SPEC with full CPI and barely measurable in browser benchmarks).

2 Threat Model

In this paper, we assume a determined attacker that aims at exploiting a software vulnerability in a program that is protected with state-of-the-art defenses (e.g., CPI [24] or ASLR-Guard [26]), and that has the capabilities for launching state-of-the-art code-reuse attacks [11, 16, 20]. We also assume that the attacker has a strong primitive, such as an arbitrary read and write, but the arbitrary read should *not* be able to reveal the location of a code pointer that could be overwritten and give control to the attacker, *unless* the safe area is somehow discovered. Under this threat model, we discuss in Sections 3 and 4 a number of possible strategies that can leak the safe area to the attacker. Later in this paper, we propose to harden IH using a technique that can effectively protect the safe area with a small and practical overhead.

3 Background and Related Work

In the following, we review relevant work on information hiding. We discuss both attacks and defenses to provide an overview of related work and hint at potential weaknesses. We show that prior work has already bypassed

several IH approaches, but these attacks all targeted defenses that hide very large areas (such as the 2^{42} byte safe area in CPI [17], or all kernel memory [22]). It is a common belief that smaller regions such as shadow stacks are not vulnerable to such attacks [26]. Later, we show that this belief is not always true.

3.1 Information Hiding

Many new defenses thwart advanced attacks by separating code pointers from everything else in memory. Although the specifics of the defenses vary, they all share a common principle: they must prevent malicious inputs from influencing the code pointers (e.g., return addresses, function pointers, and VTable pointers). For this reason, they isolate these pointers from the protected program in a *safe area* that only legitimate code can access in a strictly controlled fashion. In principle, software-based fault isolation (SFI [39]) is ideal for applying this separation. However, without hardware support, SFI still incurs nontrivial performance overhead and many defenses therefore opted for (IH) as an alternative to SFI. The assumption is that the virtual address space is large enough to *hide* the safe area by placing it in a random memory location. Since there is no pointer from the protected program referencing explicitly the safe area, even powerful information disclosure bugs [35] are useless. In other words, an attacker could potentially leak the entire layout of the protected process *but not* the safe area.

In recent years, this topic received a lot of attention and many systems emerged that rely (at least optionally) on IH. For example, Opaque CFI [27] uses IH for protecting the so called *Bounds Lookup Table* (BLT) and Oxymoron [7] uses IH for protecting the *Randomization-agnostic Translation Table* (RaTTle). Isomeron [15] needs to keep the *execution diversifier data* secret while StackArmor [41] isolates particular (potentially vulnerable) stack frames. Finally, CFCI [44] needs to hide, when segmentation is not available, a few MBs of protected memory. Although all these systems rely on IH for a different purpose, they are vulnerable to memory scanning attacks which try to locate these regions in a brute-force manner (as shown in Section 4). Since the Authenticating Page Mapper that we propose in this paper hardens IH in general, it directly improves the security of all these systems—irrespective of their actual goal.

3.2 ASLR and Information Leaks

Arguably the best known IH technique is regular *Address Space Layout Randomization* (ASLR). Coarse-grained ASLR is on by default on all major operating systems. It randomizes memory on a per-module basis. Fine-grained ASLR techniques that additionally randomize

memory on the function and/or instruction level were proposed in the literature [19, 29, 40], but have not received widespread adoption yet.

In practice, bypassing standard (i.e., coarse-grained, user-level) ASLR implementations is now common. From an attacker’s point of view, disclosing a single pointer that points into a program’s shared library is enough to de-randomize the address space [36]. Even fine-grained ASLR implementations cannot withstand sophisticated attacks where the attacker can read code with memory disclosures and assemble a payload on the fly in a JIT-ROP fashion [35].

For kernel-level ASLR, we view kernel memory as another instance of information to hide. From user space, the memory layout of the kernel is not readable and kernel-level ASLR prevents an attacker from knowing the kernel’s memory locations. However, previous work showed that it is possible to leak this information via a timing side channel [22].

In general, leaking information by abusing side channels is a viable attack strategy. Typically, an attacker uses a memory corruption to put a program in such a state that she can infer memory contents via timings [10, 17, 33] or other side channels [8]. This way, she can even locate safe areas to which no references exist in unsafe memory.

In the absence of memory disclosures, attackers may still bypass ASLR using Blind ROP (BROP) [8], which can be applied remotely to servers that fork processes several times. In BROP, an attacker sends data that causes a control transfer to another address and then observes how the service reacts. Depending on the data sent the server may crash, hang, or continue to run as normal. By distinguishing all different outcomes, the attacker can infer what code executed and identify ROP gadgets.

In this paper, we specifically focus on safe stacks (which are now integrated in production compilers) and review recent related solutions below.

3.3 Code-Pointer Integrity (CPI)

CPI is a safety property that protects all direct and indirect pointers to code [24]. CPI splits the address space in two. The normal part and a significantly large safe area that stores all code pointers of the program. Access to the safe area from the normal one is only possible through CPI instructions. Additionally, CPI provides every thread with a shadow stack, namely SafeStack, beyond the regular stack. The SafeStack is used for storing return addresses and proven-safe objects, while the regular stack contains all other data. SafeStacks are relatively small but they are all contained in a large safe area, which is hidden at a random location in the virtual address space.

Evans et al. showed how to circumvent CPI and find the safe area by probing using a side channel [17]. Depending on how the safe area is constructed, this attack may require the respawn-after-a-crash property to pull off the attack. This property is only available in (some) servers. Moreover, it is fragile, as it is very easy for an administrator to raise an alarm if the server crashes often. In Section 4, we will introduce an attack that demonstrates how we can efficiently locate CPI’s SafeStack in the context of web browsers.

3.4 ASLR-Guard

ASLR-Guard [26] is a recent defense that aims at preventing code-reuse attacks by protecting code addresses from disclosure attacks. It does so by introducing a secure storage scheme for code pointers and by decoupling the code and data regions of executable modules. A core feature is its shadow stack that it uses to separate completely the code pointers from the rest of the data. To efficiently implement this idea, again two separate stacks are used. First, the so called AG-stack which holds only code addresses is used by function calls and returns, exception handlers, etc. The second stack is used for any data operation and ensures that all code pointers and pointers to the AG-stack are encrypted. As a result, an adversary has no way of leaking the location of code images. We discuss the security of this design in Section 4.4.

3.5 Discussion

Information hiding has grown into an important building block for a myriad of defenses. While several attacks on the randomization at the heart of IH are described in the literature, it is still believed to be a formidable obstacle, witness the growing list of defenses that rely on it. Also, since the attacks to date only managed to find secret information occupying a large number of pages, it seems reasonable to conclude, as the authors of ASLR-Guard [26] do, that smaller safe areas are not so vulnerable to probing attacks. In this paper, we show that this is not always true.

4 Breaking Modern Information Hiding

In this section, we introduce two approaches towards uncovering the hidden information. First, we show however careful developers of IH approaches are, pointers to the safe area may still be unexpectedly present in the unsafe area. While this may not represent fundamental problems, there are other issues. Specifically, we show that an attacker may significantly reduce the large randomization entropy for secret data like shadow stacks by making the program spawn many threads in a controlled way, or corrupting the size of the stacks that the program spawns.

4.1 Neglected Pointers to Safe Areas

Safe stack implementations are an interesting target for an attacker and the ability to locate them in a large virtual address space would yield a powerful attack primitive. As an example, consider CPI’s SafeStack implementation that is now available in the LLVM compiler toolchain. Recall that the safe stack implementation of CPI moves any potential unsafe variables away from the native stack to make it difficult to corrupt or to gather the exact address of that stack. Any references to the safe stack in global memory that the attacker could leak would therefore break the isolation of SafeStack. Ideally for an attacker, such pointers would be available in program-specific data structures, but we exclude this possibility here and assume that no obvious information disclosure attacks are viable. However, even though the authors diligently try to remove all such pointers, the question is whether there are any references left (e.g., in unexpected places).

For this reason, we analyzed the implementation and searched for data structures that seemed plausible candidates for holding information about the location of stacks. In addition, we constructed a way for an attacker to locate said stacks without relying on guessing. In particular, we examined in detail the *Thread Control Block (TCB)* and *Thread Local Storage (TLS)*.

Whenever the system spawns a new thread for a program, it also initializes a corresponding Thread Control Block (TCB), which holds information about the thread (e.g., the address of its stack). However, once an attacker knows the location of the TCB, she also (already) has the stack location as the TCB is placed on the newly allocated stack of the thread. An exception is the creation of the main thread where the TCB is allocated in a memory region that has been mapped, with `mmap()`, during program initialization. Since the initialization of the program startup is deterministic, the TCB of the main stack is located at a fixed offset from the base address of `mmap()` (which can be easily inferred by leaked pointers into libraries).

Moreover, obtaining the address of the TCB is often easy, as a reference to it is stored in memory and passed to functions of the `pthread` library. While not visible to the programmer, the metadata required to manage threads in multi-threaded applications can also leak the address of the thread stacks. If an attacker is able to obtain this management data, she is also able to infer the location of stacks. Note that the management data is stored in the TCB because threads allocate their own stacks, so they need to free them as well. Furthermore, we found that the TCB also contains a pointer to a linked list with all TCBs for a process, so all stacks can be leaked this way.

Additionally, TLS consists of a static portion and a dynamic portion and the system happens to allocate the static portion of the TLS directly next to the TCB. The TLS portions are managed through the Dynamic Thread Vector (DTV) structure which is allocated on the heap at thread initialization and pointed to by the TCB. Leaking the location of DTV will also reveal the stack location.

Another way to obtain the location of the stacks is using global variables in `libpthread.so`. The locations of active stacks are saved in a double linked list called `stacks_used` which can be accessed if the location of the data section of `libpthread` is known to an attacker.

In summary, our analysis of the implementation reveals that references to sensitive information (in our case safe stacks) do occur in unexpected places in practice. While these issues may not be fundamental, given the complexity of the environment and the operating system, delivering a sound implementation of IH-based defenses is challenging. All references *should* be accounted for in a production defense that regards stack locations as sensitive information. We even argue that any IH-hardening solution (like the one presented in this paper) *should* take implementation flaws of defense solutions such as CPI into account, since they are common and often not under direct control of the solution (e.g., because of external code and libraries).

4.2 Attacks with Thread Spraying

While prior research has already demonstrated that information hiding mechanisms which utilize a large safe area are vulnerable to brute-force attacks [17], our research question is: are *small* safe areas without references to them really more secure than large safe areas? More generally speaking, we explore the limitations of hiding information in an address space and discuss potential attacks and challenges.

In the following, we investigate in detail CPI’s SafeStack as an illustrative example. While the safe area itself is very large (dependent on the implementation it may have sizes of 2^{42} or $2^{30.4}$ [17, 25]), a safe stack is only a few MB in size and hence it is challenging to locate it in the huge address space. We analyze the SafeStack implementation available in the LLVM compiler toolchain. As discussed above, the safe stack keeps only safe variables and return addresses, while unsafe variables are moved to an unsafe stack. Hence, an attacker—who has the possibility to read and write arbitrary memory—still cannot leak contents of the safe stack and cannot overwrite return addresses: she needs to locate the safe stack first.

We study if such an attack is feasible against web browsers, given the fact that they represent one of the most prominent attack targets. We thus compiled and

linked Mozilla Firefox (version 38.0.5) for Linux using the `-fsanitize=safe-stack` flag of the clang compiler and verified that SafeStack is enabled during runtime. We observed that safe stacks are normally relatively small: each thread gets its own safe stack, which is between 2MB (2^{21} bytes; 2^9 pages) and 8MB (2^{23} bytes; 2^{11} pages) in size. With 28 bits of entropy in the 64-bit Linux ASLR implementation, there are 2^{28} possible page-aligned start addresses for a stack. Hence, an adversary needs at least 2^{19} probes to locate a 2MB stack when sweeping through memory in a brute-force manner. In practice, such an attack seems to be infeasible. For server applications, a brute-force attack would be detectable by external means as it leads to many observable crashes [25].

However, an attacker might succeed with the following strategy to reduce the randomization entropy: while it is hard to find a *single* instance of a safe stack inside a large address space, the task is much easier if she can force the program to generate a lot of safe stacks with a certain structure and then locate just *one* of them. Thus, from a high-level perspective our attack forces the program to generate a large number of safe stacks, a technique we call *thread spraying*. Once the address space is populated with many stacks, we make sure that each stack has a certain structure that helps us to locate an individual stack within the address space. For this, we make use of a technique that we term *stack spraying*, to spray each stack in such a way that we can later easily recognize it. Finally, via a brute-force search, we can then scan the address space and locate a safe stack in a few seconds. In the following, we describe each step in more detail.

4.2.1 Thread Spraying

Our basic insight is that an adversary can abuse legitimate functions to create new stacks, and thereby decrease the entropy. Below, we explain how we performed the thread spraying step in our attack on Firefox. Furthermore, we show that the thread spraying technique is also possible in other applications, namely Chrome and MySQL.

Thread Spraying in Firefox: Our thread spraying in Firefox is based on the observation that an attacker within JavaScript can start *web workers* and each web worker is represented as a stand-alone thread. Thus, the more web workers we start, the more safe stacks are created and the more the randomization entropy drops. Thread spraying may spawn a huge number of threads. In empirical tests on Firefox we were able to spawn up to 30,000 web workers, which leads to 30,000 stacks with a size of 2MB each that populate the address space. In our attack, we implemented this with a malicious website that consists of 1,500 iframes. Each iframe, loading

a webpage from distinct domain name, allows the creation of 20 web workers. As we will show later, forcing the creation of 2,000 or even only 200 stacks is enough in practical settings to locate one of the safe stacks reliably. Fortunately, launching this lower number of concurrent threads is much less resource intensive and the performance impact is small.

Thread Spraying in Chrome: We also tested if Google Chrome (version 45.0.2454.93) is prone to thread spraying and found that Chrome only allows around 60 worker threads in the standard configuration. An investigation revealed that this number is constrained by the total amount of memory that can be allocated for worker threads. When we request more worker threads, the Chrome process aborts as it is unable to allocate memory for the newly requested thread. However, if the attacker has a write primitive, she can perform a data corruption attack [12] and modify a variable that has an effect on the size of the memory space being allocated for worker threads. In Chrome, we found that when we decrease the value of the *global* data variable `g_lazy_virtual_memory`, Chrome will allocate less memory space for a worker thread. The less space allocated, the more worker threads it can spawn. As a result, we were able to spawn up to 250 worker threads, with a default stack size of 8MB, after locating and modifying this data variable, during runtime, in the `bss` section of the Chrome binary.

Thread Spraying in MySQL: We also evaluated the thread spraying attack on the popular MySQL database server (version 5.1.65). Interestingly, MySQL creates a new thread for each new client connection. By default, the maximum number of simultaneous connections is 151 and each thread is created with a stacksize of 256KB. With 151 threads, this amounts to 37.8MB of safe stack area in the memory space which corresponds to spawning just ~19 Firefox or ~5 Chrome worker threads. This would make it hard to perform a successful thread spraying attack. However, as in the Chrome use case above, an attacker with a write primitive can corrupt exactly those variables that constrain the number of threads—using a data-oriented attack [12]. We found that the number of threads in MySQL is constrained by the global variables `max_connections` and `alarm_queue`. Increasing them, allows an attacker to create more connections and thus more threads. Since MySQL has a default timeout of 10 seconds for connections, it may be hard to keep a high number of threads alive simultaneously, but it is just as easy to overwrite the global variables `connect_timeout` and `connection_attrib`, which contains the stack size used when creating a thread for a new client connection. In a simple test we were able to create more than 1000 threads with a stacksize of 8MB.

Protecting the Thread Limits: In some applications, such as Chrome and MySQL, there are global variables that are associated explicitly or implicitly with thread creation. For example, in Chrome there is `g_lazy_virtual_memory` which, if reduced, allows for the creation of more worker threads. Placing these variables in read-only memory can potentially mitigate the thread-spraying attacks, however, it is unclear if the application’s behavior is also affected. In Section 5 we present a defense system that protects applications from all attacks discussed in this section without relying on protecting limits associated with thread creation.

4.2.2 Stack Spraying

At this point, we forced the creation of many stacks and thus the address space contains many copies of safe stacks. Next, we prepare each stack such that it contains a signature that helps us to recognize a stack later. This is necessary since we scan in the next step the memory space and look for these signatures in order to confirm that we have indeed found a safe stack (with high probability). In analogy with our first phase, we term this technique *stack spraying*.

From a technical point of view, we realize stack spraying in our attack as follows. Recall that a safe stack assumes that certain variables are safe and this is the case for basic data types such as integers or double-precision floating point values. Moreover, Firefox stores double-precision values in their hexadecimal form in memory. For instance, the number $2.261634509803921 * 10^6$ is stored as `0x4141414141414140` in memory. Additionally, calling a JavaScript function with a double-precision float value as parameter leads to the placement of this value on the safe stack since the system considers it safe. We exploit this feature to (i) fill the stack with values we can recognize and (ii) occupy as much stack space as possible. We therefore use a recursive JavaScript function in every worker which takes a large number of parameters. We call this function recursively until the JavaScript interpreter throws a JavaScript Error (*too much recursion*). As we can catch the error within JavaScript, we create as many stack frames as possible and keep the occupied stack space alive. Of course, other implementations of stack spraying are also possible.

A thread’s initial stack space contains various safe variables and return addresses before we call the recursive function the first time. Thus, this space is not controllable, but its size does not vary significantly across different program runs. For example, in our tests the initially occupied stack space had a size of approximately three memory pages (0x3000 bytes) in each worker. A sprayed stack frame consists of the values that the recursive function retrieves as parameters and is additionally

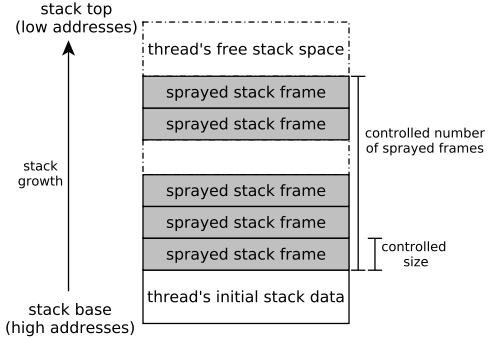

Figure 1: Memory layout of Firefox with CPI’s SafeStack filled with sprayed stack frames

interspersed with data intended to reside in a stack frame. As the size of this data is predictable, we can control the size of the stack frame with the number of parameters passed to the recursive function. While the number of sprayed stack frames is controllable via the number of recursive calls, we perform as many recursive calls as the JavaScript interpreter allows.

Figure 1 illustrates the memory layout of a sprayed safe stack after the first two phases of our attack. Since the system keeps safe variables such as double-precision floating point values on the safe stack, the memory can be filled with controlled stack frames which contain user-controlled signatures in a controllable number. Thus, we generate a repetitive pattern on the safe stacks of web workers, which leads to the following observations:

- The probability of hitting a stack during memory probing attempts increases, as the allocated space of a safe stack is filled with a recognizable signature.
- Where safe stacks are not consecutive to each other, they are separated only by small memory regions. Thus, probing with stack-sized steps is possible which reduces the number of probes even further.
- On a signature hit, we can safely read in sprayed frame sized steps towards higher addresses until we do not hit a signature anymore. This tells us that we have reached the beginning of the thread’s stack, which we can disclose further to manipulate a return address.

4.3 Scanning methodologies

During our experiments we developed multiple scanning methods fitted to different defense scenarios. In the following we shortly describe the observations leading to the development of each and evaluate them against the targeted defense measures. The first two techniques are targeted at the standard ASLR while the last technique

is also successful against an improved version. For our evaluation we assumed that an attacker can not always rely on the stacks being located close to each other. As such we implemented a simple module that can be loaded via `LD_PRELOAD` and forces each call to `mmap`, associated with a stack creation (i.e. `MAP_STACK` provided in the flags argument), to allocate memory at a random address. This means every page is a potential stack base and our first two methods are no longer effective.

4.3.1 Naïve attack on adjacent stacks

The simplest attack is based on the observation that all stacks are allocated close to each other, starting from a randomly chosen base address. To investigate this observation, we spawned 200 worker threads and performed stack spray in each one. We chose a number of parameters for the recursive function such that each sprayed stack frame had a size of one page (4096 bytes). As each thread gets a stack of 2MB in size and individual stacks are grouped closely in memory, we can treat the compound of stacks as a coherent region of approximately 2^{28} B in size. To locate a safe stack we scan towards lower addresses with 2^{28} B sized steps starting at `0x7fffffff000`, the highest possible stack base. As soon as we hit mapped memory we start searching in page sized steps for our sprayed signature. We performed this scan on three Firefox runs and needed only 16755.0 probing attempts on average (consisting of 1241.3 2^{28} B sized probes and 15513.7 page sized probes) to locate a signature and thus a safe stack. While this method is simple to implement and locates stacks with a high probability it has a chance to miss a stack region, if our single probe of a potential stack region hits the gap between two stacks by chance. While retrying with a different starting offset is possible, the next method is more fit for this purpose.

4.3.2 Optimized attack on adjacent stacks

As a variation of our previous method we modified the scanning strategy based on our observations. During three runs with Firefox, we first launched 2,000 worker threads and again performed stack spraying in each of them. Afterwards we conducted our *memory scanning*. The results are shown in Table 1. As our *memory range*, we chose `0x7FxxxxYYYYY0`, whereby the least three significant bytes are fixed (`YYYYY0`) while the fourth and fifth byte remain variable (`xxxx`). This yields a memory range of $2^{16} = 65,536$ addresses: due to 28-bit entropy for top down stack allocations, each of the chosen ranges constitutes a *potential range* for stack allocations. The probability that one of the chosen ranges is *not* a potential stack range is negligibly small.

Table 1: Memory scans in Firefox on eight different ranges after thread and stack spraying was applied- In each range, byte four and five are variable (denoted by ****). Thus, each range consists of $2^{16} = 65536$ addresses. *Mapped* denotes the number of readable addresses, *S-hits* the number of addresses belonging to the safe stack that contain our signature, and *Non S-Hits* represent safe stack addresses not containing our signature. *False S-hits* means that our signature was found at an address not being part of a safe stack.

Memory Range	Run 1				Run 2				Run 3			
	Mapped	S-Hits	Non S-Hits	False S-Hits	Mapped	S-Hits	Non S-Hits	False S-Hits	Mapped	S-Hits	Non S-Hits	False S-Hits
0x7f****000000	878	184	95	0	886	122	138	0	480	73	134	0
0x7f****202020	886	198	74	0	889	154	125	0	482	104	127	0
0x7f****404040	884	182	98	0	890	122	139	1	482	71	129	0
0x7f****606060	890	197	66	0	887	152	123	0	485	107	136	0
0x7f****808080	889	182	92	0	891	123	136	0	482	70	135	0
0x7f****a0a0a0	889	193	60	0	891	152	126	2	482	105	140	0
0x7f****c0c0c0	888	190	86	2	893	122	139	0	485	73	138	0
0x7f****e0e0e0	892	195	64	2	889	151	123	1	485	101	142	1

On average, 753.1 addresses out of 65,536 were mapped for each scan range. The ranges we tested were all potential ranges for safe stacks. 138.5 times a signature was hit, meaning we hit an address being part of a safe stack (*S-hits*). 0.4 times a signature was hit which did not belong to a safe stack. That means we hit a false positive (*false S-hits*). These false hits occur due to the signature being written by the program to non-stack regions which reside in potential stack ranges.

Choosing the three least significant bytes as a fixed value has the advantage of greatly reducing the search space: instead of probing in 2MB steps—which would be necessary to sweep the potential stack locations without a chance of missing a stack—we exploit the observation that the distance between allocated pages varies. Taking this into account leads to the conclusion that stacks are distributed in a way that gives any value of these ranges a roughly equal chance of being part of one stack. While it is not guaranteed to get a hit with this scanning approach, we cover a bigger area in less time. Additionally, in case the first run did not turn up any stack, we are free to retry the scan using a different range. With an increasing number of retries we get close to a full coverage of the scan region, but at the same time we spend less time probing a region without any stacks.

4.3.3 Locating non-adjacent stacks

With our modifications to stack ASLR the methods presented so far have a high chance of missing a stack, because they probe a memory region several times larger than a single stack. Therefore we need to assume no relation between stack locations and are forced to scan for memory of the size of a single stack. With the randomization applied we split the memory into $C = 2^{47}/2^{21} = 2^{26}$ chunks, each representing a possible 2MB stack location. We ignore the fact that some locations are already occupied by modules and heaps, as we are able to distinguish this data from stack data. Also building a complete memory map and then skipping these regions, if possible at all, would take more time than checking for a false stack hit. Without thread spraying we would be forced to

locate a single stack, which would mean we would on average need 2^{25} probes. Even with a high scanning speed this would not be feasible. However by spawning more threads we can reduce the number of probes in practice significantly.

We tested two strategies for locating these stacks. In theory every location in the address space has an equal chance of containing a stack, so scanning with a linear sweep with a step size of one stack seems like a valid approach that allows for locating all stacks eventually. However we noticed that the amount of probes required to locate any stack significantly differed from the expected amount. This can be explained by big modules being loaded at addresses our sweep reaches before any stacks. Due to this mechanic we risk sampling the same module multiple times instead of moving on to a possible stack location. As such we employed a different strategy based on a purely random selection of addresses to probe. In total we performed nine measurements and were able to locate a stack with 33,462 probes on average.

4.3.4 Crash-Resistant Memory Scanning

To verify that an attacker can indeed locate CPI’s SafeStack when conducting a memory corruption exploit against Firefox, we combined thread and stack spraying with a crash-resistant primitive introduced by recent research [18]. Crash-resistant primitives rely on probing memory while surviving or not causing at all application crashes. Using a crash-resistant primitive, it is possible to probe entire memory regions for mapped pages from within JavaScript and either receive the bytes located at the specified address or a value indicating that the access failed. In case an access violation happens, then the event is handled by an exception handler provided by the application, which eventually survives the crash. An equivalent approach is probing memory using system calls that return an error without crashing when touching unmapped memory. Equipped with crash-resistant primitives, we are free to use any strategy to locate the safe stack without the risk of causing an application crash.

We choose to scan potential ranges which may include safe stacks and hence we choose one of the ranges shown in Table 1. To counteract false positives, we employ a heuristic based on the observation that thread and stack spraying yield stacks of a predetermined size, each of which contains a large number of addresses with our signature. Determining the stack size is easily done after any address inside a stack candidate is found, because we are free to probe higher and lower addresses to locate the border between the stack’s memory and neighboring unmapped memory. Once these boundaries are known, it is possible to use memory disclosures to apply the second part of our heuristic. This heuristic is implemented in `asm.js` as an optimization. As our code is nearly directly compiled to native code it is very fast to execute. Additionally, we mainly need to index an array, with its start address set to the lower boundary, which is a heavily optimized operation in `asm.js`. If the number of entries in this array matching our sprayed values is above a certain threshold, we conclude that the memory region is indeed a stack. A further optimization we chose was to scan from higher addresses to lower addresses: we observed that stacks are usually the memory regions with the highest address in a process, which means we most likely hit a stack first when scanning from the top.

With the overhead caused by the thread and stack spraying, we are not able to use the full speed offered by the probing primitive [18]. This results in an average probing time of 46s to locate a safe stack (including the time for thread and stack spraying). The speed decrease is mainly due to the fact that we need to keep the threads and stack frames alive. Our attack achieved this by simply entering an endless loop at the end, which leads to degraded performance. However as web workers are designed to handle computational intensive tasks in the background, the browser stays responsive, but the scanning speed is affected.

Tagging safe stacks with user controlled data is not the only option for locating a safe stack. As most free stack space is zeroed out, a simple heuristic can be used to scan for zeros instead of scanning for placed markers. The advantage is that shadow stacks which separate return addresses and data are still locatable. Another possibility is to scan for known return addresses near the base of the stack: as coarse-grained ASLR randomizes shared libraries on a per-module basis and libraries are page aligned, the last twelve bits of return addresses stay the same across program runs and remain recognizable.

Without the overhead caused by the thread and stack spraying, our scanning speed is increased to 16,500 probes per second. As our approximated scanning method requires 65,536 scans per run, we are able to finish one sweep in less than 4 seconds. However, this is only the worst case estimation when not hitting any

stack. As mentioned before, we are then free to retry using a different value. On average, we are able to locate a safe stack in 2.3 seconds during our empirical evaluation.

4.4 Discussion: Implications for ASLR-Guard

In the following, we discuss the potential of a similar attack against ASLR-Guard [26]. While this defense provides strong security guarantees, it might be vulnerable to a similar attack as the one demonstrated above: as the native stack is used for the AG-stack, we can locate it using our scanning method. If the randomization of AG-stack locations is left to the default ASLR implementation (i.e., the stacks receive the same amount of entropy and potential base addresses), we can use our existing approach and only need to adjust for the size of the stacks (if different) in addition to a different scanning heuristic. This results in a longer scanning time, but if recursion can again be forced by attacker-supplied code, the resulting AG-stack will also increase in size. Combined with the thread spraying attack, we are able to generate a large number of sizable stacks. The major difference is that we are not able to spray a chosen value on the AG-stack. Further research into dynamic code generation might allow for spraying specific byte sequences as return addresses, if code of the appropriate size can be generated. While we can not evaluate the security of ASLR-Guard since we do not have access to an implementation, it seems possible to locate the AG-stack and thus disclose unencrypted code addresses.

Besides the AG-stack, there are two additional memory regions that must be hidden from an attacker. First, the code regions of executable modules are moved to a random location, but they are still potentially readable. As the *mmap-wrapper* is used, they receive an entropy of 28 bits. Since the stacks also receive the same amount of entropy, a similar attack is possible. Scanning can be done in bigger steps if a large executable module is targeted. Second, a safe area called *safe vault* is used for the translation of encoded pointers and it needs to be protected. If either of those structures is located, an adversary is able to launch a code-reuse attack. However, she would be limited to attack types that do not require access to the stack (e.g., COOP [32]). As stated in the paper, an attacker has a chance of 1 in 2^{14} to hit any of these regions with a random memory probe. This results in the possibility of exhausting the search space in roughly one second with the memory probing primitive discussed earlier. Additional steps need to be taken in order to determine the specific region hit, though. This can include signatures for code sections or heuristics to identify the safe vault.

5 Reducing the Odds for Attackers

We developed a mechanism called Authenticating Page Mapper (APM), which hinders attacks probing for the safe areas. Our mechanism is based on a user-level page fault handler authenticating accesses to inactive pages in the safe area and, when possible, also artificially inflating the virtual memory region backing the safe area.

The first strategy seeks to limit the attack surface to active safe area pages in the working set of the application. Since the working set is normally much smaller than the virtual memory size (especially for modern defenses relying on safe areas with sparse virtual memory layouts [13,24]), this approach significantly increases the entropy for the attacker. Also, since a working set is normally stable for real applications [38], the steady-state performance of APM is negligible.

The second strategy ensures an increase in the number of inactive pages not in use by the application, serving as a large trip hazard surface to detect safe area probing attacks with very high probability. In addition, since we randomize the concrete placement of the safe area within the larger inflated virtual memory space, this mitigates the impact of implementation bugs that allow an attacker to disclose the virtual (but not the physical) memory space assigned to the inflated area. Finally, this ensures that, even an attacker attempting to stress-test an application and saturate the working set of a safe area is still exposed to a very large detection surface.

Notice that deterministic isolation, and not hiding, can secure any safe area if properly applied. However, isolation in 64-bit systems has not, yet, been broadly adopted, while CPI’s SafeStack is already available in the official LLVM tool-chain [2] and there are discussions for porting it to GCC [3], as well. We therefore seek for a system that rather hardens IH, than fully protects it. To that end, APM stands as a solution until a proper replacement of IH is adopted by current defenses.

5.1 Authenticating Accesses

To authenticate accesses, APM needs to interpose on all the page faults in the safe area. Page faults are normally handled by the OS, but due to the proliferation of virtualization and the need for live migration of virtual machines, new features that enable reliable page fault handling in user space have been incorporated in the Linux kernel [6]. We rely on such features to gain control when an instruction accesses one of the safe areas to authenticate it. To authenticate the access, we rely on unforgeable execution capabilities, such as the faulting instruction pointer and stack pointer, exported by the kernel to our page fault handler and thus trusted in our threat model (arbitrary memory read/write primitives in userland). Our design draws inspiration from re-

cent hardware solutions based on instruction pointer capabilities [37], but generalizes such solutions to generic *execution capabilities* and enforces them in software (in a probabilistic but efficient fashion) to harden IH-based solutions. An alternative option is to use `SIGSEGV` handlers, but this introduces compatibility problems, since applications may have their own `SIGSEGV` handler, faults can happen inside the kernel, etc. On the other hand, `userfaultfd` [6] is a fully integrated technique for reliable page fault handling in user space for Linux.

APM is implemented as a shared library on Linux and can be incorporated in programs protected by CPI, ASLR-Guard, or any other IH-based solution by preloading it at startup (e.g., through the `LD_PRELOAD` environment variable). Upon load, we notify the kernel that we wish to register a user-level page-fault handler for each of the process’s safe areas (i.e., using the `userfaultfd` and `ioctl` system calls).

When any of the safe area pages are first accessed through a read or write operation, the kernel invokes the corresponding handler we previously registered. The handler obtains the current instruction pointer (RIP on x86-64), the stack pointer, the stack base, and the faulting memory address from the kernel, and uses this information to authenticate the access. Authentication is performed according to defense-specific authentication rules. If the memory access fails authentication, the process is terminated. In the other cases, the handler signals the kernel to successfully map a new zero page into the virtual memory address which caused the page fault.

To support CPI and SafeStack in our current implementation, we interpose on calls to `mmap()` and `pthread_create()`. In particular, we intercept calls to `mmap()` to learn CPI’s safe area. This is easily accomplished because the safe area is 4TB and it is the only such mapping that will be made. Furthermore, we intercept `pthread_create()`, which is used to initialize thread-related structures and start a thread, to obtain the address and size of the safe stack allocated for the new thread. In the following subsections, we detail how we implement authentication rules for CPI and SafeStack using our execution capabilities.

5.2 CPI’s Authentication Rules

To access a safe area without storing its addresses in data memory, CPI (and other IH-based solutions) store its base address in a CPU register not in use by the application. However, as the number of CPU registers is limited, CPI relies on the segmentation register `gs` available on x86-64 architectures to store the base address. The CPI instrumentation simply accesses the safe area via an offset from that register. Listing 1 shows an example of a safe area-accessing instruction generated by CPI.

```
mov    %gs:0x10(%rax),%rcx
```

Listing 1: x86-64 code generated by CPI to read a value from the safe area.

Since `gs` is not used for any other purpose (it was selected for this reason) and the instrumentation is assumed to be trusted, APM authenticates accesses to the CPI safe area by verifying that the *instruction pointer* points to an instruction using the `gs` register. Therefore, since the attacker needs to access the safe area before actually gaining control of the vulnerable program, only legitimate instructions part of the instrumentation can be successfully authenticated by APM.

5.3 SafeStack’s Authentication Rules

Similar to CPI’s safe area, SafeStack’s primary stack (safe stack) is also accessed through a dedicated register (RSP on x86-64 architectures) which originally points to the top of the stack. When new values need to be pushed to it, e.g., due to a function call, the program allocates space by subtracting the number of bytes needed from RSP. This occurs explicitly or implicitly through the `call` instruction. Hence, to authenticate safe stack accesses, APM relies on the *stack pointer* (RSP) to verify the faulting instruction accesses only the allocated part of the stack. The latter extends from the current value of RSP to the base of the safe stack of each thread. We also need to allow accesses the red zone on x86-64.

5.4 Inflating the Safe Area

We inflate safe areas by allocating more virtual address space than it is needed for the area. For example, when a new safe stack is allocated, we can request 10 times the size the application needs. The effect of this inflation is that a larger part of the address space becomes “eligible” for memory-access authentication, amplifying our detection surface. Inflation is lightweight, since the kernel only allocates pages and page-table entries after a page is first accessed.

We implement our inflation strategy for SafeStack (CPI’s safe region is naturally “inflated” given the full memory shadowing approach used). To inflate thread stacks, our `pthread_create()` wrapper sets the stack size to a higher value (using `pthread_attr_setstacksize()`). For the main stack, initialized by the kernel, we implement inflation by increasing the stack size (using `setrlimit()`) before the application begins executing. Similar to CPI, we rely on the `mmap()`’s `MAP_NORESERVE` flag to avoid overcommitting a large amount of virtual memory in typical production settings.

To randomize the placement of each safe stack within the inflated virtual memory area, we randomize the initial value of RSP (moving it upward into the inflated area) while preserving the base address of the stack and the TCB in place. Since the base address of each stack is saved in memory (as we describe in Section 4), a memory leak can exfiltrate its base address. Our randomization strategy can mitigate such leaks by moving the safe stack working set to a random offset from the base address and exposing guided probing attacks to a large trip hazard surface in between.

6 Evaluation

In this section, we report on experimental results of our APM prototype. We evaluate the our solution in terms of performance, entropy gains (reducing the likelihood attackers will hit the target region), and detection guarantees provided by APM coped with our inflation strategy (authenticating memory accesses to the target region and raising alerts).

We performed our experiments on an HP Z230 machine with an intel i7-4770 CPU 3.40GHz and running Ubuntu 14.04.3 LTS and Linux kernel v4.3. Unless otherwise noted, we configured APM with the default inflation factor of 10x. We repeated all our experiments 5 times and report the median (with little variations across runs).

Performance To evaluate the APM’s performance we run the SPEC2006 suite, which includes benchmarks with very different memory access patterns. For each benchmark, we prepared three versions: (1) the original benchmark, denoted as *BL* (Baseline), (2) the benchmark compiled with CPI’s SafeStack only, denoted as *SS*, and (3) the benchmark compiled with full CPI support, denoted as *CPI*. Table 2 presents our results. Note that `perlbench` and `povray` fail to run when compiled with CPI, as also reported by other researchers [17]. Therefore, results for these particular cases are excluded from the table.

Not surprisingly, the overhead imposed by APM in all benchmarks and for all configurations (i.e., either compiled using SafeStack or full CPI) is very low. The geometric mean performance overhead increase is only 0.3% for *BL+APM*, 0.0% for *SS+APM* and 1.4% *CPI+APM*.

To confirm our performance results, we evaluated the APM-induced overhead on Chrome (version 45.0.2454.93) and Firefox (version 38.0.5) by running popular browser benchmarks—also used in prior work in the area [21, 23]—i.e., sunspider, octane, kraken, html5, balls and linelayout. Across all the benchmarks, we observed essentially no overhead (0.01% and 0.56% ge-

Table 2: SPEC CPU 2006 benchmark results. We present the overhead of hardening state-of-the art defenses with APM. BL and SS refer to *baseline* and *safe stack* (respectively), and CPI refers to CPI’s safe area.

ometric mean increases on Chrome and Firefox, respectively). These results confirm that, while APM may introduce a few expensive page faults early in the execution, once the working set of the running programs is fully loaded in memory, the steady-state performance overhead is close to zero. We believe this property makes APM an excellent candidate to immediately replace traditional information hiding on today’s production platforms.

Entropy Gains With APM in place, it becomes significantly harder for an adversary to locate a safe area hidden in the virtual address space. To quantify the entropy gains with APM in place, we ran again the SPEC2006 benchmarks in three different configurations, including a parallel shadow stack [14] other than SafeStack and full CPI. We present results for a parallel shadow stack to generalize our results to arbitrary shadow stack implementations in terms of entropy gains. A parallel shadow stack is an ideal candidate for generalization, since its shadow memory-based implementation consumes as much physical memory as a regular stack, thereby providing a worst-case scenario for our entropy gain guarantees.

For each configuration, we evaluated the entropy with and without APM in place and report the resulting gains. The entropy gain is computed as $\log_2(VMM/PMM)$, where VMM is the Virtual Mapped Memory size (in pages) and PMM is the Physical Mapped Memory size (in pages). To mimic a worst-case scenario for our en-

tropy gains, we measured PMM at the very end of our benchmarks, when the program has accessed as much memory as possible resulting in the largest resident set (and lowest entropy gains). Table 3 presents our results. Once again, as also reported by other researchers [17], perlbench and povray are excluded from the CPI configuration.

As expected, our results in Table 3 show that lower stack usage (i.e., lower PMM) results in higher entropy gains. Even more importantly, the entropy gains for CPI-enabled applications are substantial. In detail, we gain 11 bits of entropy even in the worst case (i.e., xalancbmk). In other cases, (e.g., bzip2) the entropy gains go up to 28 bits of entropy.

We find our experimental results extremely encouraging, given that, without essentially adding overhead to CPI’s fastest (but low-entropy) implementation, our techniques can provide better entropy than the slowest (probabilistic) CPI implementation [25]. SafeStack’s entropy gains are, as expected, significantly lower than CPI’s, but generally (only) slightly higher than a parallel shadow stack. In both cases, the entropy gains greatly vary across programs, ranging between 2 and 11 bits of entropy. This is due to the very different memory access patterns exhibited by different programs. Nevertheless, our strategy is always effective in nontrivially increasing the entropy for a marginal impact, providing a practical and immediate improvement for information hiding-protected applications in production.

Table 3: Entropy gains with our defense. VMM, PMM, EG, and DG refer to *Virtual Mapped Memory*, *Physical Mapped Memory*, *Entropy Gains* and *Detection Guarantees* (respectively). VMM and PMM are measured in number of pages. EG is given by $\log_2(VMM/PMM)$. DG is given by $(1 - PMM/(VMM * \text{inflation_factor})) * 100$, where the *inflation_factor* is set to default 10x for stacks and 1x for the already huge CPI's safe region. GP stands for *giga pages*, i.e., $1024 * 1024 * 1024$ regular pages. A regular page has a size of 4096 bytes.

Detection Guarantees Table 3 also illustrates the detection guarantees provided by APM when coped with the default 10x inflation strategy. The detection guarantees reflect the odds of an attacker being flagged probing into the inflated trip hazard area rather than in any of the safe pages mapped in physical memory. As shown in the table, APM offers very strong detection guarantees across all our configurations. Naturally, the detection guarantees are stronger as the size of the inflated trip hazard area (i.e., $VMM * \text{inflation_factor} - PMM$) increases compared to the resident size (i.e., PMM). The benefits are, again, even more evident for CPI's sparse and huge safe area, which registered 100% detection guarantees in almost all cases. Even in the worst case (i.e., *xalancbmk*), CPI retains 316,838 trip hazard pages at the end of the benchmark, resulting in 99.97% detection guarantees.

To lower the odds of being detected, an attacker may attempt to force the program to allocate as many safe area physical pages as possible, naturally reducing the number of trip hazard pages. We consider the impact of this scenario in Firefox, with a JS-enabled attacker spraying the stack to bypass APM. Figure 2 presents our results for different inflation factors assuming an attacker able to spray only the JS-visible part of the stack (1MB) or the entire stack to its limit (2MB). As shown in the figure, in both cases, APM provides good detection guarantees for reasonable values of the inflation factor and up to 95% with a 20x inflation (full spraying setting). Even in our default configuration, with a 10x inflation, APM offers adequate detection guarantees in practice (90% for the full spraying setting).

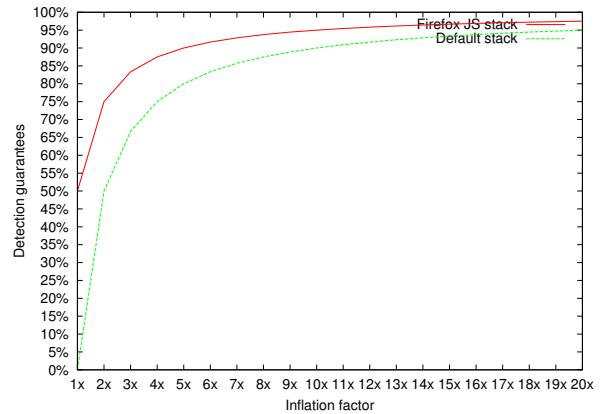

Figure 2: Effect of stack spraying (JS-visible or default stack) on our detection guarantees (DGs) across different inflation factors.

Limitations APM aims at hardening IH, but does not guarantee that a defense based on IH is fully protected against arbitrary attacks. Defenses that rely on IH should properly isolate the safe area to preserve the integrity and/or confidentiality of sensitive data. In the absence of strong (e.g., hardware-based) isolation, however, APM can transparently raise the bar for attackers, since it can offer protection without programs being aware of it (no re-compilation or binary instrumentation is needed). Nevertheless, certain attacks can still reduce the entropy and the detection guarantees provided by APM. For example, an attacker may be able to locate the base address of an inflated safe area by exploiting an implementation flaw or the recent allocation oracle side channel [28].

While the entropy is reduced, the trip hazard pages still deter guided probing attacks in the inflated area. However, if an implementation flaw or other side channels were to allow an attacker to leak a pointer to an active safe area page in use by the application (e.g., RSP), APM would no longer be able to detect the corresponding malicious access, since such page has already been authenticated by prior legitimate application accesses.

7 Conclusion

Information hiding is at the heart of some of the most sophisticated defenses against control-flow hijacking attacks. The assumption is that an attacker will not be able to locate a small number of pages tucked away at a random location in a huge address space if there are no references to these pages in memory. In this paper, we challenge this assumption and demonstrate that it is not always true for complex software systems such as Mozilla Firefox. More specifically, we examined CPI’s SafeStack since it is considered to be the state-of-the-art defense. In a first step, we analyzed the implementation and found that there were still several pointers to the hidden memory area in memory. An attacker can potentially abuse a single such pointer to bypass the defense. More seriously still, the protection offered by high entropy is undermined by thread spraying—a novel technique whereby the attacker causes the target program to spawn many threads in order to fill the address space with as many safe stacks as possible. Doing so reduces the entropy to the point that brute-force attacks become viable again. We demonstrated the practicality of thread spraying by way of an attack against Firefox, Chrome and MySQL, protected with CPI’s SafeStack.

To mitigate such entropy-reducing attacks, we propose an IH hardening strategy, namely APM. Based on a user-space page fault handler, APM allows accessing of pages on demand only and vets each first access to a currently guarded page. The additional protection provided by the page fault handler greatly improves the pseudo-isolation offered by information hiding, making it a concrete candidate to replace traditional information hiding in production until stronger (e.g., hardware-based) isolation techniques find practical applicability. Most notably, our approach can be used to harden existing defenses against control-flow hijacking attacks with barely measurable overhead.

Abstract

ASLR is no longer a strong defense in itself, but it still serves as a foundation for sophisticated defenses that use randomization for pseudo-isolation. Crucially, these defenses hide sensitive information (such as shadow stacks and safe regions) at a random position in a very large address space. Previous attacks on randomization-based information hiding rely on complicated side channels and/or probing of the mapped memory regions. Assuming no weaknesses exist in the implementation of hidden regions, the attacks typically lead to many crashes or other visible side-effects. For this reason, many researchers still consider the pseudo-isolation offered by ASLR sufficiently strong in practice.

We introduce powerful new primitives to show that this faith in ASLR-based information hiding is misplaced, and that attackers can break ASLR and find hidden regions on 32 bit and 64 bit Linux systems quickly with very few malicious inputs. Rather than building on memory accesses that probe the allocated memory areas, we determine the sizes of the *unallocated holes* in the address space by repeatedly allocating large chunks of memory. Given the sizes, an attacker can infer the location of the hidden region with few or no side-effects. We show that allocation oracles are pervasive and evaluate our primitives on real-world server applications.

1 Introduction

While Address Space Layout Randomization (ASLR) by itself no longer ranks as a strong defense against advanced attacks due to the abundance of memory disclosure bugs [1], it is still an essential foundation for more sophisticated defenses that use randomization to provide fast pseudo-isolation. Specifically, these defenses hide important sensitive information (such as shadow stacks [2], safe regions [3], or redirection tables [4]) at a random position in a very large address space. The un-

derlying and crucial assumption is that an attacker is not able to detect the location of the hidden regions.

Thus, the strength of all these defenses hinges entirely on the ASLR-provided obscurity of the hidden region. Our research question is whether such trust in the randomization schemes of modern systems like Linux is justified. In particular, we show that it is not, and introduce powerful new primitives, *allocation oracles*, that allow attackers to stealthily break ASLR on Linux and quickly find hidden regions on both 32-bit and 64-bit systems.

Randomization for information hiding Most operating systems today employ coarse-grained ASLR [5] which maps the different parts of the process (the stack, heap, and `mmap` region) in random locations in memory. The amount of randomness determines the strength of the defense. As an extreme example, the entropy for the `mmap` base on 32-bit Linux is as low as 8 bits, which means that the region can start at 256 possible locations in memory. This is well within range of a relatively stealthy brute-force attack. On 64-bit machines, however, the entropy of the `mmap` region on Linux is 28 bits and brute forcing is no longer considered practical. Unfortunately, whatever the granularity and entropy, address space randomization is vulnerable to information disclosure attacks. For example, in the absence of additional defenses and given a single code pointer, attackers can easily find other code pointers and eventually enough code to stitch together a code reuse attack [1].

However, powerful new defenses have evolved that still rely on randomization, but this time for the purpose of hiding a secret region of memory in a large address space [2, 3, 4]. Typically, they ensure the confidentiality and integrity of code pointers (such as return addresses, function pointers, and VTable pointers) [3, 6]. As manipulating a code pointer is vital for an attacker to take control of the program, preventing unauthorized access to code pointers also prevents such attacks. Thus, instead of storing code pointers in the program code, the heap, or

the stack, they place them in an *isolated* memory region. For instance, some defenses store the return addresses on an isolated “shadow” stack. Such defenses work as long as attackers cannot access the isolated region.

While it is possible to isolate these regions using techniques such as Software Fault Isolation (SFI) [7, 8], most existing solutions adopt cheaper ASLR-based *pseudo-isolation*—presumably for performance reasons or since commodity hardware-supported fault isolation can dramatically limit the size of the address space [9]. In other words, they resort to *information hiding* by placing the region at a random location in a very large virtual (and mostly inaccessible) address space and making sure that no pointers to it exist in regular memory.

The role of ASLR in information hiding is quite different to its use in countering code-reuse attacks directly, since even a strong *read* or *write* primitive ceases to be trivially sufficient for breaking the defense. Specifically, hiding all sensitive pointers forces attackers to probe the address space repeatedly (with the number of probes proportional to the size of the address space) and risk detection from crashes [10], or other observable events [11]. While Evans et al. [12] show that problematic implementations relying on huge hidden regions are still vulnerable to crashless probing attacks, more advanced defenses are not [6]. Indeed, the many new defenses that rely on information hiding show that ASLR is widely considered to offer strong isolation.

Allocation oracles Unlike previous approaches, our attack does not revolve around probing valid areas of allocated memory. Instead, we introduce new primitives to gauge the size of the *holes* in the address space. The key idea is that once an attacker knows the sizes of the holes, she can infer the start of the hidden regions. In other words, even if all the pointers into the hidden regions have been removed, the sizes of the unallocated parts of the address space “*point*” into the hidden regions.

To gauge the sizes of the holes, we introduce *allocation oracles*: information disclosure primitives that allow an attacker to allocate large chunks of memory repeatedly and thus probe for the possible sizes of the largest hole in the address space. In most cases, she can use binary search to find the exact size after a handful of probing attempts. The pre-conditions for allocation primitives are the ability to make repeated, arbitrarily large memory allocations, and to detect the success or failure of such allocation attempts. For instance, the simplest oracle might be the length field in a protocol header that controls the amount of memory a server allocates for a request [13]. More reliably, the attacker may corrupt a value in memory that is later used as an allocation size. Assuming the attacker can distinguish between success and failure of the allocations, this primitive operates as

an allocation oracle. We will show that such cases are common in real-world server programs.

Allocation oracles come in two main forms. *Ephemeral* allocation oracles perform allocations that have a short lifetime. For instance, a server which allocates memory for a client request and frees it after sending the reply. Ephemeral allocation oracles are the most effective in detecting the hidden regions. In the absence of ephemeral allocation oracles, we may find *persistent* allocation oracles. In this case, the allocation is permanent. This property alone makes attacks harder, but not impossible. In this paper, we present exploitation techniques and examples using either kind of oracle, as well as a powerful combination of the two. This combination allows an attacker to disclose the location of small hidden regions *arbitrarily located* in an *arbitrarily large* address space with *no crashes* or other detection-prone side effects.

Contributions We make the following contributions:

- We introduce new types of disclosure primitives, termed *allocation oracles*. Unlike existing primitives, allocation oracles do not work by accessing memory addresses, but instead probe the address space for “holes”. We describe primitives for both ephemeral and persistent allocations, and show how to combine them to break information hiding.
- We describe a methodology to assist an attacker in easily discovering both ephemeral and persistent allocation primitives in real programs. We show that such primitives are very common in practice. When real-world instances of our primitives are imperfect, we show how an attacker can exploit *timing side channels* to mount effective attacks.
- We show that our primitives can be exploited to mount end-to-end disclosure attacks on several real-world server programs. Our attacks render ASLR ineffective even on 64-bit (or larger) systems and show that an attacker can quickly locate hidden regions of existing defenses with little or no trace.

Organization We introduce the threat model in Section 2. Section 3 provides the necessary background for our attacks, presented in Section 4. We then describe our methodology for discovering memory allocation primitives (Section 5) and evaluate their availability and the effectiveness of the proposed attacks in Section 7. Finally, we discuss the implications for the defense mechanisms that rely on ASLR for information hiding (Section 7.6), consider mitigations (Section 8), place our attacks in the context of related work (Section 9), and draw conclusions in Section 10.

2 Threat model and assumptions

The attacks presented in this paper apply to programs that contain vulnerabilities, but are, nevertheless, protected using state-of-the-art defenses. The sensitive data, vital for the correct operation of the defense, is isolated in a hidden region by means of information hiding. Hardware-based isolation, realized with segmentation on 32 bit x86 architectures, is not available. These assumptions correspond to some of the most advanced anti-exploitation defenses for x86-64 today [3]. Note that we assume an *ideal* information hiding implementation, i.e., all sensitive information is in a hidden region at a truly random location in a large virtual address space and the code that performs this pseudo-isolation, as well as the defense itself, contain no faults. In addition, we assume that the separation of sensitive and non-sensitive data is perfect; the process memory holds no references to the hidden region, and following pointers from non-sensitive regions can never lead to pointers into the hidden region.

We further assume an attacker with arbitrary memory read and write primitives. In other words, the attacker can read or write any byte in the virtual address space. However, we consider that all sensitive data, which could allow an attacker change the control flow of the program in order to execute arbitrary code, is hidden in the hidden region. Therefore, although the attacker can read any byte in memory, she cannot probe the address space by brute force without incurring program crashes or other noticeable events with high probability.

We assume that the target application runs on a modern Linux system with memory overcommit. This is a common configuration in many production systems, either because of the pervasive use of virtualization technologies [14], or because this is required or explicitly recommended for popular and complex services, Redis [15] and Hadoop [16] among others. We also generally consider (real-world) applications that either handle allocation failures appropriately or do not crash in a way that triggers a re-randomization (e.g., by forking and using `execve` to replace the worker process image) when the allocation request cannot be serviced. The goal of the attacker is to carefully utilize memory oracles to poke holes into the information hiding and reveal the location of the hidden region.

3 Background

In this section, we illustrate the organization of a typical process' virtual memory address space. While most of the discussion is based on Linux-based operating systems, we present fairly generic address space organization principles which apply to other systems as well. Un-

Hole	Min	Max	Entropy ¹
A	130,044GiB	131,068GiB	28 bits
B	1GiB	1,028GiB	28 bits
C	4KiB	4GiB	20 bits

Table 1: Virtual memory hole ranges for a 64-bit position-independent executable (PIE) on Linux.

derstanding the memory layout of processes is vital for comprehending the mechanics of memory allocation oracles, detailed in the following sections.

The default address space of a typical x86_64 position-independent executable (PIE) on Linux (kernel version 3.14.7 used as a reference) is depicted in Figure 1. The system randomly selects an address which serves as the starting offset of the process' `mmap` space. In kernel concepts, this is a per-address-space `mmap_base` variable. Shared objects, including the PIE executable itself, are allocated in this virtual memory-mapped area, which extends towards lower addresses. Figure 1 also illustrates several *holes* (unmapped regions) fragmenting the address space. Such holes have different purposes and semantics.

To support typical dynamic memory allocations, the process relies on a separate [`heap`] space, at the lowest level managed by `brk/sbrk` calls. As the stack grows down on x86, the heap is naturally designed to grow up towards the stack. The size of the hole between these two regions is randomized. The stack, in turn, is located at a random offset from the end of the user address space (i.e., at `0x7fffffffffffff`), giving rise to another variable-sized hole at the top.

To protect against trivial exploitation of NULL pointer dereferences by the kernel [17], processes are not allowed to map or access addresses ranging from zero up to an administrator-configurable limit (i.e., `vm.mmap_min_addr`, which defaults to 64KiB). Additionally, the small hole between the stack and VDSO is typically less than 2MiB. In less than 1% of the invocations, the VDSO object will end up either adjacent to the stack or adjacent to the linker object. In both cases, the layout is effectively the same, except that the small random hole may not be present.

In practice, the uncertainty in the layout of the address space is dominated by the sizes of the large hole from `vm.mmap_min_addr` to the end of the `mmap` space (hereafter referred to as hole A), the hole between the stack and heap (named B) and the hole covering the top of the user address space (named C). While there may be holes between the loaded shared objects, those are normally of a known (fixed) size. The sizes of these holes are all uniformly distributed in the ranges shown in Table 1.

¹Calculated under the assumption that the distributions are indepen-

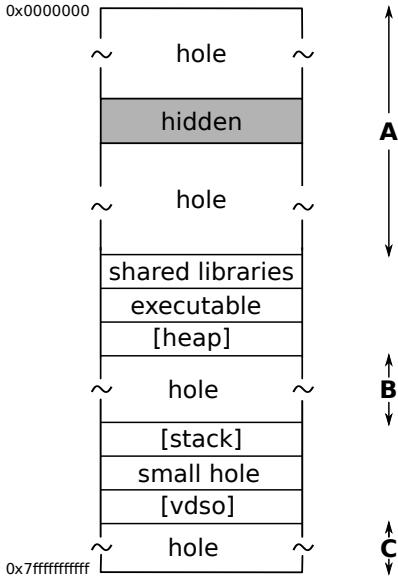

Figure 1: Virtual memory address space layout for a 64-bit position-independent executable (PIE) on Linux.

4 Memory Allocation Oracles

In this section, we thoroughly discuss the mechanics of two memory-allocation oracles, which can dramatically reduce the entropy of ASLR for accurately locating a hidden region in the virtual address space. The oracles can be realized through an *ephemeral allocation primitive* (EAP) and a *persistent allocation primitive* (PAP), respectively. Both primitives can be triggered by attacker-controlled input, say an HTTP request in a typical web server, and force a legitimate program path to allocate virtual memory with attacker-controlled size. By repeatedly using such primitives and monitoring the behavior of the target program (e.g., the error code in a HTTP response message), the attacker can infer the size of *holes* (unallocated space) in the virtual memory address space and learn key properties on its layout.

Whenever an EAP is used, the reserved virtual memory is released shortly after allocation (e.g., a short-lived per-request buffer), giving the attacker the opportunity to probe the target program multiple times. As detailed later, this allows an attacker to leak the size of the largest hole in the virtual memory address space and reduce the entropy of ASLR up to a *single* bit. The PAP, in turn, is based on reserving long-lived memory (e.g., a key-value store entry) and can be used in combination with the EAP to counteract the last bit of entropy or, by itself, to significantly reduce the entropy of ASLR.

dent. Any dependence naturally reduces the entropy.

4.1 Crafting primitives

The *ephemeral allocation primitive* (EAP) is available when a program allows *attacker-controlled input* to force the allocation of a short-lived memory object with an *attacker-controlled size*. In other words, the lifetime of the object must be such that the object is deallocated in a short amount of time (or by an attacker-controlled action, e.g. closing the connection that the object is associated with).

Even if an attacker induces the program to allocate a huge memory object of arbitrary size, such an allocation will succeed as large allocation operations typically result in an `mmap` system call. Thanks to demand paging, the system call returns right after reserving the required amount of virtual memory address space. The assignment of physical memory pages (page frames) to a virtual memory area, and even the population of the page tables, is only performed when a page is accessed for the first time. Hence, as long as the program does not immediately try to access all of the allocated virtual memory range, little physical memory is used and execution continues normally. This allows an attacker monitoring the program output to detect a *positive side effect* and verify that the corresponding address space was successfully reserved.

When the allocation size is larger than the amount of available virtual memory address space, however, such allocations will fail, typically causing the program to enter error-handling logic to return a particular error code (e.g., HTTP’s 500) to the client. This allows an attacker monitoring the program output to detect a *negative side effect* and verify that the allocation failed.

Other than monitoring program behavior for side effects, the attacker needs to fulfill two requirements to craft an EAP. First, the attacker needs to find an input which induces the program to allocate a short-lived memory object. This is, in practice, straightforward, since most programs allocate objects as part of their input-handling logic and release them afterwards. Second, the attacker needs to coerce the program to use an attacker-controlled size for the target object. While exploiting a naive program neglecting to set limits on the resources it will reserve (for instance, on the buffer size per client) is an option, in many cases the size of an allocation is calculated based on long-lived values which are stored in memory. As a result, an attacker in our threat model can rely on an arbitrary memory write vulnerability to corrupt one of those values and effect a memory allocation of a chosen size to craft an EAP. An example is an attacker able to corrupt a `buff_size` or similar global variable to control the size of a target allocation instance, a very common scenario in practice. In later sections, we substantiate this claim with empirical evidence on real-

world applications and present a methodology that can assist an attacker in the fast discovery of our primitives (Section 5).

To craft a *persistent allocation primitive* (PAP), an attacker can similarly abuse allocation instances and corrupt allocation sizes. The only difference is that a PAP relies on long-lived memory objects whose lifetime is not under attacker control. For example, a server program maintaining long-lived memory objects in a cache (spanning across several input requests) is amenable to a PAP, provided the attacker can control the allocation size. Oftentimes, however, the attacker can leverage the same primitive to obtain both an ephemeral and a persistent allocation primitive. For example, the common case of attacker-controlled allocations associated with individual client connections allow an attacker to craft either an EAP (when using nonpersistent connections) and a PAP (when using persistent connections) in a fully controlled way.

4.2 Breaking IH using the EAP

Many modern defenses depend on *information hiding* (IH) in order to protect a sensitive area which contains, for example, code pointers. We now discuss how a crafted EAP can reveal the *hidden* area (or hidden object), with few or even zero program crashes [10] and other detection-prone events [11] (hereafter, simply “crashes”). We discuss how an attacker can hide her traces even further (certainty of no crashes) in the next subsection. Here, we describe a simplified attack assuming that the defense randomizes the location of the hidden object within the largest available memory region. This assumption is fairly often verified in practice, given that if all holes in the address space are uniformly considered for hosting the hidden object, the largest hole (A) is, on average, 261 times more likely to be selected than the second largest hole. We later lift this and other assumptions on the address space organization in Section 4.3.

Once the hidden object is created, the hole size (A) is split into two new hole sizes, a large (L) and a small (S) one.² Assuming a random placement of a hidden object of size H in A , the bounds of L and S are $L_{min} = (A_{min} - H)/2$, $L_{max} = A_{max}$, $S_{min} = 0$, $S_{max} = (A_{max} - H)/2$. Hence, the distributions for the sizes L and S overlap. However, since in any given instance $L > S$ and, assuming the hidden object H is reasonably smaller than A , L is now the largest hole in the address space. Hence, an attacker can quickly identify L using EAP-based binary search (formalized in Algorithm 1, Appendix A). In detail, at each binary search iteration, the attacker performs a single EAP invocation for a given allocation size and

²For brevity, we omit explicit discussion of the case where $L = S$, which does not deviate from the common case where $L > S$.

observes its positive or negative side effects to select the allocation size for the next iteration. When the search completes, the attacker learns the largest allocation size and thus L . There can never be any confusion while we are performing the binary search for L as, if an allocation cannot be satisfied from the larger hole, it can certainly not be satisfied by the smaller one.

Since the hidden object is equally likely to have been placed below or above the midpoint of A , there’s is a 50% chance that L is the lower hole size. In this case, the location of the hidden object is precisely known: the base address of the hidden object is exactly located at `vm.mmap_min_addr+L`.

If L refers to the hole located higher than the hidden object, the uncertainty in the placement of the hidden object is the same as the uncertainty in the size of A . However, we can calculate the location of the hidden object based on the location of the `mmap` region. Given the interlinking of heap, stack, and code objects [18, 6, 1, 19], an attacker armed with an arbitrary memory read primitive can transitively explore allocated objects and discover the lowest memory mapped address. For example, in a typical quiescent application with a predictable memory layout, an attacker may simply leak `__libc_start_main`’s return address off the stack and immediately locate all the other virtual memory areas (VMAs) in the `mmap` region. Once the lowest memory mapped address `mmap_bottom` is known, the attacker can again deduce the location of the hidden object: its base address is exactly located at `mmap_bottom-L`.

Hence, the only uncertainty remaining is in the ordering of the two L - and S -sized holes, i.e., a *single* bit of entropy. In other words, an attacker probing the address space with an arbitrary memory read primitive has a 50% chance of discovering the hidden object on the first try and a 100% chance if she can tolerate a single invalid memory access. Even for nonforking server programs, if a process eventually gets restarted (either manually or automatically) with different randomization, the attacker has a 75% chance of guessing the hidden object’s location correctly after one crash, 87.5% with two crashes, 93.75% with three crashes and so on. While this attack is already fast and stealthy with great chances of going unnoticed in most practical settings, we show how to improve it even further without a single crash in the next subsection.

4.3 Using both the EAP and the PAP

When, in addition to the EAP, the attacker is in a position to employ a PAP as well (as it is often the case in practice), she can reliably break information hiding with no application crashes. In addition, she can locate the hidden object regardless of the original hole it was ran-

domly placed in (lifting our original assumptions). For simplicity, let us first consider the case of a hidden object placed somewhere in the middle of A , such that L and S are the first and second largest hole sizes in the address space. To recover L , the attacker begins by executing the EAP-only attack in Section 4.2. Subsequently, she can simply use the PAP to perform a L -sized allocation and eliminate the largest (L -sized) hole from the process' address space. Finally, she can repeat the same EAP+PAP strategy on the now largest allocation size in the address space to recover S and fill the remaining (S -sized) hole.

Since A is now completely hole-free, an attacker armed with an arbitrary memory primitive can reliably probe for the hidden object in the two possible locations in A and eliminate the remaining uncertainty. In detail, if the L -sized hole was at the beginning of the address space (and has now been filled by the PAP allocation), a read from `vm.mmap_min_addr+S` will be accessing zero-filled pages. If the S -sized hole was at the beginning of the address space, in turn, a read from `vm.mmap_min_addr+S` will be accessing pages containing data from the hidden object. In either case, by combining the EAP and the PAP, the attacker can easily disclose the location of the hidden object with no risk of crashes, quickly and stealthily exhausting information hiding's entropy.

Let us now reconsider our original assumption. In the general (if unlikely, for practical reasons³) case, the hidden object might be placed in a hole other than A . However, this is hardly a problem for an attacker armed with both the EAP and PAP. Such a zero-knowledge attacker can simply start with a single iteration of the EAP+PAP attack to fill the largest hole in the address space, then move to the second largest, and so on, until she can infer enough knowledge to first locate the hidden object's owning hole and then its location. For example, if the first largest possible hole identified is `sizeof(A)`, the attacker can learn the object is placed in either B or C . If the second largest possible hole identified is `sizeof(B)`, the attacker can learn the object is placed in C . At that point, she can perform the A -style EAP+PAP attack introduced earlier and locate the object with no crashes.

We note that exhausting the virtual address space with our iterative EAP+PAP attack strategy is not a concern in real-world scenarios. First, legitimate program allocations are normally satisfied by allocator arenas which rarely need to be extended during steady-state operations. In addition, the location of a target hidden object can in practice be determined without exhausting all the available holes. For example, an attacker could infer the location of a hidden object in A by only filling the L -sized hole and reliably reading from `vm.mmap_min_addr+L`.

³Placing the hidden object between stack and heap may impose unexpected limits on the growth of an application's data.

4.4 Using only the PAP

When allocations have to be persistent (e.g., only the PAP is available or the EAP has less desirable side effects), there are two main difficulties. First, given what we know about the hole size distributions, there might be multiple holes which can satisfy a request, but, without knowing their actual sizes, we cannot always tell which hole an allocation came from. Second, when an allocation succeeds, even if we know which hole it came from, we learn that that hole is at least as large. Contrary to the EAP though, we cannot retry a larger allocation size since we cannot "undo" the allocation.

An example serves to demonstrate. Suppose we start with the typical layout of a PIE executable (Table 1). Let us say we attempt an allocation of 130,500GiB and the allocation succeeds. The allocation was necessarily satisfied from hole A . We now have a lower bound on the size of A , yet we would like to find out its exact size. However, if we try to allocate a value in the range of 0-568GiB and the allocation succeeds, we cannot know whether the space was reserved in hole A or hole B as their size distributions now overlap.

We have designed and implemented a novel attack strategy which significantly reduces the uncertainty in the sizes of the holes. Our algorithm tracks the maximum allocatable size, as well as the allocated size, for each hole in what constitutes a *state*. Our approach then relies on two insights. First, it is highly preferential to probe using allocation sizes that can only be satisfied by a single hole. Second, when forced to perform an allocation which could have been satisfied from more than one hole, we need to fork and keep track of multiple states to model each feasible configuration of the holes in the targeted address space.

Building on these insights, our algorithm follows a cost-driven strategy to allow an attacker to select an optimal tradeoff between the number of allocation attempts and the entropy reduction obtained. We quantify this tradeoff in Section 7.5 and refer the interested reader to Appendix B for a detailed walkthrough of the formalized algorithm.

4.5 A more powerful EAP-only attack

Section 4.2 detailed how to locate the hidden object when it was placed in the largest address space hole (A). We then lifted this restriction by making use of the PAP in Section 4.3. An alternative way of stealthily probing for holes other than the largest one using the EAP only (when no PAP is available), is to try and trigger more than one EAP simultaneously. After having recovered L (Section 4.2), the attacker can simultaneously issue an allocation of L bytes while using a different allocation

request to probe for S . Even if the window is small, repeated simultaneous requests can make the chance of a false allocation arbitrarily small. When the program can afford more EAPs to be issued in parallel, the attack further improves, as the L -sized hole can be kept filled more reliably while a binary search is running to determine S . This approach generalizes to any number of holes.

4.6 Handling internal allocations

The attacks detailed in this section consider allocation primitives directly or indirectly based on `mmap`. However, when the primitive interacts with standard glibc allocation functions (e.g., `malloc`, `calloc`, `posix_memalign`, etc.), the result is one internal allocation for exceedingly large requests. Even though the requested size clearly does not fit in the largest available hole, glibc (version 2.19) allocates a new heap arena. The heap arena is allocated in the memory-mapped space and it is 64MiB-aligned. Therefore, the actual size of A that is recovered by a binary search differs from the previous end of the memory-mapped area by a random number which is 14 bits wide ($2^{26}/2^{12} = 2^{14}$).

Nevertheless, this is not a problem in practice, as the heap arenas form a circular, singly-linked, list. Therefore, an attacker armed with an arbitrary memory read primitive can navigate the links from the main allocation arena and discover all arenas in use (typically there would only be one link to follow). The main arena is a static variable in glibc, so it is located at a known (binary-dependent) offset from the highest address of the `mmap` space. Hence, as soon as the attacker leaks a pointer into the `mmap` space, she can easily account for the newly allocated heap arena as well.

5 Discovering Primitives

So far, in Section 4, we have discussed the mechanics of ephemeral and persistent memory-allocation primitives, which can assist an attacker in revealing the allocated ranges of a process in the virtual address space. In this section, we show that *dynamic data-flow tracking* (DFT) techniques applied to popular server programs can effectively assist attackers in discovering allocation instances that can potentially be abused to craft our primitives.

Discovering primitives that can result in powerful memory-allocation oracles involves identifying memory locations that, once controlled, can influence the input parameters of memory-allocation functions. Recall that, from Section 2, we assume attackers that are already in possession of (at least) one arbitrary read and write primitive. What the attacker lacks is a methodology to guide her to apply the read/write primitives and successfully craft EAPs and PAPs.

To model an attacker with arbitrary read/write control over memory, we start our analysis from a *quiescent state* of the program under attacker control. This state can be also manipulated and exercised over time by the attacker. As a simple example, consider a vulnerable web server. Assume the attacker can send a first a special-crafted HTTP request to trigger an arbitrary memory write vulnerability and gain control over memory. Next, the attacker issues a second request to invoke a memory allocation oracle. Therefore, in this particular example, our attacker-controlled quiescent state corresponds to that of an idle web server waiting for new requests. Once the second request is served, many parts of memory can be influenced either explicitly or implicitly. At one point, processing of the request triggers some memory-allocation function which serves as an oracle. It is important to stress that, depending on the server’s logic, parts of memory are overwritten (through successive allocations), while the request is processed. These parts cannot be generally controlled by the attacker using her arbitrary read/write primitives. However, the attacker *still* controls all the memory which was available in the original quiescent state (before the second request takes place). As long as memory of that state reaches a memory-allocation function, then the attacker can successfully use the oracle. Therefore, what we need to determine is the memory locations that influence memory-allocation sites and are *still* attacker-controlled, once the second HTTP request triggers memory-allocation functions.

Practically, this model can be easily realized using DFT. For our purposes, we use Memory-allocation Primitive Scanner (MAPScanner), a custom scanner based on libdft [20]. We start an application instrumented by MAPScanner, with all memory untainted, with *no* taint sources, and with all memory-allocation functions defined as sinks. Once the application is idle, we signal MAPScanner to taint all memory. At this point, the target quiescent state is defined and we assume that all memory is attacker-controlled. We then proceed and send a request to the server application. Any subsequent memory allocations that are triggered by the second request, since we have defined *zero* taint sources, wash out the taint of previous attacker-controlled memory. While the request is processed, MAPScanner reports all memory-allocation functions which are initiated with input from *still-tainted*, and therefore, *still-controlled* memory.

Notice, that, depending on the selected quiescent state and the input request, the attacker can discover more or fewer primitives. Using several complicated quiescent states, for example, those between handling two successive requests or between accepting the socket and receiving data, may uncover additional primitive candidates.

Once primitive instances are found, the attacker sim-

ply needs to locate the controlling data in memory (often a `buff_size` global variable originating from the configuration file), corrupt the data (and thus the allocation size) with an arbitrary memory write primitive, and monitor the execution for side effects. To classify a potential primitive as an EAP or PAP, the attacker will need to use the source or runtime experimentation to determine the lifetime of the corresponding allocated object along different program paths. Further, manual investigation is required to eliminate primitives that might not be usable because the value in memory is subject to additional validity checks in the attacker controlled paths.

In practice, we found that even when selecting the simplest quiescent state (i.e., idle server) and input (i.e., simple client request), an attacker can locate sufficient usable primitives to mount our end-to-end attacks (see Section 7).

6 Exploiting Timing Side Channels

Not all discovered primitives may automatically guarantee a realistic and crash-free attack. Certain types of primitives may not have any directly observable side effects (e.g., the server transparently recovering from allocation failures), making exploitation more complicated. Other types of primitives may result in program crashes (e.g., the server failing internal consistency checks), typically in both successful and unsuccessful cases, again making it difficult for an attacker to distinguish the two cases via direct observation. In both scenarios, however, an attacker can still infer the allocation behavior (success or failure) by measuring the time it takes to handle every particular request. We exemplify timing attack strategies for both the imperfect primitives presented above.

Even when a primitive has no directly observable side effects, allocation of memory and failure to allocate memory normally take a different amount of time. On Linux, for instance, a successful allocation is typically satisfied by a small VMA cache, avoiding lengthy walks of the red-black tree of virtual memory area (VMA) structures. However, on a VMA cache miss, before declaring an allocation failure, the kernel needs to walk all the nodes in the red-black tree in a compute-intensive loop, which takes measurably longer time to complete generating a *timing side channel* [21]. In fact, many kernel optimizations, such as VMA merging [22], explicitly seek to reduce the run-time impact of such expensive red-black tree walks. The timing signal becomes stronger for programs maintaining many VMAs and much stronger if the attacker can lure the program into allocating even more VMAs (however, VMA merging normally makes this difficult even for a PAP-enabled attacker). Even stronger timing side channels may be generated by the program itself. For example, to transparently recover

from allocation failures, the program may employ complex and time-consuming error-handling logic or log the event to persistent storage.

When a primitive results in program crashes in successful and unsuccessful cases, in turn, the presence and the strength of timing side channels is entirely subject to the internal cause of the crash. Interestingly, we found that the leading cause of crashes results in a very strong side channel. In fact, successful allocation-induced crashes are most commonly induced by a server attempting to fully initialize (or access) the huge allocated block, resulting in several time-consuming page faults before leading to the final out-of-memory error. As shown in Section 7, timing attacks which rely on crashes are remarkably effective in practice.

7 Evaluation

7.1 Primitive Discovery Results

We apply MAPScanner to a variety of well-known and popular server software. In particular, we consider BIND 9.9.3 (a DNS server), lighttpd 1.4.37 and nginx 1.6.2 (two popular web servers), as well as mysql 5.1.65 (a widely deployed database server). We built all programs using their default options (i.e. optimizations were enabled).

Since the presented applications have the form of a server accepting and servicing requests, we select, as the (simplest possible) attacker-controlled quiescent state, the point when the server is idle waiting for incoming connections, and, as the (simplest possible) attacker-controlled input, a default request to the server (Section 5). Of course, motivated attackers can carry out similar analyses starting from several additional quiescent states and inputs, so our results here are actually an (already sufficient) underapproximation of the real-world attack surface. Notice, finally, that we assume each server is being protected by an information-hiding-based defense mechanism which thwarts direct exploitation attempts (e.g., control-flow diversion).

Table 2 presents all the primitives discovered by our analysis. We name each instance of a primitive after the variable that an attacker needs to corrupt in memory to craft the corresponding allocation oracle. For each of the primitives, we report the type width of the memory-resident value that influences the allocation site. While 32-bit fields are only sufficient to bypass 32-bit (and not 64-bit) information hiding, we believe their availability can be indicative of the risks for 64-bit defense mechanisms—e.g., code refactoring changing an allocation size type to the common 64-bit `size_t` type may inadvertently introduce allocation oracles.

Table 2: For each particular application, we report the number of primitives found, the width of the allocation value, whether the primitive forces a crash, whether timing is necessary to determine success and if the primitive can be persistent as well. The “RE” (Residual Entropy) column assumes an attacker can reliably exploit the associated timing side channels. Values marked with (*) refer to lighttpd configured in forking mode.

	Primitive	Size	Crash-free	Timing-dependent	EAP	PAP	RE (bits)
bind	mgr->bpool	64-bit	✗	✓	✓	✗	1
	heap->size	32-bit	✓	✗	✓	Primarily	0
lighttpd	buffer->size#1	64-bit	✗	✓	✓	✗	0*
	buffer->size#2	64-bit	✗	✓	✓	✗	0*
	config_context->used	64-bit	✗	✓	✓	✗	0*
nginx	ls->pool_size	64-bit	✓	✗	✓	✓	0
	client_header_buffer_size	64-bit	✓	✗	✓	✗	1
	request_pool_size	64-bit	✓	✗	✓	✗	1
mysql	net->max_packet	32-bit	✓	✗	✓	✓	0
	net_buffer_length	32-bit	✓	✗	✓	✓	0
	connection_attrib	64-bit	✓	✗	✓	✓	0
	query_prealloc_size	64-bit	✓	✓	✓	✓	1
	records_in_block	32-bit	✓	✗	✓	✗	1

Additionally, we checked whether utilizing a primitive carried a risk of crashes (“crash-free” column). For primitives that did not provide directly observable side effects, the “timing-dependent” column indicates that the attacker needs to conduct a timing side channel attack to craft her primitives (we provide an example in Section 7.3). The EAP and PAP columns specify that the primitive can be used to perform an ephemeral and persistent allocation (respectively). Finally, we quantify the residual entropy after we perform the best attack at the attacker’s disposal for each primitive.

For each of these applications, our simple methodology was sufficient to discover 64-bit primitives able to quickly locate hidden objects with no residual entropy. In most cases, the discovered primitives were crash-free and could function as both EAPs and PAPs.

nginx and mysql are the best examples. They both provide ideal EAP+PAP attack primitives to stealthily bypass 64-bit information hiding with little effort. It is also worth noting that the `connection_attrib` primitive in mysql involves overwriting the requested stack size in a `pthread_attr_t` struct. As such, we expect a similar primitive to be available in all servers that create threads to service clients (either overwriting an application-specific attribute structure or the one in glibc).

For lighttpd, the server’s default configuration only allows the EAP-only attack, but, when the server is configured with forked worker processes, an attacker can successfully conduct the side-channel attack exemplified in Section 7.3 to eliminate all entropy and bypass information hiding.

Bind stands out as, depending on the server config-

uration, the `heap->size` primitive might be usable as an EAP or may effectively only function as a PAP. The reason for this behavior is that the effected allocation becomes part of a relatively long-lived cache. Hence, its lifetime is determined by administrator choices and performance considerations. When cached objects are not eagerly expired, the primitive may only be usable as a PAP for the duration of a practical attack.

Overall, our simple analysis shows that real-world information-hiding-protected applications stand very little chance against attackers armed with allocation oracles.

7.2 EAP+PAP attack on nginx

To illustrate how the combined EAP+PAP attack works in practice, we consider the `ls->pool_size` primitive discovered during our investigation of the nginx web server (Table 2).

When servicing a new connection, nginx’s `ngx_event_accept()` function allocates a per-connection memory pool (`c->pool`) using the size stored in the listening socket data structure associated to the socket the `accept()` originated from. `ngx_event_accept()` instantiates the pool by calling out to `ngx_create_pool()`, which eventually allocates the required memory by means of `posix_memalign()`.

Using our primitive discovery methodology, we were easily able to determine that the `size` argument to `posix_memalign()` originated from a value resident in live memory for our idle attacker-controlled quiescent state. This means that an arbitrary memory write vulnerability in any of the code that processes untrusted in-

put can be used to overwrite this value with an attacker-selected size, once the memory location is known.

We then verified that `ls->pool_size` is trivially accessible by following the `ls` field of the `ngx_connection_t` structure, a pointer to which is always available on various stack locations while the server is executing request-processing code.

Using this information, the attacker is able to craft an ephemeral allocation primitive by using an arbitrary read to navigate the pointer chain until she determines the address of `ls->pool_size`. At this point, she can effect a call to `posix_memalign()` with a size of her choosing by overwriting `ls->pool_size` and then opening a connection to the server. If the allocation request was successful, the attacker can issue an HTTP request over that new connection (positive side effect). If the allocation cannot be accommodated, the connection is forcibly closed by the server (negative side effect).

Using the same procedure, the attacker can craft a PAP by simply keeping the connection open in the last step. To conduct the complete attack, the attacker first employs the EAP to determine the size of the larger of the two holes around the hidden object (for simplicity, we only discuss the case when the hidden object is placed in the largest contiguous pre-existing hole; other scenarios are investigated in Section 4.3). Having determined the maximum allocation (i.e., hole) size, she relies on the PAP to allocate the exact size of the larger hole, taking it out of the picture. She then proceeds to conduct the EAP-based attack against the smaller hole around S . Finally, she simply probes at address `vm.mmap_min_addr+S` to complete the attack, as described in Section 4.3.

7.3 Timing-based attack on lighttpd

Next, we focus on the execution of an EAP-only attack which relies on a timing side channel. To demonstrate such an attack, we rely on the `config_context->used` primitive in lighttpd. In order craft this primitive, we configured lighttpd to use worker processes by setting the `server.max-worker` configuration variable to a non-zero value. With no loss of generality, we limit our analysis to one worker process, as an arbitrary memory access primitive makes it a matter of book-keeping to tag the workers (e.g. by writing a different value for each worker to an unused memory location), so that the attack code can target a single process.

Again using our primitive discovery methodology, we easily determined that `srv->config_context->used` is used as an argument to `calloc()` in the body of `connection_init()`. Similarly, we showed that pointers to `srv` are available in the stack frames above the event loop, which renders `srv->config_context->used` trivially accessi-

ble to an attacker equipped with arbitrary memory read/write primitives.

The second argument to `calloc()` at this call site is `sizeof(cond_cache_t)`, which amounts to 144 bytes. Since that is less than the default page size on x86, we can always find a value that will result in the allocation of any given number of pages.

Crucially, the return value from `calloc()` is never checked for failure. Therefore, the only way to determine whether the allocation succeeded or not is to send a simple request so as to drive the server to a path which will dereference the pointer. That path is simply `http_response_prepare() -> config_cond_cache_reset()`, which will iterate over all elements of the array. As a result, if the allocation fails, the worker process *immediately* crashes on trying to access the first element, resulting in a closed connection for the client. If the allocation succeeds but the allocated size is much larger than the amount of physical memory on the system, this allocation incurs *several lengthy page faults* before causing an out-of-memory (OOM) condition—on which Linux’ “OOM killer” terminates, with high reliability, the worker process. If the system can survive faulting in all the allocated pages (presumably because the allocation was “small”), the server eventually sends back a response. Using either the timing or the reception of an HTTP response, we can infer whether the attempted allocation succeeded or failed.

When the worker process crashes or is terminated by the OOM killer, the parent is notified and forks a new child in replacement (indeed one of the motivations for using worker processes in server software is for crash recovery purposes). Each new worker process inherits the address space of the parent; hence, all memory regions (including the hidden object) remain at stable virtual addresses across worker restart events.

Given the several page faults incurred before a crash, the timing side channel we rely on yields a very strong signal. In our testing, we performed the attack 40 times and were able to reliably differentiate between a successful and a failed allocation in all of them. By using the same primitive as a PAP (as is possible in this configuration), we were able to persistently allocate the recovered size for the largest hole and then repeat the EAP attack on the smaller hole as done earlier. In summary, by relying on EAP+PAP primitives and a strong timing side channel we could successfully recover the address of the hidden object and bypass information hiding in all cases in our experiments.

7.4 EAP-only attack

We evaluated the accuracy and performance of the EAP in defeating the information-hiding properties of ASLR

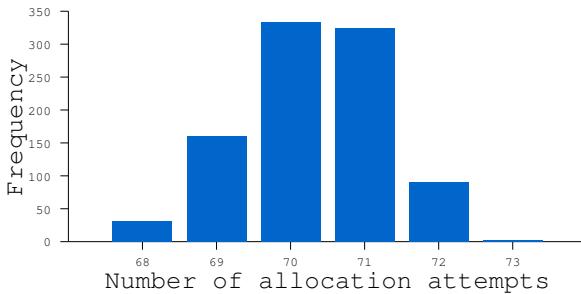

Figure 2: Histogram of the number of operations for recovering the exact hole sizes around a hidden object in an nginx executable [n=1000]

by preallocating a hidden object of a size of 2MiB in the address space of nginx (compiled as a position-independent executable) and then trying to determine the sizes of the larger and smaller holes on either side of it, as described in Section 7.2. Taking into account the complications and workarounds described in Section 4.6, we were able to exactly determine the size of both the larger and smaller hole and subsequently uncover the exact location of the hidden object, without incurring any invalid memory accesses.

Figure 2 depicts the number of required allocation attempts over 1000 runs (using different random configurations). On localhost and using gdb to effect the arbitrary memory access, the attack completed after an average of 28.20s with a median of 28.21s.

7.5 PAP-only attack

When the only primitive available to the attacker is the PAP, she needs to consider a number of tradeoffs. Clearly, the attacker is interested in reducing her entropy with respect to the position of the hidden region in the targeted address space. At the same time, different considerations might cause her to strive for minimal or rapid interaction with the target process. For example, a very large number of requests to a remote server might very well increase the chance that the attack will be noticed by network intrusion detection systems. Similarly, as the duration of the attack increases, so does the chance that unrelated process activities, such as servicing requests for other clients or periodically scheduled work, may interfere with the workings of the algorithm.

There exist two tunable parameters that affect the behavior of our PAP-only attack. One selects between the number of allocation attempts and the entropy reduction obtained, the other between entropy reduction and risk of failure.

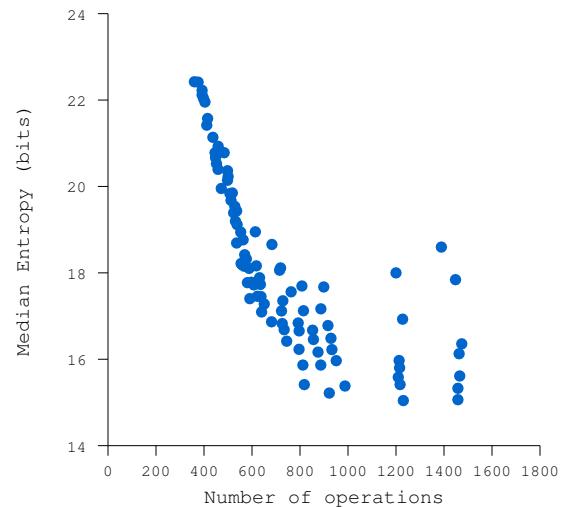

Figure 3: Parameter space exploration for the PAP-only attack

Figure 3 presents the number of allocation attempts versus the *median* of the residual entropy in the size of the largest hole after the completion of the attack, for every pair of parameter values that we explored. We can observe that extreme choices of the parameter values result in pathological behavior, either in the number of operations or in the residual entropy or both.

Conversely, there exist better parameter choices which do reasonably well for both metrics. Appendix C goes into more depth on the parameter values and their effect on the behavior of the attack.

Observe that, in attack scenarios where a number of requests on the order of a thousand is acceptable, there exist several parameters for which the median residual entropy is reduced to 15 bits. Notice also that when the size of the hidden region can be expected to be comparable to the residual entropy, the chances of successfully probing for the region are significantly increased.

For a round-trip time of 1s, even the PAP-only attack would take at most half an hour (12 minutes on average), which is still an eminently practical amount of time in many real-world settings.

7.6 Effectiveness against modern defenses

The presented attacks change the picture for the protection offered by state-of-the-art defense mechanisms that rely on information hiding. CPI’s safe area [3] and many other prior solutions [4, 23, 19, 24] rely on information hiding to protect a single hidden region. For all such solutions, our attacks in Section 4 apply directly and can

locate the hidden region with little or no crashes. Prior work has demonstrated a memory probing-based crash-free CPI bypass with roughly 110,000,000 operations on nginx [12]. Using our combined EAP and PAP crash-free attack, we can replicate their attack needing only 74 operations in the worst case (Fig. 2). This is a 1,400,000x improvement in attack efficiency, which, projected on the request time reported in [12], translates to 0.23s (rather than 97 hours) to locate the hidden region. In addition, our crash-free attack is even faster than the fast crash-prone attack presented in [12] (6s with 13 crashes).

More recent client-side probing attacks [11] offer similar guarantees (i.e., locating CPI’s safe area in 32 probes), but their probing strategy relies on exception handling rather than crash recovery, ultimately improving the attack efficiency. We note that both existing probing attacks [12, 11] exploit assumptions on CPI’s huge hidden region size (on the order of 2^{42} bytes when using a sparse table and $2^{30.4}$ when utilizing a hash table [11]) to reduce the entropy and make the attack practical. In stark contrast, our attacks make no assumptions on the region size, and doing so would allow even a PAP-only attack to succeed without crashes.

Other solutions, such as ASLR-Guard [6], SafeStack [3], and other shadow stack implementations [25], rely on information hiding to protect multiple hidden regions. For example, all the shadow stack solutions need to maintain a per-thread hidden region. We note that our attacks generalize to multi-region information hiding with essentially the same impact. In particular, while multi-threaded programs disqualify the simple EAP-only attack, our best (EAP+PAP) attack naturally extends to multi-region solutions and can quickly bypass them (although more allocations may be required).

Finally, many leakage-resilient defenses [26, 27, 28, 29] enforce execute-only memory to protect the hidden (code) region from read-based disclosure attacks [1]. However, such defenses are susceptible to execution-based disclosure attacks in crash-tolerant applications [10]. To counter such attacks, some solutions deploy booby traps in out-of-band trampolines [26, 27]. With allocation oracles, an attacker can sidestep the booby-trapped trampolines and quickly find the hidden region, enabling more practical and guided execution-based disclosure attacks against such defenses.

8 Mitigations

One strategy to defend against allocation oracles is to enforce an upper limit on the maximum amount of virtual memory that a process can allocate. This mechanism is already available on Linux (and other POSIX-compatible operating systems) via the `RLIMIT_AS` resource limit (adjustable via `setrlimit`). Setting this limit to a small,

though still sufficient for most current applications, value would thwart any attempts to probe the sizes of the larger holes in the address space. The resource limit can be set by the application itself (in which case, a defense mechanism could intercept it and adjust it to accommodate its own needs for virtual addresses) or it can be hard-capped by the administrators without any need for program adjustments. The main difficulty lies in predicting the maximum virtual address space usage under all conceivable conditions so as to never deny legitimate allocation requests for production applications. Nonetheless, its wide availability, straightforward deployment, and robustness (see below) make `RLIMIT_AS` our primary recommendation for compatible workloads and configurations.

For some classes of applications (especially those relying on memory overcommit), limiting the amount of virtual address space available may be problematic, e.g., when memory-mapping huge files. In such cases, one could switch to a strict overcommit policy and have the applications always use `mmap`’s `MAP_NORESERVE` flag for huge—but known to be benign—allocations. `MAP_NORESERVE` instructs the kernel not to count the corresponding allocations towards the overcommit limit. However, this mitigation strategy would still allow an attacker to inject the `MAP_NORESERVE` flag in `mmap` calls using memory-resident arguments and craft our primitives. Another issue with such a strict overcommit strategy is that it is incompatible with memory-hungry applications that rely on `fork` and cannot simply switch to `vfork` (the `redis` server being a prime example). This problem can only be directly mitigated with the addition of a new flag to the `clone` system call to mimic the semantics of `MAP_NORESERVE`.

In some setups, one may deploy an IDS looking for anomalous events (i.e., allocations) in a given application [30]. However, this approach generally requires per-application policies (e.g., only allow huge allocations of a specific size). A policy looking for frequent huge allocations in arbitrary applications is more generic but problematic, as an attacker can easily dilute the very few probing attempts required by our attacks over time [30].

Finally, defense mechanisms could bracket their hidden regions with randomly-sized trip hazard areas [31] to deter in-region memory probing. This is the immediate systemwide mitigation we recommend for information-hiding-based solutions already deployed in production [32]. Albeit still probabilistic (and thus prone to attacks), such solution can also provide efficient protection against other (known) side-channel attacks [31].

9 Related work

We distinguish between approaches that aim at breaking ASLR in general and approaches that try to

break more advanced defense techniques that rely on ASLR-based information hiding.

Breaking ASLR has been fertile research ground for years and became especially popular in recent years. From the outset [30], pioneering work showed that the randomization in 32-bit address spaces provide insufficient entropy against practical brute-force attacks, so we focus on 64-bit architectures (x86-64) in this section.

In practice, bypassing standard (i.e., coarse-grained, user-level) ASLR implementations is now common. For an attacker, it is, for instance, sufficient to disclose a single code pointer to de-randomize the address space [33]. Even fine-grained ASLR implementations [34] are vulnerable to attacks that start with a memory disclosure and then assemble payloads in a just-in-time fashion [1].

More advanced attack vectors rely on side channels via shared caches. Specifically, recently accessed memory locations remain in the last-level cache (LLC) which is shared by different cores on modern x86-64 processors. As it is much faster to access memory locations from the cache rather than from memory, it is possible to use this timing difference to create a side channel and disclose sensitive information. By performing three types of PRIME+PROBE attacks on the CPU caches and the TLB, Hund et al. [35] could completely break kernel-level ASLR by mapping the entire virtual address-space of a running Windows kernel. To perform a PRIME+PROBE attack, the attacker needs the mapping of memory locations to cache sets. In modern Intel processors, this mapping is complex and reverse engineering requires substantial effort [35]. However, performance counter-based and other techniques have been proposed to lower the reverse engineering effort [36].

Even without *a priori* disclosures, attackers may still break ASLR using Blind ROP (BROP) [10]. A BROP attack sends data that causes a control transfer to another address and observes the behavior of the program. By carefully monitoring server program crashes, hangs, or regular output, the attacker can infer what code executed and, eventually, identify ROP gadgets. After many probes (and crashes), she gets enough gadgets for a ROP chain. BROP is a remote attack method applicable (only) to servers that automatically respawn upon a crash.

In general, leaking information by means of side channels is often possible. To launch such an attack, an attacker typically uses memory corruption to put a program in a state that allows her to infer memory contents via timings [21, 37, 12] or other side channels [10].

As ASLR by itself does not provide sufficient protection against the attacks described above, the community is shifting to more advanced defenses that build on ASLR to hide sensitive data (such as code pointers) in a hidden region in a large address space, typically not referenced by any pointers within the attacker’s reach.

Hiding secret information in a large address space is now common practice in a score of new defenses. For example, Oxymoron [4] protects the *Randomization-agnostic Translation Table* (RaTTle) by means of information hiding, and Opaque CFI [23] protects the so-called *Bounds Lookup Table* (BLT) in a similar way. Likewise, Isomeron [19] keeps the *execution diversifier data* secret and StackArmor [25] isolates potentially vulnerable stack frames by means of hiding in a large address space. Finally, on x86-64 architectures, CFCI [24] also needs to hide a few MBs of protected memory.

One of the best-known examples of a defense that builds on ASLR-backed information hiding is Code Pointer Integrity [3]. CPI splits the address space in a standard and a safe region and stores all code pointers in the latter, while restricting accesses to the (huge) safe region to CPI-intrinsic instructions. Moreover, it also provides every thread with a shadow stack (called SafeStack in CPI) in addition to the regular stack and uses the former to store return addresses and other proven-safe objects. Both the shadow stacks (which are relatively small) and the safe region (which is huge) are hidden at a random location in the virtual address space.

By means of probing on a timing side channel, Evans et al. showed that it is possible to circumvent CPI and find the safe region [12]. However, depending on the construction of the safe region, the attack may require a few crashes or complete in several hours in order to be stealthy (i.e., crash-free). Moreover, similar to the recent CROP [11] (which instead relies on specially crafted crash-resistant primitives), this attack needs to resort to full memory probing to locate small hidden regions (unlike CPI’s) in absence of implementation flaws. Full memory probing forces the attacker to trigger many crashes and other detection-prone events, and its efficiency quickly degrades when increasing the address space entropy.

Concurrent work [31] relies on *thread spraying* to reduce the entropy in finding a per-thread hidden object. Allocation oracles can make thread spraying attacks faster by providing a more efficient disclosure primitive compared to the memory probing primitives used in [31].

Unlike all the existing attacks, *allocation oracles* demonstrate that an attacker can craft pervasively available primitives and locate the smallest hidden regions in the largest address spaces, while leaving little or no detectable traces behind.

10 Conclusions

We have shown that information hiding techniques that rely on randomization to bury a small region of sensitive information in a huge address space are not safe on modern Linux systems. Specifically, we introduced new in-

formation disclosure primitives, allocation oracles, that allow attackers to probe the holes in the address space: by repeated allocations of large chunks of memory, the attacker discovers the sizes of the largest areas of unallocated memory. Knowing the sizes of the largest holes greatly reduces the entropy of randomization-based information hiding and allows an attacker to infer the location of the hidden region with few to no crashes or noticeable side-effects. We have also shown that allocation oracles are pervasive in real-world software.

Unfortunately, information hiding underpins many of the most advanced defense mechanisms today. Without proper mitigation, they are all vulnerable to our attacks. While one may deploy more conservative memory management policies to limit the damage, we emphasize that the problem is fundamental in the sense that allocation oracles always reduce the randomization entropy, regardless of the mitigation and the address space size. In general, information hiding is vulnerable to entropy reduction by whatever means and it is not unlikely that attackers can combine allocation oracles with other techniques. In our view, it is time to reconsider our dependency on the pseudo-isolation offered by randomization and opt instead for stronger isolation solutions like software fault isolation or hardware protection.

11 Disclosure

We have cooperated with the National Cyber Security Centre in the Netherlands to coordinate disclosure of the vulnerabilities to the relevant parties.

A Base EAP-only algorithm

Algorithm 1 Binary search using the Ephemeral Allocation Primitive; sizes are in pages.

```

function DEDUCE(low, high)
  if low = high then
    return low
  if high - low = 1 then
    res  $\leftarrow$  TEMP-ALLOC(high)
    if SUCCESS(res) then
      return high
    else
      return low
    midpoint  $\leftarrow$   $\lfloor (\text{high} + \text{low}) / 2 \rfloor$ 
    res  $\leftarrow$  TEMP-ALLOC(midpoint)
    if SUCCESS(res) then
      return DEDUCE(midpoint, high)
    else
      return DEDUCE(low, midpoint - 1)
  
```

Hole	Total	Max
A	0B	131068GiB
B	0B	1028GiB
C	0B	4GiB

Table 3: Initial state for a PIE executable

B PAP-only algorithm

For each hole G , we maintain two variables, G_{total} and G_{max} . The first variable tracks the number of bytes allocated from G . The second holds the maximum number of bytes that may still be allocatable from G at any point in time. So when an allocation of size S is known to originate from G , we increase G_{total} by S and decrease G_{max} by S . Crucially, when an allocation of size S fails, we know that no hole has S bytes available. Therefore, the *max* variable for every tracked hole needs to be adjusted to S minus the pagesize (see the functions HOLE-SATISFIED, HOLE-FAILED-TO-SATISFY, called for holes that satisfied or failed to satisfy an allocation request, respectively).

```

function HOLE-SATISFIED(size, G)
   $G_{max} \leftarrow G_{max} - size$ 
   $G_{total} \leftarrow G_{total} + size$ 
function HOLE-FAILED-TO-SATISFY(size, G)
  if  $G_{max} > size - \text{pagesize}$  then
     $G_{max} \leftarrow size - \text{pagesize}$ 
  
```

A state consists of the set of *max* and *total* variables for each tracked hole. In the initial state we may have some information for the maximum size of each hole, but no bytes have been allocated during the run of our algorithm, so that $G_{total} = 0, \forall G$. Given the size distributions in Table 1, the initial state for a simple PIE executable is as given on Table 3.

Descent mode The algorithm operates in two modes. Suppose that the highest maximum value (*hmv*) is unique across all the tracked holes and G is the hole it is associated with (i.e. $\#H : G_{max} = H_{max}$). In this case, we try decreasing allocation sizes which can only be satisfied by G , in the hope that an allocation will succeed, causing G_{max} to be decremented below the next-highest maximum (*nhmv*) value so that we will remain in this mode for the next step of the algorithm.

There is an inherent tradeoff between the accuracy and the number of allocations we try. In the extreme, we could explore the interval $[nhmv, hmv]$ by starting with *hmv* and decreasing the allocation size by one page after each failed attempt. Of course, this would result in a huge number of allocation attempts, rendering the approach impractical.

```

function CALCULATE-STEPS(high, low)
    size  $\leftarrow$  high  $-$  low
    if size = pagesize then
        return [high]
    step  $\leftarrow$  size/split
    sizes  $\leftarrow$  []
    idx  $\leftarrow$  0
    for n in 0..(split  $-$  1) do
        sz  $\leftarrow$  high  $-$  n * step
        rem  $\leftarrow$  sz % pagesize
        if rem > 0 then
            sz  $\leftarrow$  sz  $-$  rem + pagesize
        if idx = 0  $\vee$  sizes[idx  $-$  1]  $\neq$  sz then
            sizes[idx]  $\leftarrow$  sz
            idx  $\leftarrow$  idx + 1

```

While larger successful allocations are desirable, we elect to trade some resolution for a reduction in the number of attempts necessary. The way we do this is by selecting a *split* factor for the interval $[nhmv, hmv]$, and trying decreasing allocations with an (approximate) step of $\frac{hmv - nhmv}{split}$ bytes (special considerations need to be made for respecting page boundaries; see the CALCULATE-STEPS function). A larger split factor results in more allocation attempts but higher chances of quickly minimizing the *max* variable of G.

At every given step, the allocation might succeed (in which case we update G_{total} and G_{max}) or it might fail and we appropriately reduce every *max* variable to just below the failed allocation size. This means that the difference between the current *hmv* and the *nhmv* keeps shrinking as allocations fail.

For reasons that will become apparent soon, we are willing to expend more allocation attempts to avoid the situation when *hmv* becomes equal to the *nhmv*. Therefore, when the last step above the *nhmv* results in a failed allocation, we reiterate the algorithm, again splitting the interval between the current *hmv* and the *nhmv* according to the split factor and trying descending allocation size using a new, smaller, step size. The algorithm continues trying ever smaller allocations using an ever finer step size, until the allocation of *nhmv* + pagesize bytes. If that allocation fails, then we have to switch into the mode where there are multiple highest maximum values (Algorithm 2, line 34).

Forking mode We are now in a state where there exist *n* holes, $G^1, \dots, G^n : G_{max}^1 = \dots = G_{max}^n = hmv$, i.e. the *hmv* has multiplicity *n*. The only way to make progress is to try an allocation smaller than *hmv*; yet if the allocation succeeds, we are not in a position to tell which hole the bytes were allocated from. What's worse, more than one hole might be able to accommodate the allocation we attempt.

Algorithm 2 Decision

```

1: function STATE-MAXES(s)
2:   res  $\leftarrow$   $\emptyset$ 
3:   for all max  $\in$  MAXES(s) do
4:     res  $\leftarrow$  res  $\cup$  max
5:   sorted_maxes  $\leftarrow$  SORT-DESCENDING(maxes)
6:   groups  $\leftarrow$  GROUP-BY-MAX(sorted_maxes)

```

This constitutes a second mode of operation for our algorithm. After we select an allocation size T , we attempt to allocate T bytes n times. If all n allocations succeed, the max values for the n holes all get reduced by the same amount; if the new maximum values are still higher than any other maximum value, we remain in the same mode. If there is now a unique (necessarily different) hm , we switch modes.

We then consider the case when k out of n allocation attempts succeed. The allocations could have come out of any set of k holes and there are $\binom{n}{k}$ possible ways to pick the successful holes out of the n we started with. At this point, we fork the current state into $\binom{n}{k}$ new ones, one for each possible combination. In each newly-created state, k holes get their *total* variables incremented and their *max* variables decremented by the allocated size, whereas the maximum values of the remaining $n - k$ states are lowered to below the allocated size (as we consider the allocation from those holes to have been a failure). After a fork, we are left with a number of active states, one of which matches the actual system state as regards the total allocated bytes for each hole.

Finally, when all n allocations fail, we need to pick a new, smaller allocation size. The obvious approach would be to halve the size for the next allocation attempt. However, this choice leads to a pathological situation. Recall that every failed allocation attempt causes all maximum variables to be set to one page below the attempted value so that, as long as the allocations all fail, the maximum values are reduced in lockstep. Consider the case when an allocation succeeds; the new maximum value for a hole G which is considered successful is set to $G'_{max} = G_{max} - allocation_size = G_{max} - G_{max}/2 = G_{max}/2$. Regarding a hole H for which the allocation was considered a failure, the *max* variable is updated to $H'_{max} = allocation_size - pagesize = H_{max}/2 - pagesize$. Since G_{max} was equal to H_{max} , the new maximum values for all the n holes will all be within a page of each other, which makes it all but certain that after one descent step we will re-enter the forking mode, which increases the chances of a combinatorial explosion in the number of active states.

To increase our chances switching back to descent mode, we elect to pick the next allocation size exactly as we do when the hm is unique.

Generalized Algorithm We extend the algorithm described above to operate when there is more than one active state. Our driving concern is to be able to differentiate between active states. To that end, we collect the highest maximum value of each state. We then attempt a descent from the highest maximum value to the next-highest maximum value using the split factor, as described for the single-state case.

Algorithm 3 Descent

```

function ALLOCATE( $m$ )
   $count \leftarrow 0$ 
  for  $i$  in  $0..m$  do
    if ALLOC() then
       $count \leftarrow count + 1$ 
  return  $count$ 

function NSTATE( $size, rest, satisfied, not\_satisfied$ )
   $holes \leftarrow rest$ 
  for all  $G$  in  $satisfied$  do
     $holes \leftarrow holes \cup$  HOLE-SATISFIED( $size, G$ )
  for all  $G$  in  $not\_satisfied$  do
     $holes \leftarrow holes \cup$  HOLE-NOT-SATISFIED( $size, G$ )
  return CREATE-STATE( $holes$ )

function DO-COMBINE( $rest, selected, previous, count, candidates, accum$ )
  if  $count = 0$  then
     $nstate \leftarrow$  NSTATE( $size, rest, selected, previous$ )
     $accum \leftarrow accum \cup nstate$  return  $accum$ 
  else if EMPTY( $candidates$ ) then return  $accum$ 
  else
     $x \leftarrow$  FIRST( $candidates$ )
     $candidates \leftarrow TAIL( $candidates$ )$ 
     $accum \leftarrow$  DO-COMBINE( $rest, selected \cup x, previous, count - 1, candidates, accum$ ) re-
  turn DO-COMBINE( $rest, selected, previous \cup x, count, candidates, accum$ )

function COMBINE( $rest, count, candidates$ )
  DO-COMBINE( $rest, \emptyset, \emptyset, count, candidates, \emptyset$ )

function UPDATE-STATES( $states, size, count, m$ )
   $nstates \leftarrow \emptyset$ 
  for all  $s \in states$  do
     $candidates \leftarrow \emptyset$ 
     $rest \leftarrow \emptyset$ 
    for all  $G \in$  HOLES( $s$ ) do
      if  $G_{max} \geq size$  then
         $candidates \leftarrow candidates \cup G$ 
      else
         $rest \leftarrow rest \cup G$ 
    if COUNT( $candidates$ )  $\geq count$  then
       $res \leftarrow$  COMBINE( $rest, count, candidates$ )
       $nstates \leftarrow nstates \cup res$ 
  return  $nstates$ 

function DESCEND( $states, m, sizes$ )
  for  $size$  in  $sizes$  do
     $count \leftarrow$  ALLOCATE()
     $states \leftarrow$  UPDATE-STATES( $states, size, count, m$ )
    if  $count > 0$  then return DECIDE( $states$ )

```

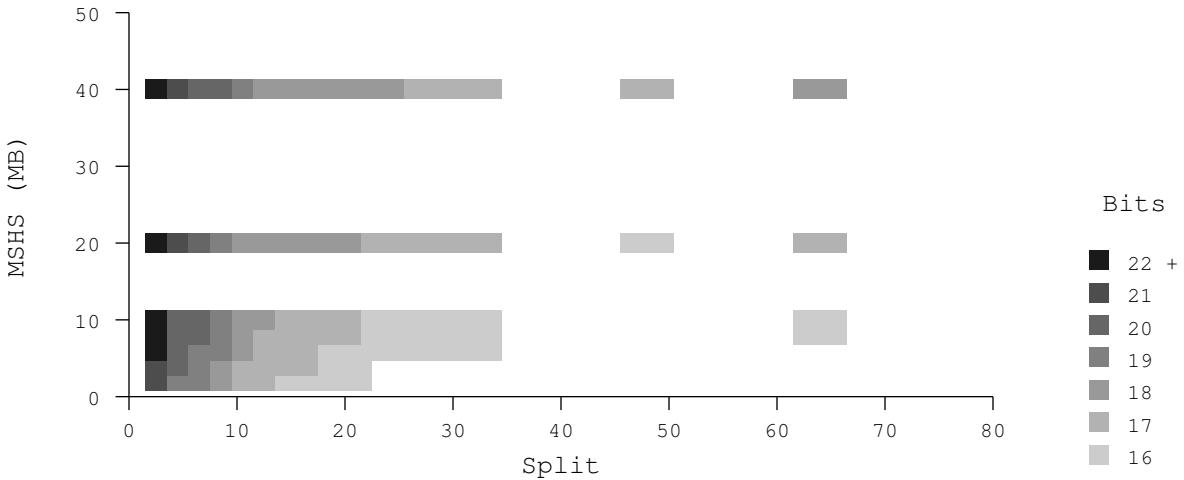

Figure 4: Residual entropy for different value combinations of the split and MSHS parameters (lighter is better)

A crucial insight is that when an allocation succeeds, all states that have a highest maximum value which cannot accommodate the successful allocation size are necessarily impossible and are pruned from the set of active states. This serves to contain the number of active states and somewhat ameliorate the combinatorial behavior of the forking mode.

The generalized algorithm (Algorithm 2) treats all cases (single or multiple states, the hmv is unique or has multiplicity n) uniformly. First, it considers the maximum values of the holes within a single state. Multiplicity is established within each state. Following that, the holes are sorted in descending order based on their maximum values and then again in descending order with regard to the multiplicity of each maximum value in the state it originated from. The number of times an allocation is repeated is determined by the multiplicity of the topmost hole; the descent takes place between that hole and the next hole of a different maximum value.

Intuitively, if we have exactly two states, S_1, S_2 with unique hmv values hmv_1, hmv_2 and that $hmv_1 = hmv_2$. Then we need try an allocation which can only be satisfied by the maximally-sized hole of either state only once; if the allocation succeeds, both states are updated and remain valid. Conversely, if hmv_1 has multiplicity two and hmv_2 only one, we need to try the allocation two times. If both allocations succeed, S_1 gets updated accordingly and S_2 gets dropped as invalid; if only one allocation succeeds, S_1 is replaced by two new states whereas S_2 is adjusted and remains live.

C Further evaluation of the PAP-only attack

When considering Figure 4 visualizes the residual accuracy (in bits) in the size of the largest hole next to the hidden object. The corresponding figure for the smaller hole appears almost identical and is omitted for brevity.

For the split factor, we investigated values ranging from 4 to 64, specifically 4, 6, 8, 10, 12, 14, 16, 20, 24, 28, 32, 48 and 64. Guided by a sampling of typical applications on workstations and servers, we considered the following upper bounds for the sizes of untracked holes: 2MiB, 4MiB, 6MiB, 8MiB, 20MiB and 40MiB.

Our evaluation of the PAP in weakening ASLR’s protection of a hidden object involved seeding the algorithm with an initial state consisting of 4 hole descriptions. Specifically, we included the maximum possible values for the holes resulting from the placement of the hidden object at a random address within hole A. Hence, our tracked holes were Large, Small, B and C.

Analyzing Figure 4, we notice the tendency for larger split values to result in lower uncertainty. This tendency is not consistent and may vary with the MSHS; for example, split=48 outperforms split=64 for larger MSHS and is overall the best choice at larger MSHS values.

The split factor of 4 is by far the worst choice. It should be mentioned that the runtime performance deteriorates to the point of being impractical when using 2 as the split factor (for reasons expounded on in B, which led us to exclude it from the parameter exploration).

What Cannot be Read, Cannot be Leveraged? Revisiting Assumptions of JIT-ROP Defenses

Abstract

Despite numerous attempts to mitigate code-reuse attacks, Return-Oriented Programming (ROP) is still at the core of exploiting memory corruption vulnerabilities. Most notably, in JIT-ROP, an attacker dynamically searches for suitable gadgets in executable code pages, even if they have been randomized. JIT-ROP seemingly requires that (i) code is *readable* (to find gadgets at run time) and (ii) executable (to mount the overall attack). As a response, Execute-no-Read (XnR) schemes have been proposed to revoke the read privilege of code, such that an adversary can no longer inspect the code after fine-grained code randomizations have been applied.

We revisit these “inherent” requirements for mounting JIT-ROP attacks. We show that JIT-ROP attacks can be mounted without ever reading any code fragments, but instead by *injecting* predictable gadgets via a JIT compiler by carefully triggering useful displacement values in control flow instructions. We show that defenses deployed in all major browsers (Chrome, MS IE, Firefox) do not protect against such gadgets, nor do the current XnR implementations protect against code injection attacks. To extend XnR’s guarantees against JIT-compiled gadgets, we propose a defense that replaces potentially dangerous direct control flow instructions with indirect ones at an overall performance overhead of less than 2% and a code-size overhead of 26% on average.

1 Introduction

Code-reuse attacks, such as Return-Oriented Programming (ROP), enable an attacker to bypass Execute-XOR-Write (X^W) policies by suitably chaining existing small code fragments (so-called *gadgets*). One of the most prominently explored concepts to defend against such attacks involves randomizing programs so that an attacker can no longer reliably identify and chain such gadgets, whether by code transformations [19, 6, 14], data region

hardening [5, 23], or whole address space randomization [4]. However, a novel class of attacks, dubbed JIT-ROP, allows for code reuse even for such diversified programs [31]. JIT-ROP leverages a memory disclosure vulnerability in combination with a scripting environment—which is part of all modern browsers—to read existing code parts, notably *after* they were randomized. Once the code has been read (e.g., using a memory disclosure vulnerability), an attacker can dynamically discover and chain gadgets for conventional code-reuse attacks.

Mounting a successful JIT-ROP attack seemingly requires the ability to (i) read code fragments and identify suitable gadgets (otherwise the adversary would not know what to combine) and to (ii) execute them (so that the overall attack can be mounted). The recently proposed Execute-no-Read (XnR) schemes [2, 11, 12] consequently strive to eliminate JIT-ROP attacks by ensuring that executable code is *non-readable*, i.e., marking code sections as executable-only while explicitly removing the read privilege. Hence an adversary can no longer inspect the code after fine-grained code randomization techniques have been applied and should thus fail to identify suitable gadgets. As a more pointed statement: what cannot be read, cannot be leveraged.

Our contributions: In this paper, we carefully revisit these seemingly inherent requirements for mounting a successful JIT-ROP attack. As our overall result, we show that JIT-ROP attacks can often be mounted without ever reading any code fragments, but by instead injecting *arbitrary, predictable* gadgets via a JIT compiler and by subsequently assembling them to suitable ROP chains without reading any code pages.

As a starting point, we show how to obtain expressive unaligned gadgets by encoding specially-crafted constants in instructions. Prior research has already shown that *explicit* constants in JavaScript statements, e.g., in assignment statements like $x = 0x12345678$, can be used to generate unaligned gadgets [1]. Browsers started to fix such vulnerabilities, e.g., by blinding explicit con-

stants (i.e., XOR-ing them with a secret key), and/or by applying fine-grained code randomization techniques (cf. Athanasakis *et al.* [1]). We show that *implicit* constants in JIT-compiled code can be exploited in a similar manner, and are hence far more dangerous in the JIT-ROP setting than commonly believed. To this end, we generate JavaScript code that emits specific offsets in relative jumps/calls in the JIT-compiled code. We show that both relative jumps and relative calls can be used to encode attacker-controllable values in an instruction’s displacement field. These values can later be used as unaligned gadgets, i.e., an attacker that controls the jump or call destination (or source) can predict the displacement and thereby generate deterministic gadgets on-the-fly, without the need to ever read them before use. We demonstrate the impact of our attack by injecting almost arbitrary two- or three-byte-wide gadgets, which enable an attacker to perform arbitrary system calls, or, more generally, obtain a Turing-complete instruction set. We show that all major browsers (Chrome, Internet Explorer, Firefox) are susceptible to this attack, even if code randomization schemes such as NOP insertion (like in Internet Explorer) are in place.

The ability to create controllable JIT-compiled code enables an adversary to conveniently assemble ROP chains without the requirement to ever read code. This challenges current XnR instantiations in that code does not have to be readable to be useful for ROP chains, highlighting the need to complement XnR with effective code pointer hiding and/or code randomization schemes also in JIT-compiled code. Unless XnR implementations additionally protect JIT-compiled code, they do not prevent attackers from reusing predictable attacker-generated gadgets, and hence from mounting JIT-ROP attacks. We stress that a complete XnR implementation that offered holistic code coverage (i.e., hiding code-pointers also in JIT-compiled code) may also be effective against our attack. However, maintaining XnR’s guarantees also for JIT-compiled and attacker-controlled code imposes additional challenges in practical settings: First, fine-grained code randomization schemes that are implemented in XnR do not add security against implicit constants, and they hence make gadget emissions, proposed in this paper, possible. In particular, the widely deployed concepts of register renaming and instruction reordering do not affect our proposed unaligned gadgets. Moreover, fine-grained code randomization techniques commonly deployed in browsers (as NOP insertion in IE) are not sufficient either, as the attacker can test the validity of its gadgets before using them. Second, the lack of code pointer hiding in JIT-compiled code in current XnR instantiations constitutes an additional vector of attack, since adversaries can then still leverage our attack to encode constants in relative calls.

We finally explored how to extend XnR’s guarantees against implicit constants in JIT-compiled code. One option would be to extend the use of call trampolines in XnR schemes also to JIT compilers, as suggested by Crane *et al.* [11, 12]. However, this will replace existing direct calls with direct jumps to trampolines, which also encode implicit constants. Furthermore, trampolines will introduce new relative offsets in their direct call instructions. As the locations of trampolines are not hidden (e.g., they can be revealed by reading the return address on stack), in the presence of an unprotected code pointer, the attacker will be able to predict encoded constants by leaking either the caller or the callee address. As an orthogonal alternative, in this paper we propose to (i) replace relative addressing with indirect calls and (ii) blind (i.e., reliably obfuscate) all explicit constants used to prepare the indirect calls. We implement our defense in V8, the JavaScript engine of Chrome, and show that our proposal imposes less than 2% performance and 26% code size overhead, while effectively preventing the attacks described in this paper.

The summarized contributions of our paper are:

- We present a novel class of attacks that encode ROP gadgets in implicit constants of JIT-compiled code. We thereby show that reading code fragments is *not* necessarily a prerequisite for assembling useful gadgets in order to mount a JIT-ROP attack.
- We demonstrate that all three major browsers (Chrome, Internet Explorer, Firefox) are susceptible to our proposed attack.
- We discuss potential shortcomings when using XnR to protect JIT-compiled code. We show that the underlying assumptions that XnR schemes build upon (such as code randomization) have to be carefully evaluated in the presence of JIT-compiled code.
- We implement a defense in V8 that replaces relative calls/jumps with indirect control flow instructions. This effectively prevents the attack proposed in this paper by removing dangerous implicit constants, exhibiting a performance overhead of 2% and a code size overhead of 26%.

The remainder of this paper is structured as follows. Section 2 provides background information on code-reuse attacks. Section 3 describes our threat model. Section 4 introduces the fundamentals of our attack and demonstrates its efficacy against three major browsers. Section 5 introduces an efficient defense against our attack. Section 6 discusses the implications of our work. Section 7 describes related work and Section 8 concludes the paper with a summary of our findings.

2 Background

We will use this section to provide background information on code-reuse attacks. We start by explaining ROP, and then provide insights on JIT-ROP, which collects code on-the-fly and thus evades existing randomization schemes like ASLR. Finally, we describe Execute-no-Read (XnR), a new defensive scheme that aims to protect against code-reuse attacks (including JIT-ROP).

2.1 Return Oriented Programming (ROP)

ROP has emerged since the wide deployment of Data Execution Prevention (DEP), which is a defense technique against regular stack overflow vulnerabilities. DEP, making the writable regions of the memory non-executable, forbids the attacker to execute the shellcode directly on the stack. As a response, attackers switched to code-reuse attacks, in which they execute *existing* code instead of injecting new code. ROP, proposed by Shacham [29], is a generalized version of the `ret-to-libc` attack [22], which redirects the control flow of the program to existing code, such as the program’s code or imported functions (e.g., in `libc`). In ROP, an attacker uses short instruction sequences (called gadgets) ending with a control flow instruction (e.g., `ret`). Return instructions are used to chain multiple gadgets together by providing their addresses as the return values on the stack. Checkoway *et al.* [8] showed that it is possible to launch ROP attacks without using return instructions, i.e., via leveraging other control flow changing instructions such as indirect jumps or calls.

Code-reuse remains a popular attack technique and has triggered a variety of defensive schemes. Most prominent, and deployed in most operating systems, is Address Space Layout Randomization (ASLR). ASLR randomizes the base addresses of memory segments and prevents an attacker from predicting the addresses of gadgets. Although ASLR is effective for pre-computed gadget chains, ASLR has known shortcomings in that it only randomizes base addresses and is too coarse-grained. An attacker can thus reveal the memory layout of an entire ASLR-protected segment with a single leaked pointer. To address this problem, fine-grained ASLR randomization schemes have been proposed that add randomness inside the segment [16, 20, 25] (we refer the reader to Larsen’s survey [21]).

2.2 JIT-ROP

To counter ASLR, Snow *et al.* proposed a new attack technique, called *just-in-time* code reuse (JIT-ROP) [31]. By leveraging the fact that an adversary is able to read randomized code sections, JIT-ROP undermines fine-

grained ASLR schemes. JIT-ROP is based on the following assumptions: (i) a memory disclosure vulnerability, allowing the attacker to read data at arbitrary locations, (ii) at least one control flow vulnerability, (iii) a scripting environment running code provided by the attacker. The basic idea of the JIT-ROP is the following:

- (J1) Repeatedly using the memory disclosure vulnerability, the attacker follows the code pointers in the memory to read as many code pages as possible.
- (J2) From the read code pages, JIT-ROP extracts gadgets (e.g., Load, Store, Jump, Move) and collects useful API function calls (e.g., `LoadLibrary`, `GetProcAddress`).
- (J3) Given the gadgets and API functions, the JIT-ROP framework takes an exploit, written in a high-level language, as an input and compiles it to a chain of gadgets and function calls that perform a code-reuse attack.
- (J4) Finally, the control flow vulnerability is used to jump to the beginning of the compiled gadget chain.

JIT-ROP demonstrates that an adversary may be able to run code-reuse attacks even in the case of fine-grained ASLR or code randomization, as she can read the code and function pointers *after* they have been randomized.

2.3 Execute-no-Read (XnR)

In an attempt to close the security weakness that JIT-ROP has demonstrated, researchers suggest marking code sections as *non-readable*. Such Execute-no-Read (XnR) schemes were proposed by Backes *et al.* [2], and were strengthened by Crane *et al.* [11, 12] shortly thereafter. The common goal is to prevent step (J1) of the JIT-ROP attack, as the attacker can no longer dynamically search for gadgets in non-readable code sections.

XnR: Lacking support for XnR pages in the current hardware, Backes *et al.* implemented XnR in software by marking code pages as *non-present* and checking the permissions inside a custom pagefault handler [2]. To increase the efficiency of this scheme, the authors propose to leave a window of N pages present. This exposes a few readable pages to the attacker, but prevents her from reading *arbitrary* code pages. As the authors suggest, at low window size ($N = 3$), the likelihood that an attacker can leverage code-reuse attacks using only the present code pages is negligible.

Readactor(++): Crane *et al.* suggested Readactor [11] and Readactor++ [12], both of which leverage hardware support to realize XnR. The authors suggest using Extended Page Tables (EPT), which were introduced recently to the hardware to assist virtualized environments. While regular page tables translate virtual addresses into physical ones, EPTs add another layer of indirection

and translate physical addresses of a VM to physical addresses of the host. EPTs allow marking pages as (non-)readable, (non-)writable, or (non-)executable, allowing enforcement of XnR in hardware. In addition, Readactor(++) hides code pointers by creating trampolines, and replacing all code pointers in readable memory with trampoline pointers. The underlying assumption of Readactor(++) is that fine-grained code diversification techniques are in place, such as function permutation, register allocation randomization, and callee-saved register save slot reordering.

Despite the fact that Readactor hid code pointers, the layout of some function tables (e.g., import tables or vtables) stayed the same. This allows an adversary to guess and reuse the function pointers from these tables [27]. Readactor++ fixed this issue by randomizing these tables (to get rid of the predictable layout) and randomly injecting pointers to illegal code (to forbid function fingerprinting by executing it).

Alternative XnR Designs: Gionta *et al.* [15] proposed HideM, which, using a split TLB technology, differentiates between memory accesses and only allows instruction fetches to access code pages. Further, HideM considers the data in the executable memory pages that need to be read and uses read policies to guarantee their security. However, although HideM might be used to enforce non-readable code, it highly depends on the hardware support (e.g., split TLB). Furthermore, HideM does not hide code pointers. In addition, Pereira *et al.* [26] designed a technique similar to Readactor(++) that aims to get non-readable code for mobile devices in ARM. One of the advantages of their approach, called Leakage-Resilient Layout Randomization (LR²), is that it is implemented in software and does not require the underlying hardware support. LR² achieves this by splitting the memory space in half (into code and data pages) and instrumenting load instructions to forbid the attacker to read code. LR² also optimizes the use of trampolines by creating only a single trampoline for each callee instead of encoding one for each callee-caller pair.

Summarizing XnR: Even though the current XnR implementations mark JIT-compiled code as non-readable, existing prototypes allow to leak JIT code pointers via JIT-compiled code. We will show that an adversary that controls the JavaScript code can still run code-reuse attacks on the code generated by the JIT compilers.

2.4 JIT-Compiled Gadgets

JIT compilation remains a major challenge for XnR implementations. During JIT compilation, the JIT engine (e.g., of a browser) compiles JavaScript code into assembly instructions to optimize performance. This is done by converting each JavaScript statement into a sequence

of corresponding assembly instructions, making the code output of the JIT compiler predictable. The deterministic JIT compilation allows an attacker to influence the code output by controlling the JavaScript code. For example, Blazakis [7] and Athanasakis *et al.* [1] propose to craft special JavaScript statements that JIT-compile into gadgets. Consider a statement with an immediate value, such as the assignment `var a=0x90909090`. The JIT engine will compile this into a sequence of assembly instructions, one of them being a `mov eax,0x90909090` instruction that encodes the attacker-chosen immediate value. After the compilation, the attacker can jump in the middle of the instruction and use the bytes of the immediate value as an unaligned gadget, such as four consecutive `nop` instructions in our simple example.

JIT Compiler Defenses: Modern JavaScript compilers prevent such unaligned gadgets by *constant blinding*. Instead of directly emitting constants in native code, compilers XOR them with randomly generated keys, making the resulting constants unpredictable. After constant blinding, the aforementioned JavaScript statement will be compiled to the following assembly instructions, effectively removing the attacker-controlled constant:

```
mov eax, (0x90909090 ⊕ KEY)
xor eax, KEY
```

For performance reasons, modern browsers only blind large constants. For example, Chrome and IE blind constants containing three or more bytes, giving the attacker a chance to emit arbitrary two-byte gadgets. Athanasakis *et al.* [1] demonstrated that two-byte gadgets are sufficient to mount a successful ROP attack, provided that (i) code sections are readable, and (ii) available gadgets happen to be followed by a `ret` instruction.

While constant blinding protects against such gadget emissions, as we will show, it does not protect against our novel form of JIT-compiled *implicit constant* gadgets.

3 Assumptions

We now describe our assumptions that we follow throughout this paper, detailing a threat model and discussing defenses that we assume are in place on the target system. These assumptions are in accordance with the recently proposed defense mechanisms against JIT-ROP, such as XnR [2] and Readactor [11].

3.1 Defense Techniques

We assume that the following defense mechanisms of the operating systems and the target application are in place:

- **Non-Executable Data:** Data Execution Policy (DEP) is enabled on the target system, e.g., by us-

- ing the NX-bit support of the hardware, marking writable memory pages non-executable.
- **Address Space Layout Randomization:** The target system deploys base address randomization techniques such as ASLR, i.e., the attacker cannot predict the location of a page without a memory disclosure vulnerability. In addition, we assume popular fine-grained ASLR schemes [20, 33, 16, 25, 17], as suggested by current XnR implementations [11, 12], are applied on the executable, libraries, and JIT-compiled code.
 - **Non-Readable Code:** We assume that all code segments are non-readable, with this being either software- [2] or hardware-enforced [11, 12], notably also assuming that JIT-compiled code is non-readable.
 - **Hidden Code Pointers:** We assume that all code pointers, except for JIT-compiled ones, are present but anonymized, e.g., via pointer indirections such as trampolines proposed by Readactor. Note that, as mentioned by Crane *et al.*, Readactor(++) could be extended to also hide code pointers in JIT-compiled code. However, there is no implementation that shows this, neither is the performance impact of such a scheme clear. In addition, having the compiler running in the same process as the attacker might give the adversary the ability to read code pointers *during* the compilation process. We thus believe that hiding all possible (direct or indirect) code pointers is a challenging task and the attacker might still be able to leak the required function addresses.
 - **JIT Hardening:** We assume modern JIT defenses such as randomized JIT pages, constant blinding, and guard pages (i.e., putting an unmapped page between mapped ones). In our attack, for simplicity, we assume that sandboxing is either disabled or can be bypassed via additional vulnerabilities. In addition, assessing the security of Control Flow Integrity (CFI) defenses in JIT compilers is out of scope of this paper, as our core contribution is to show that an attacker can *inject* gadgets, and not to discuss the actual process of diverting control flow. Instead, we demonstrate the threat of attacker-controlled code emitted by the JIT compiler.

3.2 Threat Model

In the following, we enumerate our assumptions about the attacker. This model is consistent with the threat model of previous attacks such as JIT-ROP [31] and with the XnR-based defense schemes.

- **Memory Disclosure Vulnerability:** We assume that the target program has a memory disclosure vulnerability, which can be exploited repeatedly by the attacker to disclose the *readable* memory space (i.e., we can read data, but cannot read code).
- **Control-Flow Diversion:** We assume that the target program has a control-flow vulnerability, allowing the attacker to divert the control flow to an arbitrary location. Note that this by itself does not allow the attacker to exploit the program, given the lack of ROP gadgets due to fine-grained ASLR and XnR.
- **JavaScript Environment:** We assume that the vulnerable process has a scripting environment supporting JIT compilation, for which the attacker can generate arbitrary JavaScript code. This is common for victims that use a browser to visit an attacker-controlled web site. Similarly, it applies to other programs such as PDF readers.

4 JIT-Compiled Displacement Gadgets

In this section, we discuss how an attacker can induce *new* JIT-compiled gadgets by crafting special JavaScript code. Intuitively, we show that an attacker can generate predictable JIT-compiled code such that she can reuse the code without searching for it. We introduce new techniques to trigger predictable gadgets that all modern JavaScript engines happen to generate. We demonstrate that an attacker can create and use almost arbitrary x86/x64 gadgets in modern browsers and their corresponding JavaScript engines, such as Google Chrome (V8), MS Internet Explorer (Chakra), and Mozilla Firefox (SpiderMonkey).

We introduce two techniques to emit gadgets via implicit constants. First, in Section 4.1, we leverage JavaScript’s control flow instructions and emit conditional jumps (such as `je 0x123456`) that may encode dangerous offsets. Second, in Section 4.3, we show how an attacker can leverage offsets in direct calls, such as `call 0x123456`, to create gadgets.

4.1 Conditional Jump Gadgets

Our first target is to turn offsets encoded in conditional jumps (in JIT-compiled code) into gadgets. To this end, we use JavaScript statements, such as conditionals (`if/else`) or loops (`for/while`), that are compiled to conditional jumps. Figure 1(A) shows an example. In `js_gadget`, the body of the `if` statement contains a variable-length JavaScript code. After compilation, the `if` statement is converted to a sequence of assembly instructions containing a conditional jump, which, depending on the branch condition, either jumps over the body or falls through (e.g., `je <if_body_size>`). By varying

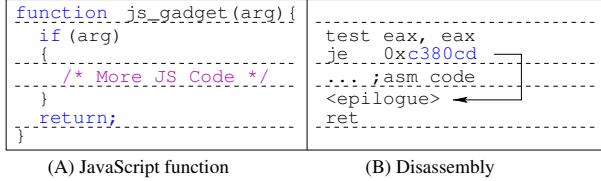

Figure 1: JavaScript function js_gadget and its corresponding disassembly

the code size inside the `if` body, we change the jump distance and thus the value encoded in the displacement field of the jump instruction in the compiled code. For example, if we aim for a `int 0x80;ret (0xcd80c3)` gadget, we have to fill the body of the `if` statement with JavaScript code that is compiled to `0xc380cd` bytes. The size of the JIT-compiled code for each JavaScript statement is fixed by the corresponding JIT compiler, and thus an attacker can precisely generate code of any arbitrary length. Note that the bytes of the size and the emitted gadget are mirrored because of the little-endian format used in x86/x64 architectures. The compiled version of `js_gadget` is shown in Figure 1(B).

Emitting such three-byte gadgets requires large portions of JavaScript code. In case the malicious JavaScript code has to be loaded via the Internet, this might drastically increase the time required for all gadgets to be in place. An attacker could overcome this limitation by utilizing the `eval` function. Instead of having ready-made JavaScript code, we thus use a function that constructs and emits all required gadgets on-the-fly. Such a script to dynamically generate arbitrary gadgets occupies less than one kilobyte.

In a naïve attack instantiation, each additional gadget will increase the overall code size. To counter this potential limitation, we can also embed smaller gadgets into the bigger ones by stacking `if` statements inside the body of another `if` statement, ideally reducing the size of the JavaScript code to the size of the biggest gadget.

Computing addresses of JavaScript functions: In order to use generated gadgets, we have to compute their addresses. We start by revealing the address of the JIT-compiled JavaScript function, which contains emitted gadgets, by employing a memory disclosure vulnerability. We can do this, for example, by passing the function as a parameter to another one, thus pushing its value on the stack. Afterwards, in the callee, we read the stack, revealing the pointer to the function's JavaScript object, which contains the code pointer to the actual (JIT-compiled) function. Note that here we assume that we know the location of the stack. This can be done by chasing the data pointers in the readable memory, until we find a pointer pointing to the stack.

Because of the predictable code output of JIT compil-

ers, we know the offsets inside the JIT-compiled function, at which conditional jumps will be emitted and can thus compute the addresses of emitted gadgets.

4.2 Conditional Jump Gadgets in Browsers

We tested this technique against three modern browsers: Chrome 33 (32-bit)/Chrome 51(64-bit), Firefox 42 (64-bit) and IE 11 (64-bit with 32-bit JavaScript engine). There are some differences that need to be taken into account for each of them. For example, Chrome compiles JavaScript functions the first time they are called, while Firefox and IE interpret them a few times until they are called too often (e.g., around 50 times for IE and 10 times for Firefox) and only then JIT-compile the JavaScript code. Therefore, to trigger the compilation we just call the function multiple times and then wait until it is compiled (which takes a few milliseconds).

Chrome: As each browser has its own JIT compiler, an attacker has to vary the JavaScript code to fill the exact number of bytes in the if body. This is just a matter of finding a mapping between JavaScript statements and the number of bytes of their JIT-compiled equivalent. We will demonstrate this by emitting a system call gadget (`int 0x80;ret`) in 32-bit Chrome. To this end, we need to emit `0xcd80c3`, i.e., we need to fill the if body with JavaScript code that is JIT-compiled to `0xc380cd` bytes. We use the following two JavaScript statements:

S1: $v=v1+v2$, compiling to 0x10 bytes, and
S2: $v=0x01010101$, compiling to 0xd bytes.

By combining these two statements, we can generate arbitrary gadgets. In our case, we use S1 0x0c 38 0c times (resulting in 0xc3 80 c0 bytes) and S2 once—summing up to 0xc3 80 cd, our desired gadget.

Note that the JavaScript statement that compiles to 0x10 bytes allows us to control each hex digit of the emitted jump distance except the last one (i.e., the least significant half-byte of the gadgets' first byte). Moreover, any JavaScript statement that compiles to an odd number of bytes allows us to control the least significant half-byte of the distance. Combining these two properties, we can generate any gadget by using these two selected JavaScript statements multiple times.

The sizes of JIT-compiled JavaScript statements differ in 64- and 32-bit versions of Chrome. In 64-bit Chrome we replace S1 with `v=v`, which is compiled to 0x10 bytes. Note, however, that even though the size of S2 in 64-bit is also changed to 0x1b bytes, we can still use it because it is compiled to an odd number of bytes.

Firefox: To generate arbitrary gadgets for Firefox, we choose the following two statements:

S1: $v=v$, compiled to 8 bytes (two of them to $0x10$), and
S2: $v+=0x1$, compiled to 0x21 bytes.

```

0x0000: call FUN_1      ; 0xe8fb1f0000
0x0005: call FUN_1      ; 0xe8f61f0000
0x000a: ...
0x2000: push ebp        ; 0x5d(@FUN_1)

```

Figure 2: Direct call

IE: IE deploys JIT-hardening mechanisms that go beyond the protections in Chrome and Firefox. IE (i) has a size limit on code segments generated by the JIT compiler, and (ii) randomly inserts NOPs (i.e., instructions that do not change the program state) in JIT-compiled code. Because of (i), we can only emit two-byte gadgets. Due to (ii), these gadgets are then further modified by inserting NOPs inside the if body and, thus, changing the value emitted in the conditional jump. The latter technique is similar to librando [17]. Nevertheless, even with these defenses in place, we can still emit arbitrary two-byte gadgets by measuring the size of the emitted code at run time. We will describe this attack in Section 4.4 in the discussion about Internet Explorer.

4.3 Direct Call Gadgets

We found that conditional jumps are not the only instructions to embed implicit constants that can be indirectly controlled by the attacker. Direct calls (e.g., `call 0x1234560`) are another example of such instructions. In our second approach, we leverage the JavaScript statements that are compiled to instructions containing direct calls.

Direct call constants: Direct calls in x86/x64 change the execution flow of the program by modifying the instruction pointer (`eip/rip`). The constant encoded in a direct call instruction represents a relative address of the callee. That is, the call instruction’s displacement field contains the distance between the addresses of the instruction following the call and the callee. Therefore, any two direct call instructions to the same function will encode different constants. For example, in Figure 2, there are two consecutive calls to the function `FUN_1` (at address `0x2000`). The constant encoded in the first call denotes the distance between `FUN_1` and the instruction following the call (i.e., the second call at `0x05`). Therefore, its value is $0x2000 - 0x5 = 0x1ff5$, which is `0xfb1f0000` encoded in little-endian.

In the example above, the difference between two consecutive direct call constants is `0x5` (the size of a direct call instruction). In general, the difference is equal to the size of the instructions between two consecutive calls. In our case, we want to use JavaScript statements to emit direct calls in the JIT-compiled code. Therefore, the difference between the constants will be the size of the in-

```

function js_call_gadget() {
    asm_call(); /* emits a call */
    asm_call();
    /* ... (many asm_call() statements) */
    asm_call();
}

```

Listing 1: JavaScript function `js_call_gadget`

structions in which the JavaScript statement is compiled.

To generalize this attack vector, we aim for a JavaScript function similar to `js_call_gadget` (Listing 1). The `asm_call()` statement is a placeholder for any JavaScript statement (not necessarily a function call) that is compiled into a sequence of instructions containing a direct call. The exact statement that replaces the placeholder depends on the target browser.

Finding callee address: Let our goal be to emit a three-byte gadget and fix its third byte to `0xc3` (`ret`). To calculate the constant encoded in the displacement field of a direct call instruction, we have to know the addresses of the call instruction and its destination. The destinations of the emitted call instructions that we have encountered are either helper functions (e.g., inline caches generated by V8) or built-in functions (such as `Math.random` or `String.substring`). The helper functions are JIT-compiled by V8 as regular functions. We can leak their addresses either by stack reading (e.g., by leaking the return address put there by the call instruction inside the helper function), or by reading the V8’s heap, where all the references of compiled helper functions are stored. In IE, the built-in functions are located in libraries and thus are randomized via fine-grained ASLR schemes [12, 11, 17]. However, their corresponding JavaScript objects (e.g., `Math.random`) contain the code pointer to the function. Knowing the structure of these JavaScript objects, which are not randomized according to our assumptions, we can get the addresses of built-in functions via a memory disclosure vulnerability. Note that after code pointer hiding, the addresses that the attacker leaks from these JavaScript objects will be the addresses of the trampolines and not the actual functions. Nevertheless, offsets, encoded in call (or jump) instructions, will also be computed relative to the trampolines and thus can be used for calculating emitted constants.

Emitting call instructions: Knowing the address of the callee, the next step is to emit direct call instructions at the correct distance. Given that we cannot influence the address where the function will be compiled, we have to acquire sufficiently large code space to cover all three-byte distances to the callee. To this end, we create a JavaScript function that spans `0x1 00 00 00` bytes after JIT compilation and consists of JavaScript statements emitting direct calls. More precisely, we require the distance between the first and the last emitted direct call

instructions to be at least 0x100000 bytes. This way, regardless of where our function is allocated, we will be guaranteed that it covers all possible three-byte distances from the callee, allowing us to emit arbitrary three-byte gadgets by carefully placing direct call instructions.

Emitting required gadgets: Creating such a large function (16 MB) emits many three-byte gadgets, and also covers all two-byte gadgets. For example, if we have a JavaScript statement that generates a call instruction and is compiled to 0x10 bytes of native code, we can create a big function containing this statement 0x100000 times. The compiled function will have 0x100000 direct call instructions 0x10 bytes apart. If we consider the least significant three bytes of the emitted displacement fields of these direct calls, they will have the following form: $0x*Y***$, where * denotes any hexadecimal digit [0-f] and Y is a constant, which encodes the least significant half-bytes of emitted values.

Because of the little-endian format used in x86/x64 architectures, Y is part of the first byte of emitted gadgets. Therefore, to emit three-byte gadgets, we must be able to set Y accordingly. To this end, we modify the value of Y by varying the size of the instructions before the first direct call. That is, we find any JavaScript statement that compiles to an odd number of bytes, and then use it up to 15 times to get any out of all possible 16 half-bytes. For example, if the least significant half-byte of the call instruction is 0x0 and we want to make it 0xd, and we have a JavaScript statement that compiles to an odd number of bytes (e.g., `i+=1` in 32-bit Chrome, 0x13 bytes), we use this statement 15 times ($0x13*15=0x11d$).

Computing addresses of emitted gadgets: Assuming that the address of the first call instruction in our function is F_{call} , and the address of the callee is F_{dest} , we can compute three bytes of the displacement field of the first call instruction by $C_1 = F_{dest} - (F_{call} + 5) \bmod 2^{24}$. If the required gadget is G, then we can compute the distance (dist) between the call instruction, emitting G, and the first call instruction: $dist = C_1 - G \bmod 2^{24}$. Using dist, we can calculate the address of the call instruction emitting G ($F_{call} + dist$), and therefore the address of the gadget (G_{addr}) which is located 1 byte after the call: $G_{addr} = (F_{call} + dist) + 1$.

4.4 Direct Call Gadgets in Browsers

We will next discuss techniques that we use to instantiate the attack in three popular browsers.

Firefox: Emission of direct call gadgets is not possible in Firefox, as the baseline JIT compiler of Firefox does not emit direct calls. Although the optimizing JIT compiler of Firefox emits direct calls, e.g., when compiling regular expressions, it only optimizes JavaScript functions after they have been executed more than 1,000 times. Trig-

gering the optimizing compiler on the large functions (as required for our attack) thus makes our attack impractical against Firefox.

Chrome: Chrome compiles most JavaScript statements to direct calls. Consequently, we have a large selection of JavaScript statements with varying post-compilation sizes. We use a statement that is compiled to 0x10 bytes of assembly code (e.g., `i=i+j` for 32-bit Chrome). For demonstration purposes, we aim to emit a system call gadget (`int 0x80; ret`), implicitly also revealing all two-byte gadgets. To this end, we create a function shown in Figure 3(A). The function starts with a sequence of JavaScript statements that align the first call instruction to 0xe. After this, the emitted call distances will be calculated relative to 0x3, i.e., $(0xe+0x5) \bmod 0x10$, where a direct call is 0x5 bytes large. Considering that the callee is at least half-byte aligned, the lower half-byte of all emitted gadgets' first bytes will be 0xd, i.e., $(0x0-0x3) \bmod 0x10$. The alignment code is followed by a sequence of call-generating statements (e.g., `i=i+j`), each of which compiles to 0x10 byte-long code. The compiled `i=i+j` statement emits a call instruction at offset 0x*e (due to alignment) as shown in Figure 3(B). Generating a sequence of 0x100000 call instructions, we are guaranteed to have an `int 0x80; ret` gadget encoded into one of the call instruction constants (Figure 3(C)).

Note that the aforementioned technique is used in the 32-bit version of Chrome. For 64-bit, we use the `v++` statement, which is compiled to 0x20 bytes (instead of 0x10) and emits a `call` instruction. Having 0x20 bytes between `call` instructions changes the upper half of the least significant byte. For example, after aligning the least significant half-byte to 0xd via padding, the emitted first bytes will be either $0x\{0,2,4,6,8,a,c,e\}d$ or $0x\{1,3,5,7,9,b,d,f\}d$, depending on the initial value of the upper half of the least significant byte. We can modify this value to our liking by adding the `i=i` statement, which is compiled to 0x10 bytes, as padding.

Internet Explorer: For the two main reasons mentioned in Section 4.1 (code size limit and NOP insertion), emitting gadgets is harder in IE. The per-function code size limit forbids us to emit 0x100000 bytes of native code, which is required to span all possible third bytes of the constants encoded in call instructions. However, in the following, we describe how an attacker can still encode gadgets in direct calls even in IE.

Emitting calls at correct distance: IE still allows us to create many small functions. These functions will be distributed in the set of pages, each of them being 0x2000 bytes large. We thus allocate many functions (200 in our case), each of them being $\lesssim 0x1000$ bytes (i.e., two functions per page). Given the alignment (0x1000) and the size (0x2000) of the spanned code pages, each page will cover two third-bytes of

<pre>function js_call_gadget_v8() { var i, j; // Align calls to 0xe i = i + j; // i=i+j 0x3a86b times i = i + j; // i=i+j 0xc5793 times i = i + j; }</pre>	<pre>0x*0: ... 0x*7: ... 0x*e: call BINARY_OP_IC ;e8 8d07feff ... 0x*7: ... 0x*e: call BINARY_OP_IC ;e8 cd80c3ff ... 0x*7: ... 0x*e: call BINARY_OP_IC ;e8 8d07fefe</pre>	
(A) JavaScript function	(B) i=i+j direct calls	(C) Bytes emitted by direct calls

Figure 3: JavaScript function emitting gadgets via direct call constants

the absolute address completely (e.g., from 0x12₃₄0000 to 0x12₃₅ff ff). Considering that the callee is not aligned to the same boundary, direct calls emitted in these pages will have three distinct third bytes in their constants, only one of them covered completely. For example, if we assume the callee to be at address 0x12₃₄5670 and the page emitted at 0x01₇₀0000, only the call instructions located in the address range [0x01705670, 0x01715670] can emit complete three-byte constants, having 0xc3 as their third byte, i.e., constants from 0x12345670 - 0x01705670 = 0x10_{c4}0000 to 0x12345670 - 0x01715670 = 0x10_{c3}0000. On the other hand, the ranges [0x01700000, 0x01705670] and [0x01715670, 0x0171ff ff] cover only parts of the constants, with 0xc4 and 0xc2 as their third bytes.

After allocating the functions, we dynamically check their addresses to find the one with the correct distance from the callee (using the same technique as described at the end of Section 4.1), i.e., the one having the correct third byte in its direct call instruction’s displacement field. Allocating 200 JavaScript functions, each of them containing 0x10000 bytes, is inefficient, especially if the code has to be downloaded to the victim’s machine. Therefore, we use eval to spam IE’s code pages with the dynamically created functions. The problem with evaluated functions is that IE does not emit direct call instructions in them and uses indirect calls instead. Therefore, we use these functions only as temporary placeholders. Once we find any evaluated function at the correct place, we deallocate it to make its place available for the subsequently compiled functions. To deallocate a JavaScript function, we set null to all of its references and wait until the garbage collector removes it (typically within less than a second).

Verifying emitted gadgets: At first sight, IE’s NOP insertion conflicts with our assumption about the predictability of JIT-compiled code. With NOP insertion, and likewise with many other fine-grained code randomization schemes, we cannot guarantee that the call instruction, which is supposed to emit the gadget, ends up

```
function js_call_gadget_IE() {
    // Padding to correct address
    var i = Math.random(); // emit direct call
    check_address(<random cookie value>);
}
```

Listing 2: JavaScript function js_call_gadget_IE

at the correct address. However, because NOPs are inserted at random, compiling the same JavaScript function multiple times actually *increases* the chance that in one of the compiled versions, the call instruction ends up at the correct place.

Following our threat model, though, we cannot read executable code segments to verify if the compiled call instruction is at the desired place. As an alternative, we read the stack, as shown in Listing 2. In js_call_gadget_IE(), the statement i=Math.random() emits a direct call. We pad the beginning of the function with a few JavaScript statements to place i=Math.random() at approximately the correct address, such that the relative address would encode the desired gadget, accounting the randomness induced by NOP insertions. We then check the correctness of the position via check_address, a JavaScript function that reads the stack to find the return instruction pointer put there by the call instruction.

Using the leaked return address, we can calculate the address of the direct call instruction emitted by i=Math.random(), verify that it is at the correct place and if so, use it as a gadget. A simple implementation of check_address is shown in Listing 3, where it uses a memory disclosure vulnerability (mem_read in this case) to read the stack from some starting point (ESP_), until it finds its own parameter (cookie). The parameter is a random number, reducing the chance that multiple positions have the same value (note that this chance can be further reduced by using multiple random parameters). After finding the cookie on the stack and thus the address of the parameter, we know the exact offset

```

function check_address(cookie) {
    // ESP_: Any address on stack
    // NEEDED_ADDRESS: address where
    //                   call must reside
    while(mem_read(ESP_) != cookie)
        ESP_ -= 4; // Check next value
    // get return address from parameter
    var ret_ = mem_read(ESP_ - 0xC);
    // get call instruction address
    var call_addr = ret_ - 5;
    return call_addr == NEEDED_ADDRESS;
}

```

Listing 3: JavaScript function *check_address*

from the parameter’s address, and from there we can tell where the return address is located. Reading the return instruction pointer, we recover the address of the corresponding call instruction and verify that it is at the correct place (NEEDED_ADDRESS in this case). We can add another call to *check_address* before *i=Math.random()* to verify if NOPs are inserted between the emitted call instructions of *i=Math.random()* and *check_address()*. If both checks (*check_address*) succeed, we will be guaranteed that no NOPs were inserted.

IE summary: An attacker can evade both aforementioned defenses and emit three-byte gadgets even in IE. To demonstrate this, we first dynamically create many JavaScript functions to get the correct third byte (0xc3). After finding the function at the correct distance from the callee, we replace it with a special function, which, after compilation, emits direct call instructions and checks their positions. We trigger the recompilation of the latter function multiple times, until the checks are true, which means that the gadget is found. In our experiments, spamming the code pages with functions took approximately four seconds, and for most of the time, we found the correct third byte on the first try. Triggering the recompilation of a function takes the following steps: (i) Remove the included JavaScript file from the head of the HTML file, (ii) wait until the function gets removed by the garbage collector, and (iii) include the JavaScript file again and trigger the compilation of the same function. Each iteration of the above steps takes around 2 seconds, most of the delay coming from the second step (waiting for the garbage collector).

For two-byte gadgets, on the other hand, an attacker can discard the third byte. In this case, she can directly compile multiple functions at once, check the positions of emitted direct calls and use the ones with the required displacements.

4.4.1 Proof-of-Concept Gadget Generation

To demonstrate the practicality of the aforementioned gadget emitting techniques, we crafted a special JavaScript code for Chrome and IE, which generated the gadgets required for the exploit. The gadgets that we aimed to generate are the ones used by Athanasakis *et al.* Namely, the set of gadgets to load the registers with the arguments used in a system call and one for the system call itself. We created these gadgets in Chrome 51 (64 bit) and IE 11 (32 bit).

Chrome: For Chrome, we targeted for the following instructions: *pop r8*; *pop r9*; *pop rcx*; *pop rdx* (to prepare the system call arguments) and *int 0x80* (to execute the system call). Being able to emit three-byte gadgets, we encoded these instructions into the following gadgets:

<i>pop r8, ret ; 4158c3</i>
<i>pop r9, ret ; 4159c3</i>
<i>pop rcx, ret ; 59c3</i>
<i>pop rdx, ret ; 5ac3</i>
<i>int 0x80, ret ; cd80c3</i>

We used both our proposed techniques for the emission of these gadgets. We generated a system call gadget via direct calls. First, we created a string representation of a JavaScript function containing *0x80000 j++* statements (*j++* takes *0x20* bytes), then we created a JavaScript function from it via *eval*, and finally we compiled it by calling the generated function. This gave us a system call gadget, together with all possible two-byte gadgets, hence also covering *pop rcx* and *pop rdx*.

For the generation of *pop r8* and *pop r9* gadgets, we used cascaded *if* statements (also created with *eval*). The JavaScript function generating the aforementioned gadgets is shown in Listing 4. As gadgets *pop r8* and *pop r9* differ by *0x100*, their corresponding *if* statements also have to be *0x100* bytes apart. Note however that in the first *if* body (F1), we add *0xed* bytes to fill up the space instead of *0x100*. This is due to the fact that an *if* statement is compiled to *0x13* bytes, which is also added to the distance between relative jumps. To get *0xed* bytes, we use *j=0x1010101 7 times (0xb1*7=0xbd)* and *j++;j=i;j=i* (*0x20+0x8+0x8=0x30*). To generate *0xc35841* bytes (F2), we use *j=0x1010101 0xd3 times (0xb1*0xd3=0x1641)*, and fill the remaining *0xC34200* bytes by using *j++ 0x61A10 times (0x20*0x61A10=0xC34200)*.

The entire gadget generation process in Chrome took ≈ 1.3 seconds, in a VirtualBox Virtual Machine running Windows 10 (Intel Core i5-4690 CPU 3.50GHz).

Internet Explorer: As we have mentioned earlier, Internet Explorer, by default, comes with a 32-bit JIT compiler. Therefore, for gadget generation we chose gadgets that would be used in a 32-bit system. For simplicity

```

function popr8r9(r8,r9) {
  var i=0,j=0;
  if(r9) {
    /* F1: fillup 0xed Bytes */
    if (r8) {
      /* F2: fillup 0xc35841 Bytes */
    }
  }
}

```

Listing 4: JavaScript function *popr8r9*

```

function syscallIE() {
  var i=0;
  i=Math.random();
  ... /* 240 times in total */
  check_address();
  i=Math.random();
  ... /* 10 times in total */
  return i;
}

```

Listing 5: JavaScript function *syscallIE*

we used the set: `popa; int 0x80`, where `popa` sets the contents all x86 registers from the stack and `int 0x80` performs the system call.

The first part of the gadget emission process in IE is finding the right distance from the callee, i.e., a page that is `0xc3` bytes away from the callee. This part was done by a JavaScript code, which simply creates and compiles big functions (in our case 200 of them, $\approx 0x10\,000$ bytes each). After finding the correct page, we deallocated it and spammed the page with 16 specially crafted JavaScript functions, each of them covering `0x1000` bytes. For example, the JavaScript function used for emitting a system call (Listing 5) contains 250 `Math.random` calls (each of them compiling to `0xc` bytes). At the correct place between these calls, i.e., when the caller is at approximately the correct distance from `Math.random`, we inserted a call to `check_address` to verify the correctness of the gadget. In case the emitted call is not at the correct place, we deallocated the function and reallocated it again. Note that the reallocation is only needed for three-byte gadgets, where we also want to control the least significant byte. For two-byte gadgets (e.g., for `popa; ret`), we only need to call `check_address` to compute the address of the call instruction, for which we already know that is at the correct place (Listing 6).

In comparison to Chrome, gadget generation in IE is probabilistic and thus the time required for it also differs. There are two sources of the variance. First, generating the large functions to search for the correct third-byte distance from the callee; and second, compiling the gadget-emitting function in the found (correct) page, and

```

function poparetIE() {
  var i=0;
  i=Math.random();
  ... /* 232 times in total */
  check_address();
  i=Math.random();
  ... /* 28 times in total */
  return i;
}

```

Table 1: Current defenses in modern browsers

recompiling it until the correct gadget is emitted. In our experiments, we created 200 large functions and got the required third-byte distance for the first time in most of the cases. Compilation of these 200 functions took ≈ 4 seconds on a physical machine running Windows 10 (Intel Core i5-6200U CPU 2.3GHz). Each recompilation in the second step took 2-3 seconds. We ran the gadget generator in IE 10 times. Generating `popa; ret` and `int 0x80; ret` took on average 32 seconds, 11 and 47 seconds being the fastest and the slowest respectively.

4.4.2 Summary of Defenses and Vulnerabilities

We have shown that an attacker can encode arbitrary gadgets by triggering implicit constants with specially-crafted JavaScript code. Combining this with the ability to leak code pointers, an adversary can guess the addresses of the emitted gadgets without reading any code, thus making the attack possible even if code pages are non-readable.

Table 1 summarizes the defense techniques of modern browsers against code-reuse attacks in JIT-compiled code. Both IE and Chrome deploy constant blinding. Furthermore, IE uses NOP insertion as a fine-grained code randomization scheme, as also suggested in libbrando [17]. However, as Table 2 shows, none of the modern browsers sufficiently protect against the proposed attacks. Only Firefox “avoids” implicit constants by not using direct calls in baseline JIT compiler, but still exposes implicit constants in relative jumps.

¹Gadgets up to two bytes can be emitted.

Attack	Chrome	Firefox	IE
Relative Jumps	✗	✗	✗ ¹
Direct calls	✗	–	✗

Table 2: Browsers vulnerable to implicit constants

5 Defense

Seeing the threat of implicit constants, we now propose a technique to defend against it. We identify two steps that the attacker needs to take for using implicit constants as gadgets: (i) The attacker must be able to emit the required gadgets, and (ii) she must be able to acquire the necessary information (e.g., leak function pointers) to compute the addresses of the emitted gadgets.

One solution to tackle this problem would be to hide code pointers, e.g., by extending Readactor(++) to also cover the JIT-compiled code, as Crane *et al.* suggested. This would hinder the attacker from executing step (ii). However, this would still allow the attacker to emit arbitrary gadgets by leveraging the implicit constants (step (i)). Furthermore, the fact that the JIT compiler runs in the same process as the attacker makes it challenging to remove all possible code pointers that could, directly or indirectly, reveal the addresses of emitted gadgets. Therefore, we propose an orthogonal defense technique that forbids the attacker to emit the gadgets in the first place (i.e., step (i)). Our defense could be complemented with holistic code pointer hiding techniques to get additional security guarantees.

The main idea of our defense can be split in two parts: (i) We convert direct calls and jumps into indirect ones, such that their destination is taken from a register, and (ii) we use constant blinding to obfuscate the constants that are emitted by step (i) and may potentially contain attacker-controlled gadgets. For step (ii), we use the same cookie that is used by V8 to blind integer constants, and is generated anew before the compilation of each function. Note that the cookie is encoded in non-readable code and cannot be leaked. However, even if the attacker was able to leak the cookie, she could only guess the immediate values emitted in the current function, and any future function will have a different cookie value.

5.1 Removing Implicit Constants from V8

We integrated our defense into V8, Chrome’s JavaScript engine. We have chosen V8 due to its popularity and due to the fact that it is vulnerable to both our suggested attacks. Moreover, since V8 JIT-compiles JavaScript directly to the native code, it emits many checks (conditional jumps) and function calls (e.g., calls to inline

caches), which makes V8 a suitable candidate for our defense prototype evaluation. For our defense technique, we changed the functions of V8 that are responsible for emitting native code. In total, we modified ≈ 200 lines of code to account for all the cases of attacker controlled relative calls or jumps.

5.1.1 Conditional Jumps

To harden conditional jumps, we modified the native code that is emitted when JavaScript conditionals (such as `if`, `while`, `for`, `do-while`) are compiled. Our basic idea is to switch from relative to absolute jumps, and blind the resulting immediate values. To this end, we first add a padding (a sequence of NOP instructions) to each compiled conditional to reserve the space for later changes. For the hardened version of the conditional jump we need 19 bytes (instead of 6 bytes). We thus append 13 NOP instructions after the existing conditional jump. At the end of the compilation, when the constants of all jumps are calculated, we convert all relative jumps to absolute jumps, eliminating the need to fill a displacement with potential gadgets.

Figure 4 illustrates the steps of the aforementioned modifications. Figure 4(A) shows the compiled `if` statement in original V8. Figure 4(B) shows the same statement with the NOP padding. Finally, Figure 4(C) shows the assembly of the hardened `if` statement. In this final form, the condition of the original jump is inverted and the original long jump (having 4 byte jump distance) is replaced with the 1-byte short jump. Consequently, the new jump is taken if the original condition was false, i.e., the fall-through case. Otherwise, we convert the relative address into the absolute one, by adding it to the current instruction pointer (`rip`). This can be done with a single instruction in x64 (`lea r10, [rip+0xc380ca]`).

As this instruction will still emit the relative address as the displacement, we split it in two instructions. First, we add the current instruction pointer to the relative address AND-ed with a random key (`rip+0xc380ca&KEY`). In the second `lea` instruction, we add the sum to the relative address AND-ed with the inverted (bitwise not) random key, resulting in the desired offset (`rip+0xc380ca`). Note that we use obfuscation by AND-ing the constant with a random key instead of XOR-ing it, because $(A + B \oplus C) \oplus C$ does not equal to $A + B$, while $(A + B \wedge C) + B \wedge \neg C$ does. Moreover, this obfuscation scheme allows us to use `lea` instructions only, which has the advantage of not modifying any flags.

5.1.2 Direct Calls

We mitigate the implicit constants in direct calls by converting the direct calls into indirect ones. To this end, we

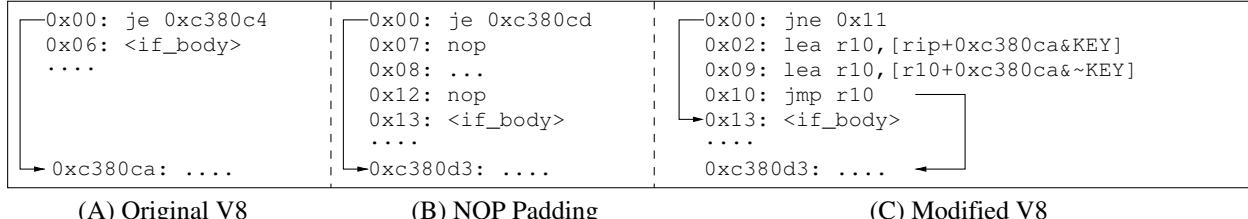

Figure 4: Steps of JIT hardening in V8

```

0x00: lea r10, [rip+ADDRESS&KEY ]
0x07: lea r10, [r10+ADDRESS&~KEY]
0x0e: call r10 ; calls 0xc380d3
0x11: ....

```

Figure 5: Hardening direct calls

distinguish whether the address of the callee is known at compile time (e.g., when calling built-in functions). If the callee’s address is known, we can move it to a scratch register (`r10`) and then execute an indirect call `mov r10, ADDRESS; call r10`. We thus emit the absolute address of the callee as the immediate value of the `mov` instruction, which is not under the control of the attacker and is thus safe—in contrast to the relative address.

If the address is unknown at compile time, we use a similar technique as we did for the conditional jumps, i.e., we convert the relative address into an absolute one (blinding the relative address during the conversion), store it in the scratch register, and then execute an indirect call, as shown in Figure 5.

5.2 Evaluation

To evaluate our defense technique we ran the V8 Benchmark Suite 7 on our modified V8. We performed each benchmark 100 times on both the modified and original V8s, and compared their corresponding averaged results. Table 3 illustrates the average scores that were returned by the benchmark suite, where a higher score indicates better performance. The modified V8 has an average overhead of less than 2%, and the worst overhead less than 3%. The observation that the overhead is negative for the *NavierStokes* benchmark can be explained by statistical variations across the different runs.

Additionally, we tested the modified V8 with microbenchmarks. To this end, we created two JavaScript functions (`ifs_true` and `ifs_false`), both of them containing 1,000,000 `if` statements. The condition of the `if` statement in `ifs_true` is always `true` (i.e., the `if` body is executed), while the condition of `ifs_false` is always `false`. This way the JIT-compiled functions will contain 1,000,000 conditional jump instructions modified by us,

each of them testing separate execution paths. Furthermore, evaluation of the expression in the `if` statements is done via a function call. Therefore, both of these functions generate 1,000,000 modified call instructions each and will thus incorporate the overhead caused by the function calls. Each run of the microbenchmark calls each of these functions 10 times. We ran the benchmark 1,000 times. We distinguish the first execution of these functions from the remaining nine, as the first execution is significantly slower due to the JIT-compiler modifying the generated intermediate functions to adjust them to the type information. Because the overhead was dominated mostly by the compiler, we did not see any overhead for the first function execution. For the remaining function executions we had 14.25% overhead in `ifs_false` and 9.81% for `ifs_true`.

Besides computational performance, our defense technique also causes a memory overhead due to added code. To measure this overhead, we compared the sizes of the functions compiled by the original and the modified versions of V8. To get the needed output from V8, we ran it with the `--print-code` flag, which outputs the disassembled code for each function after the compilation together with additional information about the compiled function including the size of the generated instructions. Running the benchmark suite with the aforementioned flag yielded that the total size of the instructions emitted by the original V8 was 1,123 kB, while the modified V8 emitted 1,411 kB, giving 287 kB of additional code, i.e., $\approx 26\%$ code size overhead. Given the significant size of the benchmark suite, and given that memory of nowadays x86/x64 systems are typically in the range of gigabytes, we think that hundreds of kB of additional code does not cause any bottlenecks on COTS systems.

6 Discussion

6.1 Defense Security Considerations

Our defense follows the general goal to remove unintended gadgets from constants in JIT-compiled code. We tailored our defense implementation towards protecting jump and call offsets. Other offsets may be usable to en-

Benchmark	Original	Modified	Overhead(%)
Richards	36,263	35,555	1.95
DeltaBlue	63,641	62,045	2.51
Crypto	33,366	32,725	1.92
RayTrace	77,198	75,488	2.21
EarleyBoyer	44,900	43,700	2.67
RegExp	6,525	6,414	1.71
Splay	21,095	20,479	2.92
NavierStokes	31,924	31,998	-0.23
Total	32,255	31,662	1.96

Table 3: Scores by the V8 benchmark (higher is faster)

code further gadgets. For example, relative addressing is frequently used in combination with the base pointer, such as when accessing parameters of a JavaScript function. As parameters are stored on the stack, they are accessed relative to the frame pointer (`ebp/rbp`). Each parameter access, after JIT-compilation, emits an assembly instruction, which contains the offset of the parameter from the frame pointer in its displacement field: `mov [ebp+0x0c],0x1`. The number of possible gadgets, in this technique, is restricted by (i) limited stack size (e.g., maximum $2^{16} - 1$ (`0xffff`) function parameters in Chrome) and (ii) stack alignment (4 or 8 bytes). In combination, this only allows generating gadgets whose opcodes are multiples of 4 (or 8) and are in the range between `0xc` and `0x40000`, and thus gives the attacker only limited capabilities. The stack size restrictions impose the same limitations on implicit gadgets encoded in relative accesses to function’s local variables.

While we think that the most important constants are blinded, we cannot exclude the existence of further ways to encode gadgets in assembly instructions. To eradicate all potential gadgets, one could prevent the JIT compiler from creating any potential gadgets (even in unaligned instructions). Most notably, G-Free [24] is a gadget-free compiler, which tries to generate gadget free binaries. However, G-Free requires multiple recompilations and code adjustments to reliably remove all possible gadgets. This will increase the runtime overhead for the JIT compilers, as the compilation time is included in their runtime.

6.2 Fine-Grained Code Randomization

An orthogonal approach to our defense would be to remove the attacker’s capability to find the gadget’s location (i.e., address). One way of doing so would be to hide code pointers, e.g., via trampolines, as suggested by Crane *et al.* [11]. If code pointers are not hidden, the attacker can read the return instruction pointer on the stack to get a pointer to the created gadget—which rep-

resents the current status in XnR implementations. This results in (i) getting access to the gadget, (ii) a possibility to verify the gadget at runtime, and (iii) the ability to retry in the case of a false result. By using similar techniques as we used against NOP insertion, the attacker can defeat fine-grained code randomizations such as the ones underlying Readactor [11]. Even though current XnR implementations do not hide code pointers in JIT-compiled code, XnR’s ideal implementation could also expand fully to the JIT-compiled code, e.g., by introducing trampolines. This, together with the fine-grained randomization schemes such as NOP insertion, would successfully protect against our attack. Note, however, that NOP insertion does not remove gadgets, but tries to reduce the chances of the attacker to guess their locations. In contrast, our proposed defense technique removes the gadgets, hence also removing the risk of the attacker doing a guesswork. Combining our technique with the extended XnR implementation would further improve the security guarantees, removing the chances of both emitting the gadgets and leaking the code layout information.

To guard against JIT-compiled gadgets, Wei *et al.* proposed to do several code modifications such as (i) securing immediate values via constant blinding, (ii) modifying internal fields of the instruction (e.g., registers being used), and (iii) randomizing the order of the parameters and local variables to randomize the offsets emitted by them [34]. However, this is not effective against the attacks proposed in Section 4, as the modifications do not secure the displacement fields emitted by relative calls/jumps. Finally, the code randomization proposed by Homescu *et al.* [17] that adds NOP instructions to randomize the code output from the JIT compiler remains ineffective if code pointers in JIT-compiled code are not hidden.

6.3 Attack Generality

A natural question is how the proposed attack generalizes, in particular to other operating systems or CPU architectures. We have evaluated the attacks against Chrome and Firefox running on Linux and IE on Windows. As we exploit properties of the JIT compilers to generate desired gadgets, the choice of the underlying operating system is arbitrary. The proposed attacks rely on the x86 system architecture (32- or 64-bit), though. In RISC architectures, such as ARM and MIPS, instruction lengths are fixed, and execution of unaligned instructions is forbidden by the hardware. However, the attacks may still apply to ARM, as an attacker could emit arbitrary two-byte values in the code if she can force the program to switch to 16-bit THUMB mode. Although this limits the attacker to using a single instruction, it still allows setting the register contents and diverting the control flow

at the same time, e.g., by using a `pop` instruction.

We implemented our defense in the 64-bit version of V8, taking advantage of the x64 architecture’s ability to directly read the instruction pointer (`rip`). This simplified the effort of converting relative addresses into absolute ones. Even though one can read the instruction pointer indirectly in 32-bit, e.g., by `call 0x0; pop eax`, such additional memory read instructions would increase the performance overhead. In addition, 32-bit features only eight general-purpose registers. While in x64 we could freely use a scratch register (`r10` for Chrome), in x86 we would likely need to save and restore the register. Similar defenses in x86-32 are thus possible, but come at an additional performance penalty. However, given that 64-bit systems are increasingly dominating the x86 market, we think that 64-bit solutions are most relevant.

7 Related Work

In the following, we will summarize existing code-reuse attacks and proposed defense mechanisms.

7.1 Code-Reuse Attacks: ROP / JIT-ROP

The most widespread defense against ROP is ASLR [32], which randomizes the base addresses of memory segments. Although it raises the bar, ASLR suffers from low entropy on 32-bit systems [30] and is not deployed in many libraries [28]. In addition, ASLR does not randomize within a memory segment, and thus leaves code at fixed offsets from the base address. Attackers can thus undermine ASLR by leaking a code pointer [18].

Researchers thus suggested fine-grained ASLR schemes that randomize code within segments. Fine-grained ASLR hides the exact code addresses from an attacker, even if a base pointer was leaked. For example, Pappas *et al.* [25] suggest diversifying code within basic blocks, such as by renaming and swapping registers, substituting instructions with semantically equivalent ones, or changing the order of register saving instructions. ASLP, proposed by Kil *et al.* [20], randomizes addresses of the functions as well as other data structures by statically rewriting an ELF executable. To increase the frequency of randomization, Wartell *et al.* propose STIR [33], which increases randomness by permuting basic blocks during program startup.

However, the invention of JIT-ROP undermined fine-grained ASLR schemes [31]. JIT-ROP assumes a memory disclosure vulnerability, which can be used by the attacker repeatedly. The attacker then follows the pointers to find executable memory, which she can read to find gadgets and build ROP chains on-the-fly.

Recently, Athanasakis *et al.* [1] proposed to extend JIT-ROP-like attacks by encoding gadgets in immediate

values of JIT-compiled code. Despite being limited to two-byte constant emission by IE, the authors managed to use aligned `ret` instructions, located at the end of each function, as the part of their gadget. Note that, in their attack, the authors were able to emit *complete* two-byte gadgets in IE. Therefore, this attack will be further limited against the 32-bit version of Chakra, which is a default JIT compiler, even for 64-bit IE. In addition, there are by now known defenses, such as constant blinding, that protect against explicit constants.

7.2 Hidden or Non-Readable Code

In reaction to JIT-ROP, researchers started to propose a great number of defensive schemes that try to hide code or function pointers. In Oxymoron, Backes *et al.* [3] aim to defend against JIT-ROP by hiding code pointers from direct calls. However, the attacker can still find indirect code pointers (e.g., return addresses on the stack or code pointers on the heap), and follow them to read the code. Davi *et al.* [13] thus proposed Isomeron, an improved defense. They keep two versions of the code at the same time, one original and another diversified using fine-grained ASLR. At each function call, they flip a coin to decide which version of the code to execute. This gives a 50% chance of success for each gadget in the chain, making it unlikely to guess correctly for long gadgets.

Gionta *et al.* [15] proposed HideM, which utilizes a split TLB to serve read and execute accesses separately, thus forbidding the attacker to read code pages. Apart from requiring hardware support, HideM also has a limitation that it does not protect function pointers, allowing the attacker to use them in code reuse attacks.

Backes *et al.* [2] and Crane *et al.* [11] proposed two independent defense techniques, XnR and Readactor, respectively, based on the same principle: making executable regions of the memory non-readable. XnR does this in software, marking executable pages non-present and checking the validity of the accesses in a custom page-fault handler. This leaves only a small window of (currently executing) readable code pages, significantly reducing the surface of gadgets an attacker can learn. Readactor uses Extended Page Tables (EPT), hardware-assisted virtualization support for modern CPUs. EPTs allow keeping all executable pages non-readable throughout the entire program execution. In addition, Readactor diversifies the *static* code of the program and hides addresses of the functions by introducing call/jump trampolines, making it impossible to guess the address of any existing code. While being effective against ROP attacks, Readactor left some pointers, such as function addresses in import tables and vtable pointers, intact, thus leaving the programs vulnerable against

function-wise code reuse attacks like return-to-libc [22] or COOP [27]. The fixes to these problems have been proposed by Crane *et al.* in their followup work Readactor++ [12]. We have demonstrated how an adversary can undermine these proposals if code pointer in JIT-compiled code are not hidden. As an orthogonal defense to hiding code pointer in JIT code, we proposed to eliminate implicit constants from JIT-compiled code to preserve XnR’s security guarantees.

Pereira *et al.* [26] designed a similar defense technique via a software-only approach for the ARM architecture. They propose Leakage-Resilient Layout Randomization (LR^2), which achieves non-readability of code in ARM by splitting the memory space in data and code pages and instrumenting load instructions to forbid code reading. Furthermore, LR^2 proposed to reduce the size overhead caused by trampolines by using a single trampoline for each callee and encoding the return address with secret per-function keys.

7.3 Defending JIT Against Attacks

Finally, we discuss research that aims to protect JIT compilers against exploitation. In JITDefender, Chen *et al.* [9] remove executable rights from the JIT-compiled code page until it is actually called by the compiler, and remove the rights when it is done executing. In this way they try to limit the time during which attackers can jump to JIT-sprayed shellcode. Although this was effective against some existing JIT-spraying attacks, JITDefender can be tricked by the attacker to keep the needed pages always executable, e.g., by keeping the executed code busy. Wu *et al.* [35] proposed RIM (Removing IMmediate), in which they rewrite instructions containing immediate values such that they cannot be used as a NOP sled. Later, Chen *et al.* [10] proposed to combine RIM and JITDefender, i.e., remove the executable rights from JIT-compiled code pages when not needed and also replace instructions containing immediate values.

In INSeRT, Wei *et al.* [34] propose fine-grained randomizations for JIT-compiled code. Their technique combines (i) removing immediate values via XORing them with random keys (i.e., constant blinding); (ii) register randomization; and (iii) displacement randomization (e.g., changing the order of parameters and local variables). Furthermore, INSeRT randomly inserts trapping instruction sequences, trying to catch attackers diverting the control flow. Still, its randomization neither affects call/jump displacements, nor would randomization without hiding code actually hinder our approach.

Most related to our attack are the defensive JIT randomization approaches proposed by Homescu *et al.* [17]. They propose librando, a library that uses NOP insertions to randomize the code offsets of JIT-compiled code. We

have demonstrated that even browsers leveraging NOP insertion (like IE) are susceptible to our proposed attack and thus proposed a non-probabilistic defense.

8 Conclusion

We have shown that commodity browsers do not protect against code reuse in attacker-generated, JIT-compiled code. Our novel attack challenges the assumption of XnR schemes in that we demonstrate that an attacker can create predictable ROP gadgets *without* the need to read them prior to use. To close this gap, we suggested to extend XnR schemes with our proposed countermeasure that eliminates all critical implicit constants in JIT-compiled code, effectively defending against our attack. Our defense evaluation shows that such practical defenses impose little performance overhead.

Acknowledgment

The authors would like to thank the anonymous reviewers for their valuable comments. Moreover, we are grateful for the guidance from our shepherd, Ben Livshits, during the process of finalizing the paper. We also want to thank Stefan Nürnberger, Dennis Andriesse, and David Pfaff for their comments during the writing process of the paper.

zxcvbn: Low-Budget Password Strength Estimation

Daniel Lowe Wheeler
Dropbox Inc.

Abstract

For over 30 years, password requirements and feedback have largely remained a product of *LUDS*: counts of lower- and uppercase letters, **digits** and **symbols**. LUDS remains ubiquitous despite being a conclusively burdensome and ineffective security practice.

`zxcvbn` is an alternative password strength estimator that is small, fast, and crucially no harder than LUDS to adopt. Using leaked passwords, we compare its estimations to the best of four modern guessing attacks and show it to be accurate and conservative at low magnitudes, suitable for mitigating online attacks. We find 1.5 MB of compressed storage is sufficient to accurately estimate the best-known guessing attacks up to 10^5 guesses, or 10^4 and 10^3 guesses, respectively, given 245 kB and 29 kB. `zxcvbn` can be adopted with 4 lines of code and downloaded in seconds. It runs in milliseconds and works as-is on web, iOS and Android.

1 Introduction

Passwords remain a key component of most online authentication systems [32], but the quest to replace them [20] is an active research area with a long history of false starts and renewed enthusiasm (recently e.g., [33]). Whatever the future may hold for passwords, we argue that one of the most unusable and ineffective aspects of password authentication as encountered in 2016 truly does belong in the past: composition requirements and feedback derived from counts of lower- and uppercase letters, **digits** and **symbols** – *LUDS* for short.

LUDS requirements appear in many incarnations: some sites require digits, others require the presence of at least 3 character classes, some banish certain symbols, and most set varying length minimums and maximums [21, 29, 52]. It is also now commonplace to provide real-time password feedback in the form of visual strength bars and dynamic advice [50, 28]. As with pass-

word requirements, inconsistent LUDS calculations tend to lurk behind these feedback interfaces [25].

We review the history of LUDS in Section 2 as well as its usability problems and ineffectiveness at mitigating guessing attacks, facts that are also well known outside of the security community [23, 44]. But because it isn’t obvious what should go in place of LUDS, Section 3 presents a framework for evaluating alternatives such as `zxcvbn`. We argue that anything beyond a small client library with a simple interface is too costly for most would-be adopters, and that estimator accuracy is most important at low magnitudes and often not important past anywhere from 10^2 to 10^6 guesses depending on site-specific rate limiting capabilities.

The Dropbox tech blog presented an early version of `zxcvbn` in 2012 [55]. We’ve made several improvements since, and Section 4 presents the updated algorithm in detail. At its core, `zxcvbn` checks how common a password is according to several sources – common passwords according to three leaked password sets, common names and surnames according to census data, and common words in a frequency count of Wikipedia 1-grams. For example, if a password is the 55th most common entry in one of these ranked lists, `zxcvbn` estimates it as requiring 55 attempts to be guessed. Section 5.2.3 demonstrates that this simple minimum rank over several lists is responsible for most of `zxcvbn`’s accuracy.

Section 4 generalizes this idea in two ways. First, it incorporates other commonly used password patterns such as dates, sequences, repeats and keyboard patterns. Similar to its core, `zxcvbn` estimates the attempts needed to guess other pattern types by asking: if an attacker knows the pattern, how many attempts would they need to guess the instance? For example, the strength of the QWERTY pattern `zxcvfr` is estimated by counting how many other QWERTY patterns have up to six characters and one turn. Second, Section 4 generalizes beyond matching single patterns by introducing a search heuristic for multi-pattern sequences. That way, C0mpaq999

can be matched as the common password C0mpaq followed by the repeat pattern 999.

We simulate a professional guessing attack in Section 5 by running four attack models in parallel via Ur et al.’s Password Guessability Service [51, 8]. For each password in a test set sampled from real leaks, we take the minimum guess attempts needed over these four models as our conservative gold standard for strength. Section 5 measures accuracy by comparing strength estimations of each password to this gold standard. We investigate two other estimators in addition to zxcvbn: the estimator of KeePass Password Safe [5] (hereafter KeePass) as it is the only other non-LUDS estimator studied in [25],¹ and NIST entropy, an influential LUDS estimator reviewed in Section 2.

Our experiments are motivated by two intended uses cases: smarter password composition requirements and strength meters. Given a good estimator, we believe the best-possible strength requirement both in terms of usability and adopter control becomes a minimum check: does it take more than N attempts to guess the password? If not, tell the user their choice is too obvious and let them fix it however they want. For such a policy, an adopter needs confidence that their estimator won’t overestimate below their chosen N value. Similarly, smarter strength meters need to know over what range their estimator can be trusted.

Contributions:

- We demonstrate how choice of algorithm and data impacts accuracy of password strength estimation, and further demonstrate the benefit of matching patterns beyond dictionary lookup. We observe that KeePass and NIST substantially overestimate within the range of an online guessing attack and suggest a fix for KeePass.
- We show zxcvbn paired with 1.5MB of compressed data is sufficient to estimate the best-known guessing attacks with high accuracy up to 10^5 guesses. We find 245 kB is sufficient to estimate up to 10^4 guesses, and 29 kB up to 10^3 guesses.
- We present the internals of zxcvbn in detail, to serve immediately as a LUDS replacement for web and mobile developers, and in the future as a reference point that other estimators can measure against and attempt to beat.
- We present an evaluation framework for low-cost estimators to help future improvements balance security, usability, and ease of adoption.

¹We exclude Google’s estimator, a server-side estimator with no details available.

2 Background and Related Work

2.1 LUDS

LUDS has its roots at least as far back as 1985, tracing to the U.S. Defense Department’s influential *Password Management Guideline* [12] (nicknamed the Green Book) and NIST’s related *Password Usage of the Federal Information Processing Standards* series that same year [13]. The Green Book suggested evaluating password strength in terms of guessing space, modeled as $S = A^M$, where S is the maximum guess attempts needed to guess a password, M is the password’s length, and A is its alphabet size. For example, a length-8 password of random lowercase letters and digits would have a guessing space of $S = (26 + 10)^8$, and a passphrase of three random words from a 2000-word dictionary would have $S = 2000^3$. S is often expressed in bits as $M \cdot \log_2(A)$, a simple metric that is properly the *Shannon entropy* [47] when every password is assigned randomly in this way.

While this metric works well for machine-generated passwords, NIST’s related guideline applied similar reasoning to user-selected passwords at a time before much was known about human password habits. This erroneous randomness assumption persists across the Internet today. For example, consider our pseudocode summary of the metric NIST recommends (albeit with some disclaimers) in its most recent Special Publication 800-63-2 *Electronic Authentication Guideline* of August 2013 [22], commonly referred to as *NIST entropy* (hereafter NIST):

```

1: function NIST_ENTROPY( $p, dict$ )
2:    $e \leftarrow 4 + 2 \cdot p[2:8].len + 1.5 \cdot p[9:20].len + p[21:].len$ 
3:    $e \leftarrow e + 6$  if  $p$  contains upper and non-alpha
4:    $e \leftarrow e + 6$  if  $p.len < 20$  and  $p \notin dict$ 
5:   return  $e$ 
```

That is, NIST adds 4 bits for the first character in a password p , 2 bits each for characters 2 through 8, progressively fewer bits for each additional character, 6 more bits if both an uppercase and non-alphabetic character are used – so far, all LUDS. Up to now the 0 in Passw0rd would give it a higher entropy than QJqUbPpA. NIST recommends optionally adding up to 6 more bits if the password is under 20 characters and passes a dictionary check,² the idea being that longer passwords are likely to be multiword passphrases that don’t deserve a bonus. Even then, assuming Passw0rd fails the dictionary check and QJqUbPpA passes, these sample passwords would oddly have equal scores.

NIST entropy remains influential on password policy. Shay et al. [48] studied Carnegie Mellon University’s

²a non-LUDSian detail.

policy migration as part of joining the InCommon Federation and seeking its NIST-entropy-derived Silver Assurance certification [9], to give one notable example.

Whether used for feedback or for requirements, the goal of any LUDS formulation is ultimately to guide users towards less guessable passwords,³ and herein lies the first problem – it’s ineffective. Numerous studies confirm that people use types of characters in skewed distributions [27, 38, 48]: title case, all caps, digit suffixes, some characters more often than others within a class – to give only a small taste. Worse, the most commonly used patterns in passwords cannot be captured by character class counts, such as words, dates, and keyboard patterns. By taking tens of millions of leaked passwords and comparing NIST entropy to the guess order enumeration of a modern password cracker, Weir et al. [53] conclusively demonstrated that even with an added dictionary check and varied parameters, LUDS counts cannot be synthesized into a valid metric for password guessability. In a collaboration with Yahoo, Bonneau [19] found that a six-character minimum length policy exhibited almost no difference in online guessing resistance compared to no length requirement.

The second problem with LUDS is its high usability cost [34]. Any LUDS requirement beyond a low minimum length check necessarily disallows many strong passwords and places a burden on everyone, instead of a subgroup with a known risk of having their password guessed. Florêncio and Herley [29] studied the password policies of 75 American websites and concluded that policy stringency did not correlate with a heightened need for security, but rather with absence of competition and insulation from the consequences of poor usability.

This usability problem is compounded by policy inconsistency among sites. Wang and Wang [52] studied the password composition policies of 50 sites in 2015 (30 from mainland China, the rest mostly American) and found that no two sites enforced the same policy. Bonneau and Preibusch [21] found 142 unique policies in a 2010 survey of 150 high-traffic sites. As a result of these inconsistent policies, people often have to jump through unique hoops upon selecting new passwords [23].

Password feedback is similarly inconsistent across the Internet. Carnavalet and Mannan [25] investigated the registration flows of 18 prominent services spanning multiple countries, platforms, and product domains, and with three exceptions (Google, Dropbox, and KeePass), they found simple but widely inconsistent LUDS-based calculations powering visual feedback, sometimes combined with dictionary checks.

³Proximate goals might include compliance or perception of security, both of which still derive from a notion of guessing resistance in most instances.

2.2 Password Guessing

In their seminal 1979 publication, Morris and Thompson [43] conducted one of the first studies of password habits and detailed the early UNIX history of co-evolving password attacks and mitigations. The decades that followed have seen immense development in password guessing efficiency.

Our gold standard for measuring a password’s *strength* is the minimum attempts needed to guess it over four modern guessing attacks, obtained by running the `min_auto` configuration of Ur et al.’s Password Guessability Service [8] (hereafter PGS), demonstrated in [51] to be a conservative estimate of an experienced and well-resourced professional. We run two cutting-edge attacks from the literature, consisting of a PCFG model [54] with Komanduri’s improvements [36] and a Smoothed Order-5 Markov model [39]. Because our gold standard should be a safe lower bound not just over the theoretical best attacks, but also the best-productized attacks in common use by professionals, we further run Hashcat [2] and John the Ripper [3] mangled dictionary models with carefully tuned rule sets.

Throughout this paper, we will differentiate between *online guessing*, where an attacker attempts guesses through a public interface, and *offline guessing*, where, following a theft of password hashes, an attacker makes guesses at a much higher rate on their own hardware. We recommend [30] for a more detailed introduction to guessing attacks.

2.3 Guessing Resistance

We focus on guessing resistance techniques that influence usability, as opposed to developments in cryptography, abuse detection, and other service-side precautions.

The idea of a *proactive password checker*, a program that offers feedback and enforces policy at composition time, traces to the late 80s and early 90s with pioneering work by Nagle [45], Klein [35], Bishop [17] and Spafford [49]. Eight days after the Morris worm, which spread in part by guessing weak passwords, Nagle presented his *Obvious Password Detector* program that rejected any password that didn’t have a sufficient number of uncommon triplets of characters. Klein focused on dictionary checks with various transformations, such as reversed token lookup, common character substitutions, and stemming, but also recommended LUDS rules including the rejection of all-digit passwords. In his `pwcheck` program, Bishop introduced a concise language for system administrators to formulate composition rules in terms of dictionary lookups, regular expression matching, and relations to personal information. This language is also one of the first to allow customized

user feedback, a precursor to today’s ubiquitous password strength meters. None of these early rule-based systems estimate password strength, making it hard to correctly balance usability and answer whether a password is sufficiently unguessable.

Spafford and others proposed space-efficient dictionary lookup techniques using Bloom filters [49, 40] and decision trees [15, 18]. These approaches similarly do not directly estimate guessing resistance or compare their output to modern guessing attacks, providing instead a binary pass/fail. Yan [56] highlights the need to catch patterns beyond dictionary lookups, something we find modest supporting evidence for in Section 5.2.3.

Castelluccia et al. [24] propose maintaining a production database of character *n*-gram counts in order to model a password’s guessability with an adaptive Markov model. Schechter et al. [46] outline a *count-min sketch* datastructure to allow all passwords that aren’t already too popular among other users. Both of these proposals have the advantage of modeling a service’s unique password distribution. Both aggregate information that, if stolen, aid offline cracking attacks, and both include noise mitigations to reduce that threat. We argue in Section 3 that their respective requirements to maintain and secure custom production infrastructure at scale is too costly for most would-be adopters.

Dell’Amico and Filippone [26] detail a Monte Carlo sampling method that converts a password’s probability as computed by any generative model into an estimate of a cracker’s guessing order when running that model. Given that some of today’s best guessing techniques are built on probabilistic models [39, 54, 36], the benefit of this approach is fast and accurate estimation of guessing order, even up to as high as 2^{80} (10^{24}) guesses. But while the conversion step itself is time- and space-efficient, we haven’t encountered investigations in the literature that limit the size of the underlying probability model to something that would fit inside a mobile app or browser script. Comparing space-constrained probabilistic estimators to today’s best guessing attacks (or perhaps a minimum over several parallel attacks as we do) would be valuable future work. Melicher et al.’s concurrent and independent research on lean estimation with Recurrent Neural Networks is quite promising [42].

Turning to open-source industry contributions, `zxcvbn` and KeePass [5] were originally designed for password strength feedback, but we consider them here for policy enforcement as well. Industry adoption of `zxcvbn` is growing, currently deployed by Dropbox, Stripe, Wordpress, Coinbase, and others. KeePass (reviewed in [25]) matches several common patterns including a dictionary lookup with common transformations, then applies an *optimal static entropy encoder* documented in their help center [4] to search for the

simplest set of candidate matches covering a password. We extracted KeePass into a stand-alone command-line utility such that we could compare it against realistic guessing attacks in Section 5.

Telepathwords [37] offers some of the best real-time password feedback currently available. It employs a client-server architecture that is hosted as a stand-alone site, and does not output a guess attempt estimate or equivalent, so we do not evaluate it as a candidate LUDS alternative.

Ur et al. [50] and Egelman et al. [28] studied the effect of strength meters on password composition behavior. The consensus is that users do follow the advice of these meters for accounts of some importance; however, both studies employed LUDS metrics to power their meters as is common in the wild, conditionally with an added dictionary check in the case of [50]. Our aim is to provide strength meters with more accurate underlying estimation.

3 Evaluation Framework

While the problems of LUDS are well understood, it isn’t obvious what should go in its place. We motivate some of the important dimensions and reference two LUDS methods for comparison: NIST as well 3class8 – the easy-to-adopt requirement that a password contain 8 or more characters of at least 3 types.

It should be no harder than LUDS to adopt

In the wider scheme of password authentication, composition policy and feedback are small details. Bonneau and Preibusch [21] demonstrated that the big details – cryptography and rate-limiting, for example – are commonly lacking throughout the Internet with little economic incentive to do better. To then have a starting chance of widespread adoption, a LUDS alternative cannot be harder than LUDS to adopt. We believe this realistically eliminates alternatives that require hosting and scaling special infrastructure from mainstream consideration, whereas small client libraries with simple interfaces are more viable. To give an example, the following is working web integration code for a policy that disallows passwords guessable in under 500 attempts according to `zxcvbn`:

```
var zxcvbn = require('zxcvbn');
var meets_policy = function(password) {
    return zxcvbn(password).guesses > 500;
};
```

This sample assumes a CommonJS module interface. For comparison, Appendix A lists our implementation of 3class8 back-to-back with two other `zxcvbn` integration options.

It should only burden at-risk users

Users face many threats in addition to guessing attacks, including phishing, keylogging, and credential reuse attacks. Because guessing attacks often rank low on a user’s list of worries, short and memorable password choices are often driven by rational cost-benefit analysis as opposed to ignorance [31]. To encourage less guessable choices, a LUDS alternative must accept this reality by imposing as few rules as possible and burdening only those facing a known guessing risk. As examples, words should be recognized and weighted instead of, as with space-efficient dictionary lookups, rejected. All-digit and all-lowercase passwords – respectively the most common password styles in mainland China and the U.S. according to a comprehensive study [38] – should similarly be weighted instead of rejected via blanket rules. `3class8` is a prime offender in this category.

While underestimation harms usability, overestimation is arguably worse given an estimator’s primary goal of mitigating guessing attacks. In Section 5 we measure accuracy and overestimation as separate quantities in our comparison of alternative estimators. We find KeePass and NIST tend to overestimate at lower magnitudes.

It should estimate guessing order

The security community’s consensus definition of a password’s strength is *the number of attempts that an attacker would need in order to guess it* [26]. Strength estimators should thus estimate this guessing order directly, versus an entropy, percentage, score, or binary pass/fail. This detail provides adopters with an intuitive language for modeling guessing threats and balancing usability. An alternative should further measure its estimations against real guessing attacks and communicate its accuracy bounds. For example, given enough samples, [26] is accurate up to the highest feasible guessing ranges, whereas with 1.5MB of data, `zxcvbn` is only highly accurate up to 10^5 guesses.

It should be accurate at low magnitudes

Online guessing attacks are a threat that password authentication systems must defend against continually. While rate limiting and abuse detection can help, passwords guessable in, say, 10 to 100 guesses could remain vulnerable to capable adversaries over time. As we show in Section 5.2, NIST greatly overestimates password strength at low magnitudes. Similarly, `3class8` permits obvious choices such as `Password1!`. A strict improvement over LUDS in terms of security, then, is to improve accuracy at low guessing magnitudes.

Past an online guessing threshold, the benefit of accurate estimation becomes more situation-dependent. Referencing the *online-offline chasm* of [30], the added security benefit from encouraging or requiring stronger passwords might only start to appear after many orders of

magnitude past an online guessing cutoff, indicating a substantial usability-security trade-off that often won’t be justified. While we focus on online attack mitigation, key stretching techniques such as Argon2 [16] can further render offline attacks unfeasible at higher guessing magnitudes.

For the remainder of this paper, we will use 10^6 guesses as our approximate online attack cutoff, citing the back-of-the-envelope upper limit estimation in [30] for a depth-first online attack (thus also bounding an online trawling attack). By studying leaked password distributions, [30] also points out that an attacker guessing in optimal order would face a reduction in success rate by approximately 5 orders of magnitude upon reaching 10^6 guesses.

While we use 10^6 as an online cutoff for safe and simple analysis in Section 5, we recognize that an upper bound on online guessing is highly dependent on site-specific capabilities, and that some sites will be able to stop an online attack starting at only a few guesses. This motivates our next item:

It should have an adjustable size

An estimator’s accuracy is greatly dependent on the data it has available. Adopters should be given control over this size / accuracy trade-off. Some might want to bundle an estimator inside their app, selecting a smaller size. We expect most will want to asynchronously download an estimator in the background on demand, given that password creation only happens once per user and typically isn’t the first step in a registration flow. Current bandwidth averages should factor into this discussion: a South Korean product might tolerate a gzipped-5MB estimator (downloadable in 2 seconds at 20.5Mbps national average in Q3 2015 [14]⁴), whereas 1.5MB is a reasonable global upper bound in 2016 (2.3 seconds at 5.1Mbps Q3 2015 global default). Need should also factor in: a site that is comfortable in its rate-limiting might only need accurate estimation up to 10^2 guesses.

4 Algorithm

We now present the internals of `zxcvbn` in detail. Sections 4.2 and 4.3 explain how common token lookup and pattern matching are combined into a single guessing model. Section 4.4 is primarily about speed, providing a fast algorithm for finding the simplest set of matches covering a password. We start with a high-level sketch.

4.1 Conceptual Outline

`zxcvbn` is non-probabilistic, instead heuristically estimating a guessing attack directly. It models passwords

⁴We cite figures from Akamai’s State of the Internet series.

as consisting of one or more concatenated patterns. The 2012 version of `zxcvbn` assumes the guesser knows the pattern structure of the password it is guessing, with bounds on how many guesses it needs per pattern. For example, if a password consists of two top-100 common words, it models an attacker who makes guesses as concatenations of two words from a 100-word dictionary, calculating 100^2 as its worst-case guess attempt estimate.

To help prevent overly complex matching, `zxcvbn` now loosens the 2012 assumption by instead assuming the attacker knows the patterns that make up a password, but not necessarily how many or in which order. To illustrate the difference, compare the respective 2012 and 2016 analyses of `jessiah03`:

```
jess(name) i(word) ah0(surname) 3(bruteforce)
jessia(name) h03(bruteforce)
```

The 2012 version has no bias against long pattern sequences, matching `i` and `jess` as common words. (`jessia` is in the common surname dictionary at about rank 3.5k, `jess` is at about rank 440, and `jessiah` is in neither dictionary.) To give another example, the random string `3vMs3o7B7eTo` is now matched as a single brute-force region by `zxcvbn`, but as a 5-pattern sequence by the 2012 version, including `7eT` as a 133ted “let.”

To formalize this difference in behavior, at a high level, both versions consist of three phases: match, estimate and search. Given a plaintext password input, the pattern matching phase finds a set S of overlapping matches. For example, given `lenovo1111` as input, this phase might return `lenovo` (password token), `eno` (English “one” backwards), `no` (English), `no` (English “on” backwards), `1111` (repeat pattern), and `1111` (Date pattern, 1/1/2011). Next, the estimation phase assigns a guess attempt estimation to each match independently. If `lenovo` is the 11007th most common password in one of our password dictionaries, it’ll be assigned 11007, because an attacker iterating through that dictionary by order of popularity would need that many guesses before reaching it. The final phase is to search for the sequence of non-overlapping adjacent matches S drawn from \mathcal{S} such that S fully covers the password and minimizes a total guess attempt figure. In this example, the search step would return [`lenovo` (token), `1111` (repeat)], discarding the date pattern which covers the same substring but requires more guesses than the repeat. `zxcvbn`’s formalized assumption about what an attacker knows is represented by the following search heuristic:

$$\underset{S \subseteq \mathcal{S}}{\operatorname{argmin}} D^{|S|-1} + |S|! \prod_{m \in S} m.\text{guesses} \quad (1)$$

$|S|$ is the length of the sequence S , and D is a constant. The intuition is as follows: if an attacker knows the pattern sequence with bounds on how many guesses needed

for each pattern, the Π term measures how many guesses they would need to make in the worst case. This Π term, by itself, is the heuristic employed by the 2012 version. With the added $|S|!$ term, the guesser now knows the number of patterns in the sequence but not the order. For example, if the password contains a common word c , uncommon word u , and a date d , there are $3!$ possible orderings to try: `cud`, `ucd`, etc.

The $D^{|S|-1}$ term attempts to model a guesser who additionally doesn’t know the length of the pattern sequence. Before attempting length- $|S|$ sequences, `zxcvbn` assumes that a guesser attempts lower-length pattern sequences first with a minimum of D guesses per pattern, trying a total of $\sum_{l=1}^{|S|-1} D^l \approx D^{|S|-1}$ guesses for sufficiently large D . For example, if a password consists of the 20th most common password token t with a digit d at the end – a length-2 pattern sequence – and the attacker knows the $D = 10000$ most common passwords, and further, td is not in that top-10000 list (otherwise it would have been matched as a single token), the D^1 term models an attacker who iterates through those 10000 top guesses first before moving on to two-pattern guessing. While an attacker might make as few as 10 guesses for a single-digit pattern or as many as tens of millions of guesses iterating through a common password dictionary, we’ve found $D = 1000$ to $D = 10000$ to work well in practice and adopt the latter figure for `zxcvbn`.

In practical terms, the additive D penalty and multiplicative $|S|!$ penalty address overly complex matching in different ways. When two pattern sequences of differing length have near-equal Π terms, the $|S|!$ factor biases towards the shorter sequence. The D term biases against long sequences with an overall low Π term.

4.2 Matching

The matching phase finds the following patterns:

pattern	examples
<code>token</code>	<code>logitech</code> <code>10giT3CH</code> <code>ain't</code> <code>parliamentarian</code> <code>1232323q</code>

The token matcher lowerscases an input *password* and checks membership for each substring in each frequency-ranked dictionary. Additionally, it attempts

each possible l33t substitution according to a table. An input @BA1one is first lowercased to @ba1one. If the l33t table maps @ to a and 1 to either i or l, it tries two additional matches by subbing [$\text{@}\rightarrow\text{a}$, $\text{l}\rightarrow\text{i}$] and [$\text{@}\rightarrow\text{a}$, $\text{l}\rightarrow\text{l}$], finding abalone with the second substitution.

Taking a cue from KeePass, sequence matching in zxvcvbn looks for sequences where each character is a fixed Unicode codepoint distance from the last. This has two advantages over the hardcoded sequences of the 2012 version. It allows skipping, as in 7531, and it recognizes sequences beyond the Roman alphabet and Arabic numerals, such as Cyrillic and Greek sequences. Unicode codepoint order doesn't always map directly to human-recognizable sequences; this method imperfectly matches Japanese kana sequences as one example.

The repeat matcher searches for repeated blocks of one or more characters, a rewrite of the 2012 equivalent, which only matched single-character repeats. It tries both greedy $(.+)\backslash 1+$ and lazy $(.+)?\backslash 1+$ regular expressions in search of repeated regions spanning the most characters. For example, greedy beats lazy for aabaab, recognizing (aab) repeated over the full string vs (a) repeated over aa, whereas lazy beats greedy for aaaaa, matching (a) spanning 5 characters vs (aa) spanning 4. The repeat matcher runs a match-estimate-search recursively on its winning repeated unit, such that, for example, repeated words and dates are identified.

The keyboard matcher runs through *password* linearly, looking for chains of adjacent keys according to each of its keyboard adjacency graphs. These graphs are represented as a mapping between each key to a clockwise positional list of its neighbors. The matcher counts chain length, number of turns, and number of shifted characters. On QWERTY, zxvcvfr\$321 would have length 10, 2 turns, and 2 shifted characters. QWERTY, DVORAK, and Windows and Mac keypad layouts are included by default. Additional layouts can be prepackaged or dynamically added.

Date matching considers digit regions of 4 to 8 characters, checks a table to find possible splits, and attempts a day-month-year mapping for each split such that the year is two or four digits, the year isn't in the middle, the month is between 1 and 12 inclusive, and the day is between 1 and 31 inclusive. For example, a six-digit sequence 201689 could be broken into 2016-8-9, 20-16-89, or 2-0-1689. The second candidate would be discarded given no possible month assignment, and the third discarded because 0 is an invalid day and month. Given multiple valid splits, the choice with year closest to a reference year of 2016 wins. Two-digit years are matched as 20th- or 21st-century years, depending on whichever is closer to 2016. For ease of portability, date matching does not filter improper Gregorian dates; for example, it allows Feb. 29th on a non-leap year.

4.3 Estimation

Next, a guess attempt estimate *guesses* is determined for each match $m \in \mathcal{S}$. The guiding heuristic is to ask: if an attacker knows the pattern, how many guesses might they need to guess the instance? Green Book-style guessing space calculations then follow, but for patterns instead of random strings, where a guesser attempts simpler or more likely patterns first.

For tokens, we use the frequency rank as the estimate, because an attacker guessing tokens in order of popularity would need at least that many attempts. A reversed token gets a doubled estimate, because the attacker would then need to try two guesses (normal and reversed) for each token. A conservative factor of 2 is also added for an obvious use of uppercase letters: first-character, last-character, and all caps. The capitalization factor is otherwise estimated as

$$\frac{1}{2} \sum_{i=1}^{\min(U,L)} \binom{U+L}{i} \quad (2)$$

where U and L are the number of uppercase and lowercase letters in the token. For example, to guess paSsw0rd, an attacker would need to try a guessing space of 8 different single-character capitalizations plus 28 different two-character capitalizations. The $1/2$ term converts the total guessing space into an average attempts needed, assuming that each capitalization scheme is equally likely – this detail could be improved by better modeling observed distributions of capitalization patterns in leaked password corpora. The $\min()$ term flips the lowercasing game into an uppercasing game when there are more upper- than lowercase letters, yielding 8 for PAsWORD.

Guesses for keyboard patterns are estimated as:

$$\frac{1}{2} \sum_{i=1}^L \sum_{j=1}^{\min(T,i-i)} \binom{i-1}{j-1} SD^j \quad (3)$$

where L is the length of the pattern, T is the number of terms, D is the average number of neighbors per key (a tilde has one neighbor on QWERTY, the ‘a’ key has four) and S is the number of keys on the keyboard. For T turns throughout a length L keyboard pattern, we assume a guesser attempts lower-length, lower-turn patterns first, starting at length 2. The binomial term counts the different configuration of turning points for a length- i pattern with j turns, with -1 added to each term because the first turn is defined to occur on the first character. The $\min()$ term avoids considering more turns than possible on a lower-length pattern. The sequence might have started on any of S keys and each turn could have gone any of D ways on average, hence the $S \cdot D^j$. Equation 3 estimates about 10^3 guesses for kjhgfdsa on QWERTY and 10^6

guesses for `kjhgt543`. Shifted keys in the pattern add a factor according to expression 2, where L and U become shifted and unshifted counts.

Repeat match objects consist of a base repeated n times, where a recursive match-estimate-search step previously assigned a number of guesses g to the base. Repeat guess attempts are then estimated as $g \cdot n$. For example, `nownownow` is estimated as requiring 126 guesses: now is at rank 42 in the Wiktionary set, times 3.

Sequences are scored according to $s \cdot n \cdot |d|$, where s is the number of possible starting characters, n is the length, and d is the codepoint delta (e.g., -2 in 9753). s is set to a low constant 4 for obvious first choices like 1 and Z, set to 10 for other digits, or otherwise 26, an admittedly Roman-centric default that could be improved.

For dates, we assume guessers start at 2016 and guess progressively earlier or later dates, yielding a ballpark of $365 \cdot |2016 - \text{year}|$

Finally, bruteforce matches of length l are assigned a constant $C = 10$ guesses per character, yielding a total estimate of C^l . The 2012 version performs a guessing space calculation, treating bruteforce regions as random, and determines a cardinality C that adds 26 if any lowercase letters are present, 26 if uppercase, 10 if digits, and 33 for one or more symbols. This dramatically overestimates the common case, for example a token that isn't in the dictionary. The 2012 version scores `Teiubesc` (Romanian for "I love you") as $(26 + 26)^8 \approx 10^{14}$, whereas `zxcvbn` now estimates it 6 orders of magnitude lower at 10^8 . (Thanks to the addition of RockYou'09 data, it also matches it as a common password at rank 10^4).

4.4 Search

Given a string `password` and a corresponding set of overlapping matches \mathcal{S} , the last step is to search for the non-overlapping adjacent match sequence S that covers `password` and minimizes expression (1). We outline a dynamic programming algorithm that efficiently accomplishes this task. The idea is to iteratively find the optimal length- l sequence of matches covering each length- k character prefix of `password`. It relies on the following initial state:

```

1:  $n \leftarrow \text{password.length}$ 
2:  $\mathcal{B}_{opt} \leftarrow [] \times n$ 
3:  $\Pi_{opt} \leftarrow [] \times n$ 
4:  $l_{opt} \leftarrow 0$ 
5:  $g_{opt} \leftarrow \text{null}$ 

```

\mathcal{B}_{opt} is a backpointer table, where $\mathcal{B}_{opt}[k][l]$ holds the ending match in the current optimal length- l match sequence covering the length- k prefix of `password`. $\Pi_{opt}[k][l]$ correspondingly holds the product term in ex-

pression (1) for that sequence. When the algorithm terminates, g_{opt} holds the optimum guesses figure and l_{opt} holds the length of the corresponding optimal sequence. Note that if no length- l sequence exists such that it scores lower than every alternative sequence with fewer matches covering the same k -prefix, then $l \notin \mathcal{B}_{opt}[k]$.

Each match object m has a guess value $m.guesses$ and covers a substring of `password` at indices $m.i$ and $m.j$, inclusive. The search considers one character of `password` at a time, at position k , and for each match m ending at k , evaluates whether adding m to any length- l optimal sequence ending just before m (at $m.i - 1$) leads to a new candidate for the optimal match sequence covering the prefix up to k :

```

1: function SEARCH( $n, \mathcal{S}$ )
2:   for  $k \in 0$  to  $n - 1$ 
3:      $g_{opt} \leftarrow \infty$ 
4:     for  $m \in \mathcal{S}$  when  $m.j = k$ 
5:       if  $m.i > 0$ 
6:         UPDATE( $m, l + 1$ ) for  $l \in \mathcal{B}_{opt}[m.i - 1]$ 
7:       else
8:         UPDATE( $m, 1$ )
9:       BF_UPDATE( $k$ )
10:      return UNWIND( $n$ )

```

Instead of including a bruteforce match object in \mathcal{S} for every $O(n^2)$ substring in `password`, bruteforce matches are considered incrementally by BF_UPDATE:

```

1: function BF_UPDATE( $k$ )
2:    $m \leftarrow \text{bruteforce from } 0 \text{ to } k$ 
3:   UPDATE( $m, 1$ )
4:   for  $l \in \mathcal{B}_{opt}[k - 1]$ 
5:     if  $\mathcal{B}_{opt}[k - 1][l]$  is bruteforce
6:        $m \leftarrow \text{bruteforce from } \mathcal{B}_{opt}[k - 1][l].i \text{ to } k$ 
7:       UPDATE( $m, l$ )
8:     else
9:        $m \leftarrow \text{bruteforce from } k \text{ to } k$ 
10:      UPDATE( $m, l + 1$ )

```

That is, at each index k , there are only three cases where a bruteforce match might end an optimal sequence: it might span the entire k -prefix, forming a length-1 sequence, it might extend an optimal bruteforce match ending at $k - 1$, or it might start as a new single-character match at k . Note that given the possibility of expansion, it is always better to expand by one character than to append a new bruteforce match, because either choice would contribute equally to the Π term, but the latter would increment l .

The UPDATE helper computes expression (1) and updates state if a new minimum is found. Thanks to the Π_{opt} table, it does so without looping:

```

1: function UPDATE( $m, l$ )
2:    $\Pi \leftarrow m.guesses$ 
3:   if  $l > 1$ 
4:      $\Pi \leftarrow \Pi \times \Pi_{opt}[m.i - 1][l - 1]$ 
5:    $g \leftarrow D^{l-1} + l! \times \Pi$ 
6:   if  $g < g_{opt}$ 
7:      $g_{opt} \leftarrow g$ 
8:      $l_{opt} \leftarrow l$ 
9:    $\Pi_{opt}[k][l] \leftarrow \Pi$ 
10:   $\mathcal{B}_{opt}[k][l] \leftarrow m$ 

```

At the end, UNWIND steps through the backpointers to form the final optimal sequence:

```

1: function UNWIND( $n$ )
2:    $S \leftarrow []$ 
3:    $l \leftarrow l_{opt}$ 
4:    $k \leftarrow n - 1$ 
5:   while  $k \geq 0$ 
6:      $m \leftarrow \mathcal{B}_{opt}[k][l]$ 
7:      $S.prepend(m)$ 
8:      $k \leftarrow m.i - 1$ 
9:      $l \leftarrow l - 1$ 
10:    assert  $l = 0$ 
11:    return  $S$ 

```

Each match $m \in \mathcal{S}$ is considered only once during the search, yielding a runtime of $O(l_{max} \cdot (n + |\mathcal{S}|))$, where l_{max} is the maximum value of l_{opt} over each k iteration. In practice, l_{max} rarely exceeds 5, and this method rapidly terminates even for passwords of hundreds of characters and thousands of matches.

4.5 Deployment

`zxcvbn` is written in CoffeeScript and compiled via an npm build flow into both a server-side CommonJS module and a minified browser script. The ranked token lists take up most of the total library size: each is represented as a sorted comma-separated list of tokens which then get converted into an object, mapping tokens to their ranks. The browser script is minified via UglifyJS2 with instructions on how to serve as gzipped data.

`zxcvbn` works as-is on most browsers and javascript server frameworks. Because iOS and Android both ship with javascript interpreters, `zxcvbn` can easily interface with most mobile apps as well. JSContext on iOS7+ or UIWebView for legacy support both work well. Running javascript with or without a web view works similarly on Android.

Dropbox uses `zxcvbn` for feedback and has never enforced composition requirements other than a 6-character minimum. For those implementing requirements, we suggest a client-side soft enforcement for simplicity,

such as a submit button that is disabled until the requirement is met. Because different versions and ports give slightly different estimates, we suggest those needing server-side validation either skip client-side validation or make sure to use the exact same build across their server and various clients. `zxcvbn` ports exist for Java, Objective-C, Python, Go, Ruby, PHP, and more.

4.6 Limitations

`zxcvbn` doesn't model interdependencies between patterns, such as common phrases and other collocations. However, its ranked password dictionaries include many phrases as single tokens, such as `opensesame`. It only matches common word transformations that are easy to implement given limited space; it doesn't match words with deleted letters and other misspellings, for example. Unmatched regions are treated equally based on length; the English-sounding made-up word `novanoid` gets the same estimate as a length-8 random string, and unmatched digits and symbols are treated equally even though some are more common than others.

5 Experiments

We investigate how choice of algorithm and dataset impacts the estimation accuracy of a realistic guessing attack. We also show the impact of matching patterns beyond token lookup. Our experiments employ a test set of 15k passwords from the RockYou'09 leak [7]. Appendix C includes the same analysis on a 15k sample from the Yahoo'12 leak [11]. We close the Section with runtime benchmarks for `zxcvbn`.

5.1 Methodology

Algorithms and Data

The algorithms we selected for our experiment – NIST, KeePass, and `zxcvbn` – estimate guess attempts or equivalent (excludes [49, 17]) and can operate without a backing server (excludes [46, 24]).

For our password strength gold standard, as introduced in Section 2.2, we ran the `min_auto` configuration of PGS [8] with the same training data found to be most effective in [51]. The PGS training data (roughly 21M unique tokens) consists of the RockYou'09 password leak (minus a randomly sampled 15k test set), Yahoo'12 leak (minus a similar 15k test set), MySpace'06 leak, 1-grams from the Google Web Corpus, and two English dictionaries. To make brute force guessing attacks infeasible, the 15k test sets are sampled from the subset of passwords that contain at least 8 characters. Of the four attacks, we ran the Markov attack up through 10^{10} guesses, John the Ripper and Hashcat up through 10^{13} ,

and PCFG up to 10^{14} . Detailed specifics can be found in [51].

While our test data is distinct from our training data, it is by design that both include samples from the same RockYou’09 distribution; our aim is to simulate an attacker with knowledge of the distribution they are guessing. While a real attacker wouldn’t have training data from their target distribution, they might be able to tailor their attack by deriving partial knowledge – common locales and other user demographics (RockYou includes many Romanian-language passwords in addition to English), site-specific vocabulary (game terminology, say), and so on.

Our estimators are given ranked lists of common tokens as their training data, with one separately ranked list per data source. NIST and KeePass do not make use of rank, instead performing membership tests on a union of their lists. Rather than attempting to precisely match the training sources supplied to PGS, our estimator sources more closely match those used in the current production version of `zxcvbn`. For example, in the spirit of free software, we avoid the Google Web Corpus which is only available through a license via the Linguistic Data Consortium. Instead of counting top passwords from the MySpace’06 leak, our estimators use the Xato’15 corpus which is over 200 times bigger.

In all, we count top tokens from the PGS training portion of RockYou’09 and Yahoo’12 (test sets are excluded from the count), Xato’15, 1-grams from English Wikipedia, common words from a Wiktionary 29M-word frequency study of US television and film [10], and common names and surnames from the 1990 US Census [1]. Appendix B has more details on our data sources and algorithm implementations.

We experiment with three estimator training set sizes by truncating the frequency lists at three points: 100k (1.52 MB of gzipped storage), 10k (245 kB), and 1k (29.3 kB). In the 10k set, for example, each ranked list longer than 10k tokens is cut off at that point.

Metrics

When PGS is unable to guess a password, we exclude it from our sample set S . On each sampled password $x_i \in S$, we then measure an algorithm’s estimation error by computing its order-of-magnitude difference Δ_i from PGS,

$$\Delta_i = \log_{10} \frac{g_{alg}(x_i)}{g_{pgs}(x_i)} \quad (4)$$

where g_{alg} is the guess attempt estimate of the algorithm and g_{pgs} is the minimum guess order of the four PGS guessing attacks. For example, $\Delta_i = -2$ means the algorithm underestimated guesses by 2 orders of magnitude compared to PGS for password x_i .

We compare PGS to the estimator algorithms in three ways. First, to give a rough sense of the shape of estimator accuracy, we show log-log scatter plots spanning from 10^0 to 10^{15} guesses, with g_{pgs} on the x axis, g_{alg} on the y axis, and a point for every $x_i \in S$. Second, we show the distribution of Δ_i as a histogram by binning values to their nearest multiple of .5, corresponding to half-orders of magnitude. Third, we calculate the following summary statistics:

$$|\Delta| = \frac{1}{|S|} \sum_{i \in S} |\Delta_i| \quad (5)$$

$$\Delta^+ = \frac{1}{|S|} \sum_{i \in S} \begin{cases} \Delta_i & \text{if } \Delta_i \geq 0 \\ 0 & \text{if } \Delta_i < 0 \end{cases} \quad (6)$$

$|\Delta|$ gives a sense of accuracy, equally penalizing under- and overestimation. Δ^+ measures overestimation. Fewer and smaller overestimations improve (reduce) this metric. We calculate summary statistics within an online range $g_{pgs} < 10^6$ and separately higher magnitudes.

One comparison challenge is that KeePass and NIST output entropy as bits, whereas we want to compare algorithms in terms of guesses. While commonplace among password strength estimators, including the 2012 version of `zxcvbn`, it is mathematically improper to apply entropy, a term that applies to distributions, to individual events. Neither KeePass nor NIST formalize the type of entropy they model, so we assume that n bits of strength means guessing the password is equivalent to guessing a value of a random variable X according to

$$n = H(X) = - \sum_i p(x_i) \log_2 p(x_i) \quad (7)$$

Assuming the guesser knows the distribution over X and tries guesses x_i in decreasing order of probability $p(x_i)$, a lower bound on the expected number of guesses $E[G(X)]$ can be shown [41] to be:

$$E[G(X)] \geq 2^{H(X)-2} + 1 \quad (8)$$

provided that $H(X) \geq 2$. We use this conservative lower bound to convert bits into guesses. Had we additionally assumed a uniform distribution, our expected guesses would be $2^{H(X)-1}$, a negligible difference for our logarithmic accuracy comparisons.

5.2 Results

Of the RockYou 15k test set, PGS cracked 39.68% within our online guessing range of up to 10^6 guesses and 52.65% above 10^6 , leaving 7.67% unguessed.

5.2.1 Choice of Algorithm

Figures 1-3 give a sense of how algorithm choice affects guess attempt estimation. The solid diagonal corresponds to $\Delta = 0$, indicating estimator agreement with

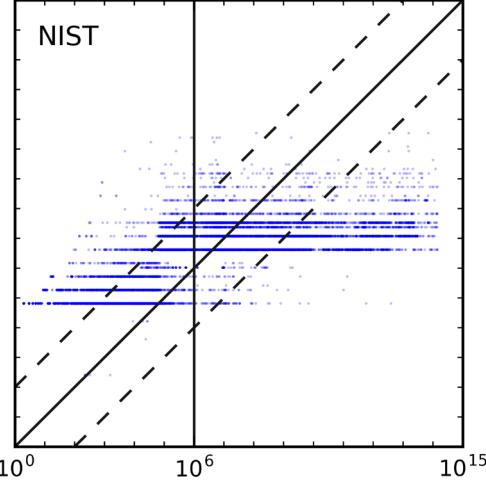

Figure 1: PGS (x axis) vs. NIST (y axis), 100k token set. Points on the solid diagonal indicate agreement between PGS and NIST ($\Delta_i = 0$). Points above the solid diagonal indicate overestimation. Points above the top dashed diagonal indicate overestimation by more than two orders of magnitude ($\Delta_i > 2$).

PGS. Points above the top / below the bottom dotted lines over/underestimate by more than 2 orders of magnitude ($\Delta_i > 2$ above the top line, $\Delta_i < -2$ below the bottom line). Points to the left of $g_{pgs} = 10^6$ indicate samples potentially susceptible to online guessing as argued in Section 3.

NIST and KeePass both exhibit substantial horizontal banding in the low online range. Figure 2 shows that a KeePass estimate of about $10^{4.5}$ can range anywhere from about 10^{-25} to 10^6 PGS guesses. Figure 1 shows that NIST has a similar band at about $10^{4.8}$, and that NIST tends to overestimate in the online range and lean towards underestimation at higher magnitudes. In Table 1 we measured NIST and KeePass to be respectively off by $|\Delta| = 1.81$ and 1.43 orders of magnitude on average within the online range. We conclude neither are suitable for estimating online guessing resistance; however, we expect KeePass could fix its low-order banding problem by incorporating token frequency rank instead of a fixed entropy for each dictionary match.

Figure 3 demonstrates that zxcvbn grows roughly linear with PGS up until about 10^5 , corresponding to the maximum rank of the 100k token set. Both zxcvbn and KeePass suffer from a spike in overestimation approximately between 10^5 and 10^7 . We speculate this is because PGS is trained on 21M unique tokens and, in one attack, tries all of them in order of popularity before moving onto more complex guessing. Hence, the greatest overestimation in both cases happens between the estimator dictionary cutoff and PGS dictionary cutoff, high-

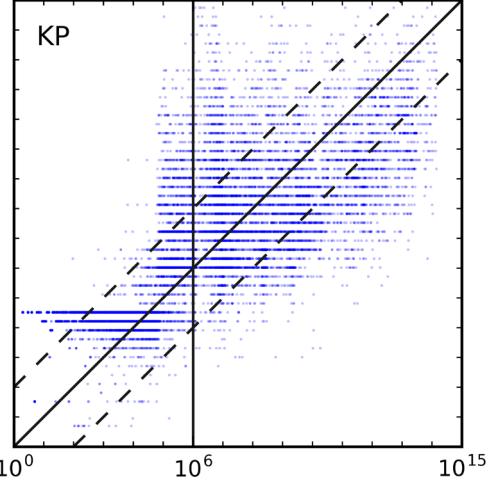

Figure 2: PGS (x) vs. KeePass (y), 100k token set.

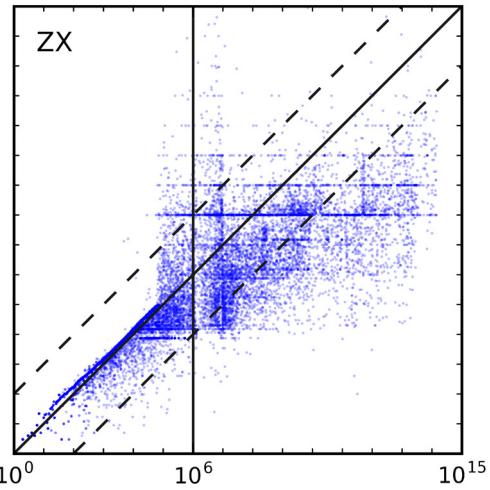

Figure 3: PGS (x) vs. zxcvbn (y), 100k token set.

lighting the sensitivity of estimator dictionary size.

The horizontal banding at fixed orders of magnitude in zxcvbn corresponds to bruteforce matches where no other pattern could be identified. Detailed in Section 4, zxcvbn rewards 10^l guesses for length- l unmatched regions. zxcvbn has comparable but slightly worse $|\Delta|$ and Δ^+ than NIST past the online range. Given both have a low Δ^+ , this primarily demonstrates a usability problem at higher magnitudes (overly harsh feedback).

Figure 4 counts and normalizes Δ_i in bin multiples of .5, demonstrating that zxcvbn is within $\pm .25$ orders of magnitude of PGS about 50% of the time within the online range. The sharp drop-off to the right indicates infrequent overestimation in this range. Figure 4 also shows that, within the online range, NIST and KeePass accuracy could be improved by respectively dividing their estimates by about 10^2 and 10^1 guesses; however, both

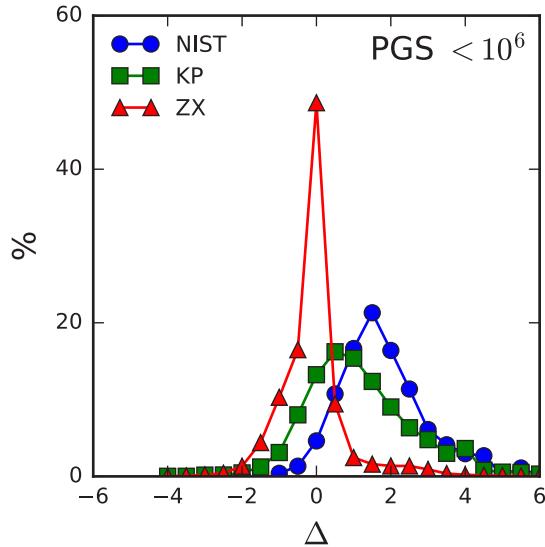

Figure 4: Δ histograms, 100k token set, online attack range ($g_{pgs} < 10^6$). zxvcvbn spikes at $\Delta = 0$ then conservatively falls off to the right.

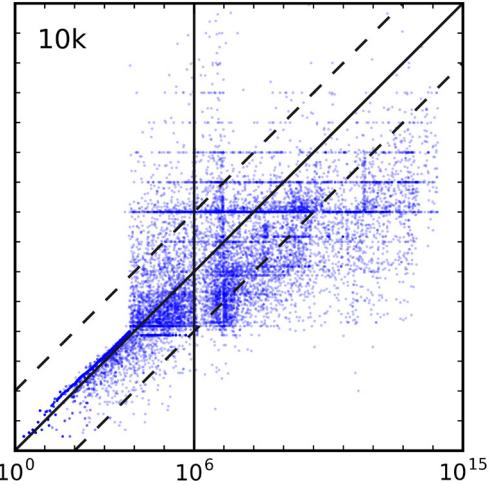

Figure 5: PGS (x) vs. zxvcvbn (y), 10k token set.

would still exhibit substantial overestimation tails.

5.2.2 Choice of Data

We now contrast a single algorithm zxvcvbn with varying data. Figures 3, 5, and 6 show zxvcvbn with the 100k, 10k and 1k token sets. The noticeable effect is linear growth up until 10^5 , 10^4 and 10^3 , respectively. Overestimation is nearly non-existent in these respective ranges.

Within the online range, $|\Delta|$ and Δ^+ noticeably improve with more data. Past the online range, more data makes the algorithm more conservative, with progressively higher $|\Delta|$ and lower Δ^+ .

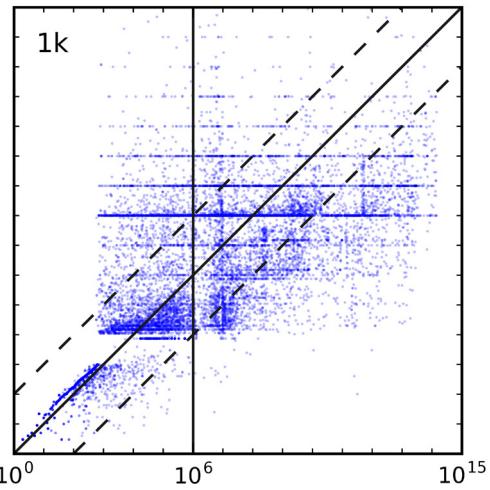

Figure 6: PGS (x) vs. zxvcvbn (y), 1k token set.

5.2.3 Impact of Pattern Matching

We lastly measure the impact of matching additional patterns beyond token lookup. Figure 7 shows a variant of zxvcvbn that recognizes case-insensitive token lookups only. Differences from Figure 3 include noticeably more overestimation before 10^5 and more prominent horizontal banding.

For our $|\Delta|$ and Δ^+ figures, we show the cumulative effect of starting with case-insensitive token matching only, and then incrementally matching additional types of patterns. Overall the impact is small compared to supplying additional data, but the space- and time- cost is near-zero, hence we consider these extra patterns a strict

	PGS < 10^6		PGS > 10^6	
	$ \Delta $	Δ^+	$ \Delta $	Δ^+
NIST-100k	1.81	1.79	2.04	0.14
KP-100k	1.43	1.31	1.81	0.70
ZX-100k	0.58	0.27	2.20	0.21
ZX-1k	1.47	1.23	2.13	0.46
ZX-10k	0.82	0.53	2.18	0.28
ZX-100k	0.58	0.27	2.20	0.21
 ZX-100k:				
tokens only	0.68	0.48	1.85	0.30
+reversed/133t	0.68	0.47	1.87	0.29
+date/year	0.60	0.35	2.13	0.23
+keyboard	0.60	0.34	2.13	0.22
+repeat	0.57	0.28	2.19	0.21
+sequence	0.58	0.27	2.20	0.21

Table 1: $|\Delta|$ and Δ^+ summary statistics. The top, middle and bottom portions correspond to Sections 5.2.1-5.2.3, respectively.

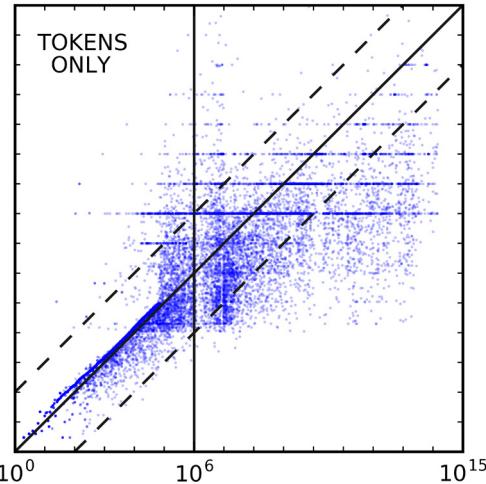

Figure 7: PGS (x) vs. zxcvbn (y), 100k token set, case-insensitive token lookups only. Table 1 shows the cumulative benefit of matching additional patterns.

improvement.

Within the online range, $|\Delta|$ shrinks by 15% after all pattern types are included. Δ^+ shrinks by 44%. As with adding more data, past 10^6 , adding patterns increases estimator conservatism, with a progressively higher $|\Delta|$ and lower Δ^+ .

5.3 Performance Benchmarks

To measure zxcvbn runtime performance, we concatenated the RockYou’09 and Yahoo’12 test sets into a single 30k list. We ran through that sample 1000 times, recording zxcvbn runtime for each password, and finally averaged the runtimes across the batches for each password. We obtained the following runtime percentiles in milliseconds:

	25^{th}	50^{th}	75^{th}	99.9^{th}	max
Chrome (ms)	0.31	0.44	0.60	3.34	27.33
node (ms)	0.38	0.53	0.72	3.00	29.61

We checked that these numbers are comparable to running a single batch, to verify that we avoided caching effects and other interpreter optimizations. Our trials used 64-bit Chrome 48 and 64-bit node v5.5.0 on OS X 10.10.4 running on a late 2013 MacBook Pro with a 2.6 GHz Intel Core i7 Haswell CPU.

5.4 Limitations

Because we measured estimator accuracy against the current best guessing techniques, accuracy will need to be reevaluated as the state of the art advances. By including training and test data from the same distribution, we

erred on the side of aggressiveness for our guessing simulation; however, test data aside, to the extent that PGS and zxcvbn are trained on the same or similar data with the same models, we expect similar accuracy at low magnitudes up until zxcvbn’s frequency rank cutoff (given a harder guessing task, that range might span a lower percentage of the test set). Our experiments measured estimator accuracy but not their influence on password selection behavior; a separate user study would be valuable, with results that would likely depend on how competing estimators are used and presented.

6 Conclusion

To the extent that our estimator is trained on the same or similar password leaks and dictionaries as employed by attackers, we’ve demonstrated that checking the minimum rank over a series of frequency ranked lists, combined with light pattern matching, is enough to accurately and conservatively predict today’s best guessing attacks within the range of an online attack. zxcvbn works entirely client-side, runs in milliseconds, and has a configurable download size: 1.5MB of compressed storage is sufficient for high accuracy up to 10^5 guesses, 245 kB up to 10^4 guesses, or 29 kB up to 10^3 guesses. zxcvbn can be bundled with clients or asynchronously downloaded on demand. It works as-is on most browsers, browser extensions, Android, iOS, and server-side javascript frameworks, with ports available in several other major languages. In place of LUDS, it is our hope that client-side estimators such as zxcvbn will increasingly be deployed to allow more flexibility for users and better security guarantees for adopters.

Acknowledgments

I’d like to thank Tom Ristenpart for shepherding this paper as well as the anonymous reviewers for their helpful comments. Thanks to Blase Ur, Sean Segreti, Henry Dixon, and the rest of the Password Research Group for their advice and help running the Password Guessability Service. Thanks to Mark Burnett for his password corpus. Thanks to Rian Hunter for extracting the KeePass estimator into a standalone Mono binary. Thanks to Devdatta Akhawe, Andrew Bortz, Hongyi Hu, Anton Mityagin, Brian Smith, and Josh Lifton for their feedback and guidance. Last but not least, a big thanks to Dropbox for sponsoring this research.

A zxcvbn vs. 3class8

We made the claim that zxcvbn is no harder to adopt than LUDS strategies such as 3class8. We provided a CommonJS implementation in

Section 3 that rejects passwords guessable in 500 attempts according to zxcvbn. For comparison, here we provide our implementation of 3class8 back-to-back with equivalent zxcvbn integrations using two other common JavaScript module interfaces: global namespacing and Asynchronous Module Definition with RequireJS.

```
var meets_3class8 = function(password) {
  var classes = 0;
  if /[a-z]/.test(password) {classes++;}
  if /[A-Z]/.test(password) {classes++;}
  if /\d/.test(password) {classes++;}
  if /[\\W_]/.test(password) {classes++;}
  return classes >= 3 and password.length > 8;
}

// in .html: <script src="zxcvbn.js"></script>
var meets_policy_global = function(password) {
  return zxcvbn(password).guesses > 500;
};

requirejs(["path/to/zxcvbn"], function(zxcvbn) {
  var meets_policy_amd = function(password) {
    return zxcvbn(password).guesses > 500;
  };
});
```

B Experiment implementation details

For the sake of reproducibility, we detail the specifics of the algorithms and data we employed in our experiments.

Algorithms

KeePass: We downloaded the C# source of KeePass 2.31 released on 1/9/2016 and extracted its strength estimator into a stand-alone Mono executable that takes a token dictionary as input.

NIST: calculated as specified in Section 2. The NIST 2013 guideline [22] does not precisely define the dictionary check but recommends applying common word transformations. We ignore case and check for reversed words and common 133t substitutions, the same as in zxcvbn. NIST specifies awarding up to 6 bits for passing the dictionary check, decreasing to 0 bits at or above 20 characters, but doesn’t otherwise specify how to award bits. We award a full 6 bits for passwords at or under 10 characters, 4 bits if between 11 and 15, and otherwise 2 bits. NIST recommends a dictionary of at least 50k tokens. The 100k token set described in Section 5 consists of about 390k unique tokens (consisting of several lists ending up to rank-100k).

zxcvbn: Outlined in detail in Section 4.

Data

Within each data source, all tokens were lowercased, counted, and sorted by descending count. When multiple lists contained the same token, that token was filtered from every list but the one with the lowest (most popular) rank. We made use of the following raw data:

RockYou: 32M passwords leaked in 2009 [7], excluding a random 15k test set consisting of passwords of 8 or more characters.

Yahoo: 450k passwords leaked in 2012 [11], excluding a random 15k test set consisting of passwords of 8 or more characters. We cut this list off at 10k top tokens, given the smaller size of the leak.

Xato: Mark Burnett’s 10M password corpus, released in 2015 on Xato.net and compiled by sampling thousands of password leaks

over approximately 15 years. These passwords mostly appear to be from Western users. The authors confirmed with Burnett that the RockYou set is not sampled in Xato; however, Xato likely includes a small number of samples from the Yahoo set. Given the relative sizes of the two sets, Yahoo could at most make up 4.5% of Xato; however, we expect a much smaller percentage from talking to Mark.

Wikipedia: 1-grams from the English Wikipedia database dump of 2015-10-2. We include all Wikipedia articles but not previous revisions, edit histories, template files, or metadata. We parse text from wiki markup via the open-source `WikiExtractor.py` and tokenize according to the Penn Treebank method [6].

Wiktionary: Words from a 2006 Wiktionary word frequency study counting 29M words from US television and film [10]. This list balances Wikipedia’s formal English with casual language and slang. 40k unique tokens.

USCensus: Names and surnames from the 1990 United States Census [1] ranked by frequency as three separate lists: surnames, female names, and male names. We cut surnames off at 10k tokens.

C Yahoo Analysis

For reference, we reproduce the results of Section 5.2 with a sample of Yahoo’12 passwords instead of RockYou’09. Of the 15k test set, PGS cracked 29.05% within our Section 3 online guessing cutoff at 10^6 guesses and 60.07% above 10^6 , leaving 10.88% unguessed.

Choice of Algorithm

Figures 8-10 respectively show PGS vs NIST, KeePass, and zxvcvbn, with each estimator supplied with the same 100k token set. As in the RockYou sample, NIST and KeePass exhibit substantial horizontal banding and overestimate at low magnitudes. At higher magnitudes, NIST tends to underestimate.

Figure 10 demonstrates that zxvcvbn grows roughly linear with PGS, leaning towards underestimation, up until 10^5 guesses. Observable in the RockYou sample but more pronounced here, KeePass and zxvcvbn both experience a spike in overestimation between 10^5 and 10^7 . We offer the same explanation as with RockYou: PGS is trained on a little over 10^7 unique tokens, some of which are long and unrecognized by the estimators. PGS occasionally succeeds making single-token guesses at these higher magnitudes, leading to a spike in inaccuracy between estimator dictionary cutoff and PGS dictionary cutoff.

In Figure 11, we see a similar Δ_i spike at zero for zxvcvbn followed by a sharp decline to the right, indicating high accuracy and low overestimation within an online range.

Choice of Data

Figures 12-13 show PGS vs. zxvcvbn with 10k and 1k token sets, respectively. We observe the same noticeable effect as with RockYou: high accuracy at low magnitudes up until the max token rank cutoff at 10^4 and 10^3 , respectively. Referring to Table 2, $|\Delta|$ and Δ^+ noticeably improve with more data within the online range. Past the online range, more data makes the algorithm more conservative, with progressively higher $|\Delta|$ and lower Δ^+ .

Impact of Pattern Matching

Figure 14 shows a variant of zxvcvbn, supplied with the 100k token set, that matches case-insensitive token lookups only. We similarly observe more overestimation before $g_{pgs} = 10^5$ and more prominent horizontal banding at higher magnitudes compared to Figure 10.

The bottom portion of Table 2 shows the cumulative effect of matching additional pattern types. Within the online range, $|\Delta|$ and Δ^+ shrink by about 5% and 46%, respectively.

	PGS < 10^6		PGS > 10^6	
	$ \Delta $	Δ^+	$ \Delta $	Δ^+
NIST-100k	1.46	1.43	2.19	0.13
KP-100k	1.24	1.05	1.85	0.83
ZX-100k	0.74	0.19	2.45	0.26
ZX-1k	0.74	0.19	2.45	0.26
ZX-10k	0.91	0.39	2.40	0.32
ZX-100k	1.42	1.04	2.28	0.50
ZX-100k:				
tokens only	0.78	0.35	2.13	0.33
+reversed/133t	0.79	0.33	2.19	0.32
+date/year	0.74	0.26	2.35	0.28
+keyboard	0.74	0.25	2.36	0.27
+repeat	0.73	0.19	2.43	0.26
+sequence	0.74	0.19	2.45	0.26

Table 2: $|\Delta|$ and Δ^+ summary statistics.

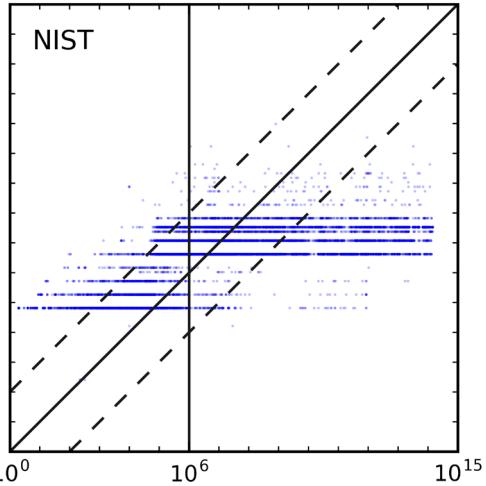

Figure 8: PGS (x) vs. NIST (y), 100k token set.

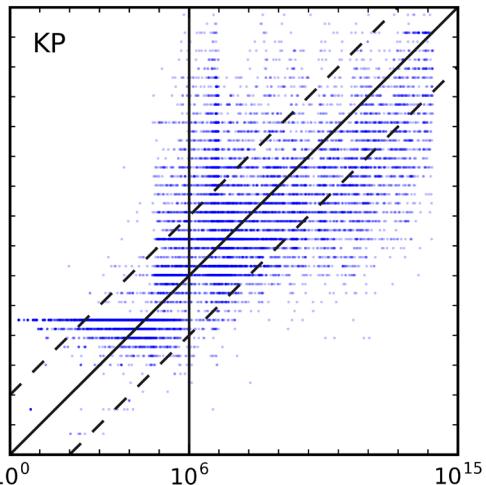

Figure 9: PGS (x) vs. KeePass (y), 100k token set.

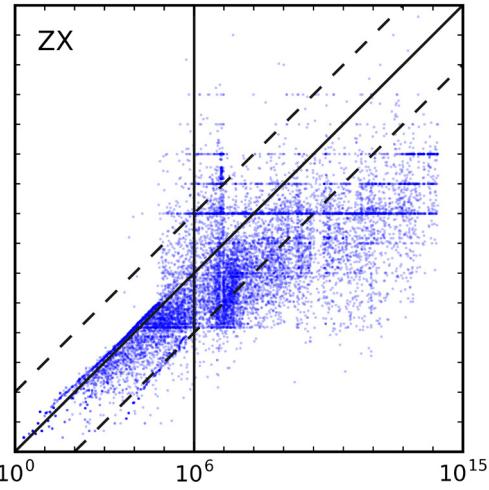

Figure 10: PGS (x) vs. zxvcvbn (y), 100k token set.

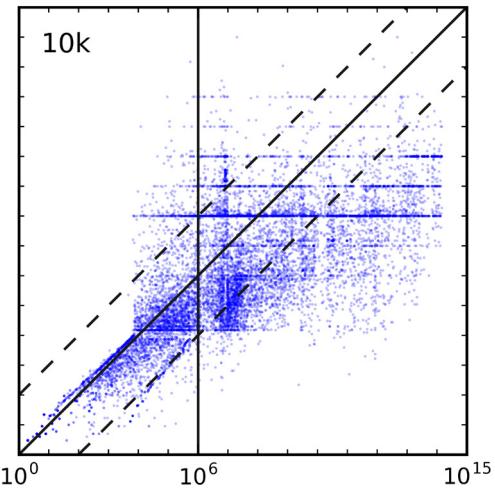

Figure 12: PGS (x) vs. zxvcvbn (y), 10k token set.

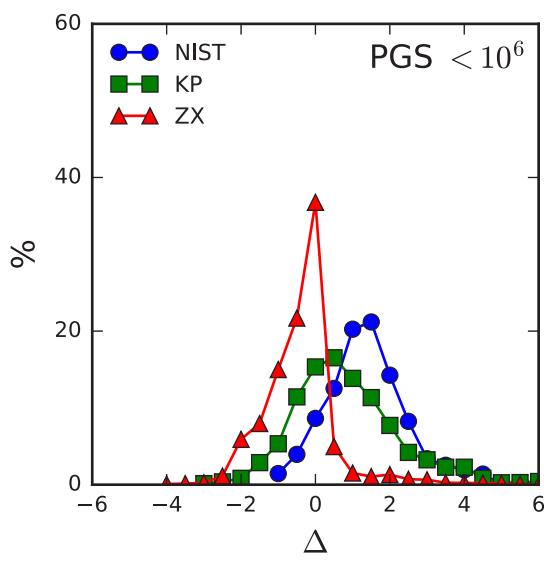

Figure 11: Δ histograms, 100k token set, online attack range ($g_{pgs} < 10^6$). zxvcvbn spikes at $\Delta = 0$ then conservatively falls off to the right.

Fast, Lean, and Accurate: Modeling Password Guessability Using Neural Networks

William Melicher, Blase Ur, Sean M. Segreti, Saranga Komanduri,
Lujo Bauer, Nicolas Christin, Lorrie Faith Cranor
Carnegie Mellon University

Abstract

Human-chosen text passwords, today’s dominant form of authentication, are vulnerable to guessing attacks. Unfortunately, existing approaches for evaluating password strength by modeling adversarial password guessing are either inaccurate or orders of magnitude too large and too slow for real-time, client-side password checking. We propose using artificial neural networks to model text passwords’ resistance to guessing attacks and explore how different architectures and training methods impact neural networks’ guessing effectiveness. We show that neural networks can often guess passwords more effectively than state-of-the-art approaches, such as probabilistic context-free grammars and Markov models. We also show that our neural networks can be highly compressed—to as little as hundreds of kilobytes—without substantially worsening guessing effectiveness. Building on these results, we implement in JavaScript the first principled client-side model of password guessing, which analyzes a password’s resistance to a guessing attack of arbitrary duration with sub-second latency. Together, our contributions enable more accurate and practical password checking than was previously possible.

1 Introduction

Text passwords are currently the most common form of authentication, and they promise to continue to be so for the foreseeable future [53]. Unfortunately, users often choose predictable passwords, enabling password-guessing attacks. In response, proactive password checking is used to evaluate password strength [19].

A common way to evaluate the strength of a password is by running or simulating password-guessing techniques [35, 59, 92]. A suite of well-configured guessing techniques, encompassing both probabilistic approaches [37, 65, 93] and off-the-shelf password-recovery tools [74, 83], can accurately model the vulnerability of

passwords to guessing by expert attackers [89]. Unfortunately, these techniques are often very computationally intensive, requiring hundreds of megabytes to gigabytes of disk space, and taking days to execute. Therefore, they are typically unsuitable for real-time evaluation of password strength, and sometimes for any practically useful evaluation of password strength.

With the goal of gauging the strength of human-chosen text passwords both more accurately and more practically, we propose using artificial neural networks to guess passwords. Artificial neural networks (hereafter referred to as “neural networks”) are a machine-learning technique designed to approximate highly dimensional functions. They have been shown to be very effective at generating novel sequences [49, 84], suggesting a natural fit for generating password guesses.

In this paper, we first comprehensively test the impact of varying the neural network model size, model architecture, training data, and training technique on the network’s ability to guess different types of passwords. We compare our implementation of neural networks to state-of-the-art password-guessing models, including widely studied Markov models [65] and probabilistic context-free grammars [59, 93], as well as software tools using mangled dictionary entries [74, 83]. In our tests, we evaluate the performance of probabilistic models to large numbers of guesses using recently proposed Monte Carlo methods [34]. We find that neural networks guess passwords more successfully than other password-guessing methods in general, especially so beyond 10^{10} guesses and on non-traditional password policies. These cases are interesting because password-guessing attacks often proceed far beyond 10^{10} guesses [44, 46] and because existing password-guessing attacks underperform on new, non-traditional password policies [79, 80].

Although more effective password guessing using neural networks is an important contribution on its own, we also show that the neural networks we use can be highly compressed with minimal loss of guessing ef-

fectiveness. Our approach is thus far more suitable than existing password-guessing methods for client-side password checking. Most existing client-side password checkers are inaccurate [33] because they rely on simple, easily compressible heuristics, such as counting the number of characters or character classes in a password. In contrast, we show that a highly compressed neural network more accurately measures password strength than existing client-side checkers. We can compress such a neural network into hundreds of kilobytes, which is small enough to be included in an app for mobile devices, bundled with encryption software, or used in a web page password meter.

To demonstrate the practical suitability of neural networks for client-side password checking, we implement and benchmark a neural-network password checker in JavaScript. This implementation, which we have released as open-source software,¹ is immediately suitable for use in mobile apps, browser extensions, and web page password meters. Our implementation gives real-time feedback on password strength in fractions of a second, and it more accurately measures resistance to guessing than existing client-side methods.

In summary, this paper makes three main contributions that together substantially increase our ability to detect and help eliminate weak passwords. First, we propose neural networks as a model for guessing human-chosen passwords and comprehensively evaluate how varying their training, parameters, and compression impacts guessing effectiveness. In many circumstances, neural networks guess more accurately than state-of-art techniques. Second, leveraging neural networks, we create a password-guessing model sufficiently compressible and efficient for client-side proactive password checking. Third, we build and benchmark a JavaScript implementation of such a checker. In common web browsers running on commodity hardware, this implementation models an arbitrarily high number of adversarial guesses with sub-second latency, while requiring only hundreds of kilobytes of data to be transferred to a client. Together, our contributions enable more accurate proactive password checking, in a far broader range of common scenarios, than was previously possible.

2 Background and Related Work

To highlight when password strength matters, we first summarize password-guessing attacks. We then discuss metrics and models for evaluating password strength, as well as lightweight methods for estimating password strength during password creation. Finally, we summarize prior work on generating text using neural networks.

¹https://github.com/cupslab/neural_network_cracking

2.1 Password-Guessing Attacks

The extent to which passwords are vulnerable to guessing attacks is highly situational. For phishing attacks, keyloggers, or shoulder surfing, password strength does not matter. Some systems implement rate-limiting policies, locking an online account or a device after a small number of incorrect attempts. In these cases, passwords other than perhaps the million most predictable are unlikely to be guessed [39].

Guessing attacks are a threat, however, in three other scenarios. First, if rate limiting is not properly implemented, as is believed to have been the case in the 2014 theft of celebrities’ personal photos from Apple’s iCloud [50], large-scale guessing becomes possible. Second, if a database of hashed passwords is stolen, which sadly occurs frequently [20, 23, 27, 45, 46, 67, 73, 75, 87], an offline attack is possible. An attacker chooses likely candidate passwords, hashes them, and searches the database for a matching hash. When a match is found, attackers can rely on the high likelihood of password reuse across accounts and try the same credentials on other systems [32]. Attacks leveraging password reuse have real-world consequences, including the recent compromise of Mozilla’s Bugzilla database due to an administrator reusing a password [76] and the compromise of 20 million accounts on Taobao, a Chinese online shopping website similar to eBay, due to password reuse [36].

Third, common scenarios in which cryptographic key material is derived from, or protected by, a password are vulnerable to large-scale guessing in the same way as hashed password databases for online accounts. For instance, for password managers that sync across devices [52] or privacy-preserving cloud backup tools (e.g., SpiderOak [82]), the security of files stored in the cloud depends directly on password strength. Furthermore, cryptographic keys used for asymmetric secure messaging (e.g., GPG private keys), disk-encryption tools (e.g., TrueCrypt), and Windows Domain Kerberos Tickets [31] are protected by human-generated passwords. If the file containing this key material is compromised, the strength of the password is critical for security. The importance of this final scenario is likely to grow with the adoption of password managers and encryption tools.

2.2 Measuring Password Strength

Models of password strength often take one of two conceptual forms. The first relies on purely statistical methods, such as Shannon entropy or other advanced statistical approaches [21, 22]. However, because of the unrealistically large sample sizes required, we consider these types of model out of scope. The second conceptual approach is to simulate adversarial password guess-

ing [34, 65, 89]. Our application of neural networks follows this method. Below, we describe the password-guessing approaches that have been widely studied in academia and used in adversarial password cracking, all of which we compare to neural networks in our analyses. Academic studies of password guessing have focused on probabilistic methods that take as input large password sets, then output guesses in descending probability order. Password cracking tools rely on efficient heuristics to model common password characteristics.

Probabilistic Context-Free Grammars One probabilistic method uses probabilistic context-free grammars (PCFGs) [93]. The intuition behind PCFGs is that passwords are built with template structures (e.g., 6 letters followed by 2 digits) and terminals that fit into those structures. A password’s probability is the probability of its structure multiplied by those of its terminals.

Researchers have found that using separate training sources for structures and terminals improves guessing [59]. It is also beneficial to assign probabilities to unseen terminals by smoothing, as well as to augment guesses generated by the grammar with passwords taken verbatim from the training data without abstracting them into the grammar [60]. Furthermore, using natural-language dictionaries to instantiate terminals improves guessing, particularly for long passwords [91].

Markov Models Using Markov models to guess passwords, first proposed in 2005 [70], has recently been studied more comprehensively [37, 65]. Conceptually, Markov models predict the probability of the next character in a password based on the previous characters, or context characters. Using more context characters can allow for better guesses, yet risks overfitting. Smoothing and backoff methods compensate for overfitting. Researchers have found that a 6-gram Markov model with additive smoothing is often optimal for modeling English-language passwords [65]. We use that configuration in our analyses.

Mangled Wordlist Methods In adversarial password cracking, software tools are commonly used to generate password guesses [44]. The most popular tools transform a wordlist (passwords and dictionary entries) using mangling rules, or transformations intended to model common behaviors in how humans craft passwords. For example, a mangling rule may append a digit and change each ‘a’ to ‘@’. Two popular tools of this type are Hashcat [83] and John the Ripper (JtR, [74]). While these approaches are not directly based on statistical modeling, they produce fairly accurate guesses [89] quickly, which has led to their wide use [44].

2.3 Proactive Password Checking

Although the previously discussed password-guessing models can accurately model human-created passwords [89], they take hours or days and megabytes or gigabytes of disk space, making them too resource-intensive to provide real-time feedback to users. Current real-time password checkers can be categorized based on whether they run entirely client-side. Checkers with a server-side component can be more accurate because they can leverage large amounts of data. For instance, researchers have proposed using server-side Markov models to gauge password strength [26]. Others have studied using training data from leaked passwords and natural-language corpora to show users predictions about what they will type next [61].

Unfortunately, a server-side component introduces substantial disadvantages for security. In some cases, sending a password to a server for password checking destroys all security guarantees. For instance, passwords that protect an encrypted volume (e.g., TrueCrypt) or cryptographic keys (e.g., GPG), as well as the master password for a password manager, should never leave the user’s device, even for proactive password checking. As a result, accurate password checking is often missing from these security-critical applications. In cases when a password is eventually sent to the server (e.g., for an online account), a real-time, server-side component both adds latency and opens password meters to powerful side-channel attacks based on keyboard timing, message size, and caching [81].

Prior client-side password checkers, such as those running entirely in a web browser, rely on heuristics that can be easily encoded. Many common meters rate passwords based on their length or inclusion of different character classes [33, 88]. Unfortunately, in comprehensive tests of both client- and server-side password meters, all but one meter was highly inaccurate [33]. Only zxcvbn [94, 95], which uses dozens of more advanced heuristics, gave reasonably accurate strength estimations. Such meters, however, do not directly model adversarial guessing because of the inability to succinctly encode models and calculate real-time results. In contrast, our approach models adversarial guessing entirely on the client side.

2.4 Neural Networks

Neural networks, which we use to model passwords, are a machine-learning technique for approximating highly dimensional functions. Designed to model human neurons, they are particularly adept at fuzzy classification problems and generating novel sequences. Our method of generating candidate password guesses draws heavily on previous work that generated the probability of

the next element in a string based on the preceding elements [49, 84]. For example, in generating the string *password*, a neural network might be given *passwor* and output that *d* has a high probability of occurring next.

Although password creation and text generation are conceptually similar, little research has attempted to use insights from text generation to model passwords. A decade ago, neural networks were proposed as a method for classifying passwords into two very broad categories (weak or strong) [30], but that work did not seek to model the order in which passwords would be guessed or other aspects of a guessing attack. To our knowledge, the only proposal to use neural networks in a password-guessing attack was a recent blog post [71]. In sharp contrast to our extensive testing of different parameters to make neural networks effective in practice, that work made few refinements to the application of neural networks, leading the author to doubt that the approach has “any practical relevance.” Additionally, that work sought only to model a few likely password guesses, as opposed to our use of Monte Carlo methods to simulate an arbitrary number of guesses.

Conceptually, neural networks have advantages over other methods. In contrast to PCFGs and Markov models, the sequences generated by neural networks can be inexact, novel sequences [49], which led to our intuition that neural networks might be appropriate for password guessing. Prior approaches to probabilistic password guessing (e.g., Markov models [26]) were sufficiently memory-intensive to be impractical on only the client-side. However, neural networks can model natural language in far less space than Markov models [68]. Neural networks have also been shown to transfer knowledge about one task to related tasks [97]. This is crucial for targeting novel password-composition policies, for which training data is sparse at best.

3 System Design

We experimented with a broad range of options in a large design space and eventually arrived at a system design that 1) leverages neural networks for password guessing, and 2) provides a client-side guess estimation method.

3.1 Measuring Password Strength

Similarly to Markov models, neural networks in our system are trained to generate the next character of a password given the preceding characters of a password. Figure 1 illustrates our construction. Like in Markov models [34, 65], we rely on a special password-ending symbol to model the probability of ending a password after a sequence of characters. For example, to calculate the probability of the entire password ‘bad’, we would

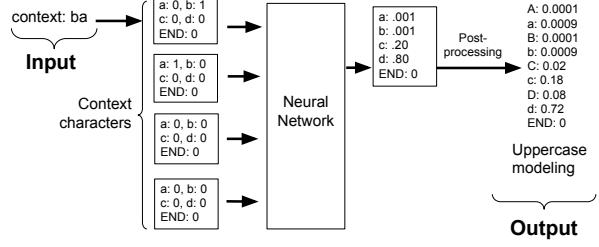

Figure 1: **An example of using a neural network to predict the next character of a password fragment.** The network is being used to predict a ‘d’ given the context ‘ba’. This network uses four characters of context. The probabilities of each next character are the output of the network. Post processing on the network can infer probabilities of uppercase characters.

start with an empty password, and query the network for the probability of seeing a ‘b’, then seeing an ‘a’ after ‘b’, and then of seeing a ‘d’ after ‘ba’, then of seeing a complete password after ‘bad’. To generate passwords from a neural network model, we enumerate all possible passwords whose probability is above a given threshold using a modified beam-search [64], a hybrid of depth-first and breadth-first search. If necessary, we can suppress the generation of non-desirable passwords (e.g., those against the target password policy) by filtering those passwords. Then, we sort passwords by their probability. We use beam-search because breadth-first’s memory requirements do not scale, and because it allows us to take better advantage of GPU parallel processing power than depth-first search. Fundamentally, this method of guess enumeration is similar to that used in Markov models, and it could benefit from the same optimizations, such as approximate sorting [37]. A major advantage over Markov models is that the neural network model can be efficiently implemented on the GPU.

Calculating Guess Numbers In evaluating password strength by modeling a guessing attack, we calculate a password’s *guess number*, or how many guesses it would take an attacker to arrive at that password if guessing passwords in descending order of likelihood. The traditional method of calculating guess numbers by enumeration is computationally intensive. For example, enumerating more than 10^{10} passwords would take roughly 16 days in our unoptimized implementation on an NVidia GeForce GTX 980 Ti. However, in addition to guess number enumeration, we can also estimate guess numbers accurately and efficiently using Monte Carlo simulations, as proposed by Dell’Amico and Filippone [34].

3.2 Our Approach

There are many design decisions necessary to train neural networks. The design space forces us to decide on

the modeling alphabet, context size, type of neural network architecture, training data, and training methodology. We experiment along these dimensions.

Model Architectures In this work, we use recurrent neural networks because they have been shown to be useful for generating text in the context of character-level natural language [49, 84]. Recurrent neural networks are a specific type of neural network where connections in the network can process elements in sequences and use an internal memory to remember information about previous elements in the sequence. We experiment with two different recurrent architectures in Section 5.1.

Alphabet Size We focus on character-level models, rather than more common word-level models, because there is no established dictionary of words for password generation. We also complement our analysis with exploratory experiments using syllable-level models in Section 5.1. We decided to explore hybrid models based on prior work in machine learning [68]. In the hybrid construction, in addition to characters, the neural network is allowed to model sub-word units, such as syllables or tokens. We chose to model 2,000 different tokens based on prior work [68] and represent those tokens the same way we would characters. A more thorough study of tokenized models would explore both more and fewer tokens. Using tokenized structures, the model can then output the probability of the next character being an ‘a’ or the token ‘pass’. We generated the list of tokens by tokenizing words in our training set along character-class boundaries and selecting the 2,000 most frequent ones.

Like prior work [26], we observed empirically that modeling all characters unnecessarily burdens the model and that some characters, like uppercase letters and rare symbols, are better modeled outside of the neural network. We can still create passwords with these characters by interpreting the model’s output as templates. For example, when the neural network predicts an ‘A’ character, we post-process the prediction to predict both ‘a’ and ‘A’ by allocating their respective probabilities based on the number of occurrences of ‘a’ and ‘A’ in the training data—as shown in Figure 1. The intuition here is that we can reduce the amount of resources consumed by the neural network when alternate heuristic approaches can efficiently model certain phenomena (e.g., shifts between lowercase and uppercase letters).

Password Context Predictions rely on the context characters. For example, in Figure 1, the context characters are ‘ba’ and the target prediction is ‘d’. Increasing the number of context characters increases the training

time, while decreasing the number of context characters could potentially decrease guessing success.

We experimented with using all previous characters in the password as context and with only using the previous ten characters. We found in preliminary tests that using ten characters was as successful at guessing and trained up to an order of magnitude faster, and thus settled on this choice. When there are fewer than ten context characters, we pad the input with zeros. In comparison, best-performing Markov models typically use five characters of context [34, 65]. While Markov models can overfit if given too much context, neural networks typically overfit when there are too many parameters.

Providing context characters in reverse order—e.g., predicting ‘d’ from ‘rowssap’ instead of ‘passwor’—has been shown to sometimes improve performance [48]. We empirically evaluate this technique in Section 5.1.

Model Size We must also decide how many parameters to include in models. To gauge the effect of changing the model size on guessing success, we test a large neural network with 15,700,675 parameters and a smaller network with 682,851 parameters. The larger size was chosen to limit the amount of time and GPU memory used by the model, which required one and a half weeks to fully train on our larger training set. The smaller size was chosen for use in our browser implementation because it could realistically be sent over the Internet; compressed, this network is a few hundred kilobytes. We evaluate the two sizes of models with a variety of password policies, since each policy may respond differently to size constraints, and describe the results in Section 5.1.

Transference Learning We experimented with a specialized method of training neural networks that takes advantage of *transference learning*, in which different parts of a neural network learn to recognize different phenomena during training [97]. One of the key problems with targeting non-traditional password policies is that there is little training data. For example, in our larger training set, there are 105 million passwords, but only 2.6 million satisfy a password policy that requires a minimum of 16 characters. The sparsity of training samples limits guessing approaches’ effectiveness against such non-traditional policies. However, if trained on all passwords, the learned model is non-optimal because it generates passwords that are not accurate for our target policy even if one ignores passwords that do not satisfy the policy. Transference learning lets us train a model on all passwords, yet tailor its guessing to only longer passwords.

When using transference learning, the model is first trained on all passwords in the training set. Then, the lower layers of the model are frozen. Finally, the model is retrained only on passwords in the training set that fit

the policy. The intuition is that the lower layers in the model learn low-level features about the data (e.g., that ‘a’ is a vowel), and the higher layers learn higher-level features about the data (e.g., that vowels often follow consonants). Similarly, the lower layers in the model may develop the ability to count the number of characters in a password, while the higher level layers may recognize that passwords are typically eight characters long. By fine-tuning the higher-level parameters, we can leverage what the model learned about all passwords and retarget it to a policy for which training data is sparse.

Training Data We experimented with different sets of training data; we describe experiments with two sets of passwords in Sections 4.1 and 5.2, and also with including natural language in training data in Section 5.1. For machine-learning algorithms in general, more training data is better, but only if the training data is a close match for the passwords we test on.

3.3 Client-Side Models

Deploying client-side (e.g., browser-based) password-strength-measuring tools presents severe challenges. To minimize the latency experienced by users, these tools should execute quickly and transfer as little data as possible over the network. Advanced guessing tools (e.g., PCFG, Markov models, and tools like JtR and Hashcat) run on massively parallel servers and require on the order of hundreds of megabytes or gigabytes of disk space. Typically, these models also take hours or days to return results of strength-metric tests, even with recent advances in efficient calculation [34], which is unsuitable for real-time feedback. In contrast, by combining a number of optimizations with the use of neural networks, we can build accurate password-strength-measuring tools that are sufficiently fast for real-time feedback and small enough to be included in a web page.

3.3.1 Optimizing for Model Size

To deploy our prototype implementation in a browser, we developed methods for succinctly encoding it. We leveraged techniques from graphics for encoding 3D models for browser-based games and visualizations [29]. Our encoding pipeline contains four different steps: weight quantization, fixed-point encoding, ZigZag encoding, and lossless compression. Our overall strategy is to send fewer bits and leverage existing lossless compression methods that are natively supported by browser implementations, such as gzip compression [41]. We describe the effect that each step in the pipeline has on compression in Section 5.3. We also describe encoding a short wordlist of passwords in Bloom filters.

Weight Quantization First, we quantized the weights of the neural network to represent them with fewer digits. Rather than sending all digits of the 32-bit floating-point numbers that describe weights, we only send the most significant digits. Weight quantization is routinely used for decreasing model size, but can increase error [68]. We show the effect of quantization on error rates in Section 5.3. We experimentally find that quantizing weights up to three decimal digits leads to minimal error.

Fixed-point Encoding Second, instead of representing weights using floating-point encoding, we used fixed-point encoding. Due to the weight-quantization step, many of the weight values are quantized to the same values. Fixed-point encoding allows us to more succinctly describe the quantized values using unsigned integers rather than floating point numbers on the wire: one could internally represent a quantized weight between -5.0 and 5.0 with a minimum precision of 0.005, as between -1000 and 1000 with a precision of 1. Avoiding the floating-point value would save four bytes. While lossless compression like gzip partially reduces the need for fixed-point encoding, we found that such scaling still provides an improvement in practice.

ZigZag Encoding Third, negative values are generally more expensive to send on the wire. To avoid sending negative values, we use ZigZag encoding [8]. In ZigZag encoding, signed values are encoded by using the last bit as the sign bit. So, the value of 0 is encoded as 0, but the value of -1 is encoded as 1, 1 is encoded as 2, -2 is encoded as 3, and so on.

Lossless Compression We use regular gzip or deflate encoding as the final stage of the compression pipeline. Both gzip and deflate produce similar results in terms of model size and both are widely supported natively by browsers and servers. We did not consider other compression tools, like LZMA, because their native support by browsers is not as widespread, even though they typically result in slightly smaller models.

Bloom Filter Word List To increase the success of client-side guessing, we also store a word list of frequently guessed passwords. As in previous work [89], we found that for some types of password-cracking methods, prepending training passwords improves guessing effectiveness. We stored the first two million most frequently occurring passwords in our training set in a series of compressed Bloom filters [69].

Because Bloom filters cannot map passwords to the number of guesses required to crack, and only compute

existence in a set, we use multiple Bloom filters in different groups: in one Bloom filter, we include passwords that require fewer than 10 guesses; in another, all passwords that require fewer than 100 guesses; and so on. On the client, a password is looked up in each filter and assigned a guess number corresponding to the filter with the smallest set of passwords. This allows us to roughly approximate the guess number of a password without increasing the error bounds of the Bloom filter. To drastically decrease the number of bits required to encode these Bloom filters, we only send passwords that meet the requirements of the policy and would have neural-network-computed guess numbers more than three orders of magnitude different from their actual guess numbers. We limited this word list to be about 150KB after compression in order to limit the size of our total model. We found that significantly more space would be needed to substantially improve guessing success.

3.3.2 Optimizing for Latency

We rely on precomputation and caching to make our prototype sufficiently fast for real-time feedback. Our target latency is near 100 ms because that is the threshold below which updates appear instantaneous [72].

Precomputation We precompute guess numbers instead of calculating guess numbers on demand because all methods of computing guess numbers on demand are too slow to give real-time feedback. For example, even with recent advances in calculation efficiency [34], our fastest executing model, the Markov model, requires over an hour to estimate guess numbers of our test set passwords, with other methods taking days. Precomputation decreases the latency of converting a password probability to a guess number: it becomes a quick lookup in a table on the client.

The drawback of this type of precomputation is that guess numbers become inexact due to the quantization of the probability-to-guess-number mapping. We experimentally measure (see Section 5.3) the accuracy of our estimates, finding the effect on accuracy to be low. For the purpose of password-strength estimation, we believe the drawback to be negligible, in part because results are typically presented to users in more heavily quantized form. For instance, users may be told their password is “weak” or “strong.” In addition, the inaccuracies introduced by precomputation can be tuned to result in safe errors, in that any individual password’s guess number may be an underestimate, but not an overestimate.

Caching Intermediate Results We also cache results from intermediate computations. Calculating the probability of a 10-character password requires 11 full computa-

tions of the neural network, one for each character and one for the end symbol. By caching probabilities of each substring, we significantly speed up the common case in which a candidate password changes by having a character added to or deleted from its end. We experimentally show the benefits of caching in Section 5.3.

Multiple Threads On the client side, we run the neural network computation in a separate thread from the user interface for better responsiveness of the user interface.

3.4 Implementation

We build our server-side implementation on the Keras library [28] and the client-side implementation on the neocortex browser implementation [5] of neural networks. We use the Theano back-end library for Keras, which trains neural networks faster by using a GPU rather than a CPU [17, 18]. Our implementation trains networks and guesses passwords in the Python programming language. Guess number calculation in the browser is performed in JavaScript. Our models typically used three long short-term memory (LSTM) recurrent layers and two densely connected layers for a total of five layers. On the client side, we use the WebWorker browser API to run neural network computations in their own thread [10].

For some applications, such as in a password meter, it is desirable to conservatively estimate password strength. Although we also want to minimize errors overall, on the client we prefer to underestimate a password’s resistance to guessing, rather than overestimate it. To get a stricter underestimate of guess numbers on our client-side implementation, we compute the guess number without respect to capitalization. We find in practice that our model is able to calculate a stricter underestimate this way, without overestimating many passwords’ strength. We don’t do this for the server-side models because those models are used to generate candidate password guesses, rather than estimating a guess number. After computing guess numbers, we apply to them a constant scaling factor, which acts as a security parameter, to make the model more conservative at the cost of making more errors. We discuss this tradeoff more in Section 5.3.

4 Testing Methodology

To evaluate our implementation of neural networks, we compare it to multiple other password cracking methods, including PCFGs, Markov models, JtR, and Hashcat. Our primary metric for guessing accuracy is the guessability of our test set of human-created passwords. The guessability of an individual password is measured by how many guesses a guesser would take to crack a

password. We experiment with two sets of training data and with five sets of test data. For each set of test data, we compute the percentage of passwords that would be cracked after a particular number of guesses. More accurate guessing methods correctly guess a higher percentage of passwords in our test set.

For probabilistic methods—PCFG, Markov models, and neural networks—we use recent work to efficiently compute guess numbers using Monte Carlo methods [34]. For Monte Carlo simulations, we generate and compute probabilities for at least one million random passwords to provide accurate estimates. While the exact error of this technique depends heavily on each method, guess number, and individual password, typically we observed 95% confidence intervals of less than 10% of the value of the guess-number estimate; passwords for which the error exceeded 10% tended to be guessed only after more than 10^{18} guesses. For all Monte Carlo simulations, we model up to 10^{25} guesses for completeness. This is likely an overestimate of the number of guesses that even a well-resourced attacker could be able to or would be incentivized to make against one password.

To calculate guessability of passwords using mangling-rule-based methods—JtR and Hashcat—we enumerate all guesses that these methods make. This provides exact guess numbers, but fewer guesses than we simulate with other methods. Across our different test sets, the mangling-rule-based methods make between about 10^{13} and 10^{15} guesses.

4.1 Training Data

To train our algorithms, we used a mixture of leaked and cracked password sets. We believe this is ethical because these password sets are already publicly available and we cause no additional harm with their use.

We explore two different sets of training data. We term the first set the Password Guessability Service (*PGS*) training set, used by prior work [89]. It contains the Rockyou [90] and Yahoo! [43] leaked password sets. For guessing methods that use natural language, it also includes the web2 list [11], Google web corpus [47], and an inflection dictionary [78]. This set totals 33 million passwords and 5.9 million natural-language words.

The second set (the *PGS++* training set) augments the *PGS* training set with additional leaked and cracked password sets [1, 2, 3, 6, 7, 9, 12, 13, 14, 15, 16, 20, 23, 25, 42, 43, 55, 56, 57, 62, 63, 67, 75, 77, 85, 90]. For methods that use natural language, we include the same natural-language sources as the *PGS* set. This set totals 105 million passwords and 5.9 million natural-language words.

4.2 Testing Data

For our testing data we used passwords collected from Mechanical Turk (MTurk) in the context of prior research studies, as well as a set sampled from the leak of plaintext passwords from 000webhost [40]. In addition to a common policy requiring only eight characters, we study three less common password policies shown to be more resistant to guessing [66, 80]: 4class8, 3class12, and 1class16, all described below. We chose the MTurk sets to get passwords created under more password policies than were represented in leaked data. Passwords generated using MTurk have been found to be similar to real-world, high-value passwords [38, 66]. Nonetheless, we chose the 000webhost leak to additionally compare our results to real passwords from a recently leaked password set. In summary, we used five testing datasets:

- **1class8:** 3,062 passwords longer than eight characters collected for a research study [59]
- **1class16:** 2,054 passwords longer than sixteen characters collected for a research study [59]
- **3class12:** 990 passwords that must contain at least three character classes (uppercase letters, lowercase letters, symbols, digits) and be at least twelve characters long collected for a research study [80]
- **4class8:** 2,997 passwords that must contain all four character classes and be at least eight characters long collected for a research study [66]
- **webhost:** 30,000 passwords randomly sampled from among passwords containing at least eight characters in the 000webhost leak [40]

4.3 Guessing Configuration

PCFG We used a version of PCFG with terminal smoothing and hybrid structures [60], and included natural-language dictionaries in the training data, weighted for each word to count as one tenth of a password. We also separated training for structures and terminals, and trained structures only on passwords that conform to the target policy. This method does not generate passwords that do not match the target policy.

For PCFG, Monte Carlo methods are not able to estimate unique guess numbers for passwords that have the same probability. This phenomenon manifests in the Monte Carlo graphs with jagged edges, where many different passwords are assigned the same guess number (e.g., in Figure 5c before 10^{23}). We assume that an optimal attacker could order these guesses in any order, since they all have the same likelihood according to the model. Hence, we assign the lowest guess number to all of these guesses. This is a strict overestimate of PCFG’s guessing effectiveness, but in practice does not change the results.

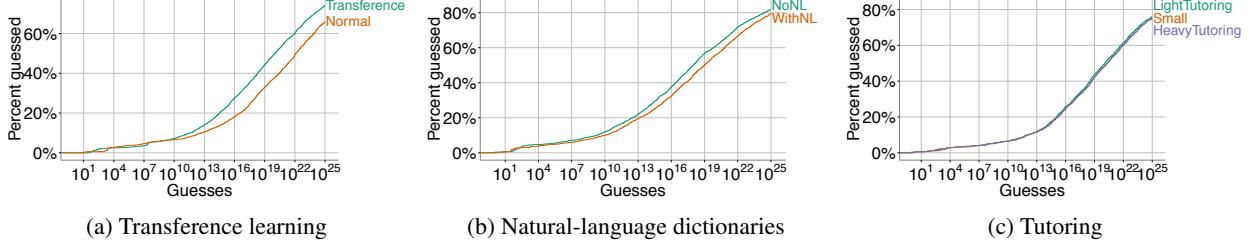

Figure 2: **Alternative training methods for neural networks.** The x -axes represent the number of guesses in log scale. The y -axes show the corresponding percentage of 1class16 passwords guessed. In (b), *WithNL* is a neural network trained with natural-language dictionaries, and *NoNL* is a neural network trained without natural-language dictionaries.

Markov Models We trained 4-, 5-, and 6-gram models. Prior work found the 6-gram models and additive smoothing of 0.01 to be an effective configuration for most password sets [65]. Our results agree, and we use the 6-gram model with additive smoothing in our tests. We discard guesses that do not match the target policy.

Mangling Wordlist Methods We compute guess numbers using the popular cracking tools Hashcat and John the Ripper (JtR). For Hashcat, we use the best64 and gen2 rule sets that are included with the software [83]. For JtR, we use the SpiderLabs mangling rules [86]. We chose these sets of rules because prior work found them effective in guessing general-purpose passwords [89]. To create the input for each tool, we uniques and sorted the respective training set by descending frequency. For JtR, we remove guesses that do not match the target policy. For Hashcat, however, we do not do so because Hashcat’s GPU implementation can suffer a significant performance penalty. We believe that this models a real-world scenario where this penalty would also be inflicted.

5 Evaluation

We performed a series of experiments to tune the training of our neural networks and compare them to existing guessing methods. In Section 5.1, we describe experiments to optimize the guessing effectiveness of neural networks by using different training methods. These experiments were chosen primarily to guide our decisions about model parameters and training along the design space we describe in Section 3.2, including training methods, model size, training data, and network architecture. In Section 5.2, we compare the effectiveness of the neural network’s guessing to other guessing algorithms. Finally, in Section 5.3, we describe our browser implementation’s effectiveness, speed, and size, and we compare it to other browser password-measuring tools.

5.1 Training Neural Networks

We conducted experiments exploring how to tune neural network training, including modifying the network size, using sub-word models, including natural-language dictionaries in training, and exploring alternative architectures. We do not claim that these experiments are a complete exploration of the space. Indeed, improving neural networks is an active area of research.

Transference Learning We find that the transference learning training, described in Section 3.2, improves guessing effectiveness. Figure 2a shows in log scale the effect of transference learning. For example, at 10^{15} guesses, 22% of the test set has been guessed with transference learning, as opposed to 15% without transference learning. Using a 16 MB network, we performed this experiment on our 1class16 passwords because they are particularly different from the majority of our training set. Here, transference learning improves password guessing mostly at higher guess numbers.

Including Natural-Language Dictionaries We experimented with including natural-language dictionaries in the neural network training data, hypothesizing that doing so would improve guessing effectiveness. We performed this experiment with 1class16 passwords because they are particularly likely to benefit from training on natural-language dictionaries [91]. Networks both with and without natural language data were trained using the transference learning method on long passwords. Natural language was included with the primary batch of training data. Figure 2b shows that, contrary to our hypotheses, training on natural language decreases the neural network’s guessing effectiveness. We believe neural networks do not benefit from natural language, in contrast to other methods like PCFG, because this method of training does not differentiate between natural-language dictionaries and password training. However, training data could be enhanced with natural language in other ways, perhaps yielding better results.

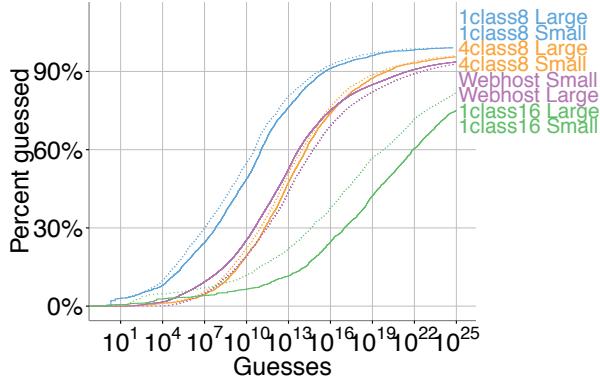

Figure 3: **Neural network size and password guessability.** Dotted lines are large networks; solid lines are small networks.

Password Tokenization We find that using hybrid, sub-word level password models does not significantly increase guessing performance at low guess numbers. Hybrid models may represent the same word in multiple different ways. For example, the model may capture a word as one token, ‘pass’, or as the letters ‘p’, ‘a’, ‘s’, ‘s’. Because Monte Carlo simulations assume that passwords are uniquely represented, instead of using Monte Carlo methods to estimate guess numbers, we calculated guess numbers by enumerating the most probable 10^7 guesses. However, at this low number of guesses, we show this tokenization has only a minor effect, as shown in Figure 4b. We conducted this experiment on long passwords because we believed that they would benefit most from tokenization. This experiment shows that there may be an early benefit, but otherwise the models learn similarly. We consider this result to be exploratory both due to our low guessing cutoff and because other options for tuning the tokenization could produce better results.

Model Size We find that, for at least some password sets, neural network models can be orders of magnitude smaller than other models with little effect on guessing effectiveness. We tested how the following two model sizes impact guessing effectiveness: a large model with 1,000 LSTM cells or 15,700,675 parameters that uses 60 MB, and a small model with 200 LSTM cells or 682,851 parameters that takes 2.7 MB.

The results of these experiments are shown in Figure 3. For 1class8 and 4class8 policies, the effect of decreasing model size is minor but noticeable. However, for 1class16 passwords, the effect is more dramatic. We attribute differences between the longer and shorter policies with respect to model size to fundamental differences in password composition between those policies. Long passwords are more similar to English language phrases, and modeling them may require more parameters, and hence larger networks, than modeling shorter

passwords. The webhost test set is the only set for which the larger model performed worse. We believe that this is due to the lack of suitability of the particular training data we used for this model. We discuss the differences in training data more in Section 5.2.

Tutored Networks To improve the effectiveness of our small model at guessing long passwords, we attempted to tutor our small neural network with randomly generated passwords from the larger network. While this had a mild positive effect with light tutoring, at a roughly one to two ratio of random data to real data, the effect does not seem to scale to heavier tutoring. Figure 2c shows minimal difference in guessing accuracy when tutoring is used, and regardless of whether it is light or heavy.

Backwards vs. Forwards Training As described in Section 3.2, processing input backwards rather than forwards can be more effective in some applications of neural networks [48]. We experiment with guessing passwords backwards, forwards, and using a hybrid approach where half of the network examines passwords forwards and the other half backwards. We observed only marginal differences overall. At the point of greatest difference, near 10^9 guesses, the hybrid approach guessed 17.2% of the test set, backwards guessed 16.4% of the test set and forwards guessed 15.1% of the test set. Figure 4a shows the result of this experiment. Since the hybrid approach increases the amount of time required to train with only small improvement in accuracy, for other experiments we use backwards training.

Recurrent Architectures We experimented with two different types of recurrent neural-network architectures: long short-term memory (LSTM) models [54] and a refinement on LSTM models [58]. We found that this choice had little effect on the overall output of the network, with the refined LSTM model being slightly more accurate, as shown in Figure 4c.

5.2 Guessing Effectiveness

Compared to other individual password-guessing methods, we find that neural networks are better at guessing passwords at a higher number of guesses and when targeting more complex or longer password policies, like our 4class8, 1class16, and 3class12 data sets. For example, as shown in Figure 5b, neural networks guessed 70% of 4class8 passwords by 10^{15} guesses, while the next best performing guessing method guesses 57%.

Models differ in how effectively they guess specific passwords. *MinGuess*, shown in Figure 5, represents an idealized guessing approach in which a password is considered guessed as soon as it is guessed by any of our

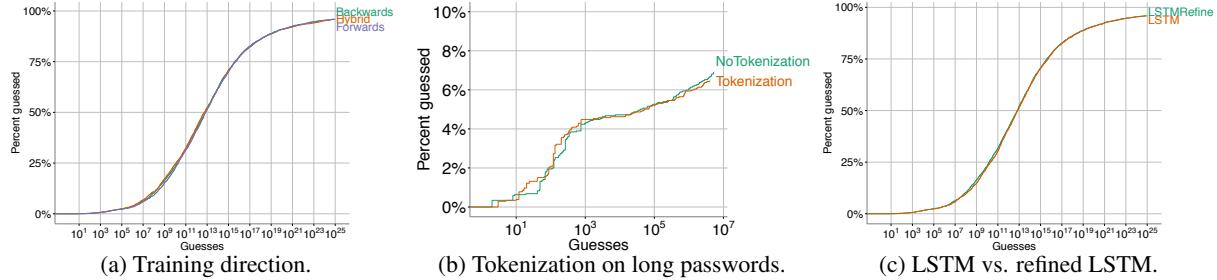

Figure 4: **Additional tuning experiments.** Our LSTM experiments tested on complex passwords with 16M parameters. We found very little difference in performance. Our experiments on tokenization examined long passwords. Our experiments on training direction involved training backwards, forwards, and both backwards and forwards with 16M parameters on complex passwords.

guessing approaches, including neural networks, Markov models, PCFG, JtR, and Hashcat. That MinGuess outperforms neural networks suggests that using multiple guessing methods should still be preferred to using any single guessing method for accurate strength estimation, despite the fact that neural networks generally outperform other models individually.

For all the password sets we tested, neural networks outperformed other models beginning at around 10^{10} guesses, and matched or beat the other most effective methods before that point. Figures 5–6 show the performance of the different guessing methods trained with the PGS data set, and Figures 7–8 show the same guessing methods trained with the PGS++ data set. Both data sets are described in more detail in Section 4.1. In this section, we used our large, 15.7 million parameter neural network, trained with transference learning on two training sets. While performance varies across guessing method and training set, in general we find that the neural networks’ performance at high guess numbers and across policies holds for both sets of training data with one exception, discussed below. Because these results hold for multiple training and test sets, we hypothesize that neural networks would also perform well in guessing passwords created under many policies that we did not test.

In the webhost test set using the PGS++ training data, neural networks performed worse than other methods. For webhost, all guessing methods using the PGS++ data set were less effective than the PGS data set, though some methods, such as PCFG, were only slightly affected. Because all methods perform worse, and because, when using the PGS training data, neural networks do better than other methods—similar to other test sets—we believe that the PGS++ training data is particularly ineffective for this test set. As Figure 3 shows, this is the only data set where a smaller neural network performs significantly better than the larger neural network, which suggests that the larger neural network model is fitting itself more strictly to low-quality data, which limits the larger network’s ability to generalize.

Qualitatively, the types of passwords that our implementation of neural networks guessed before other methods were novel passwords that were dissimilar to passwords in the training set. The types of passwords that our implementation of neural networks were late to guess but that were easily guessable by other methods often were similar to words in the natural-language dictionaries, or were low-frequency occurrences in the training data.

Resource Requirements In general, PCFGs require the most disk, memory, and computational resources. Our PCFG implementation stored its grammar in 4.7GB of disk space. Markov models are the second largest of our implementations, requiring 1.1GB of disk space. Hashcat and JtR do not require large amounts of space for their rules, but do require storing the entire training set, which is 756MB. In contrast, our server-side neural network requires only 60MB of disk space. While 60MB is still larger than what could effectively be transferred to a client without compression, it is a substantial improvement over the other models.

5.3 Browser Implementation

While effective models can fit into 60MB, this is still too large for real-time password feedback in the browser. In this section, we evaluate our techniques for compressing neural network models, discussed in Section 3.3, by comparing the guessing effectiveness of the compressed models to all server-side models—our large neural network, PCFG, Markov models, JtR, and Hashcat.

Model Encoding Our primary size metric is the gziped model size. Our compression stages use the JSON format because of its native support in JavaScript platforms. We explored using the MsgPack binary format [4], but found that after gzip compression, there was no benefit for encoding size and minor drawbacks for decoding speed. The effects of different pipeline stages on compression are shown in Table 1.

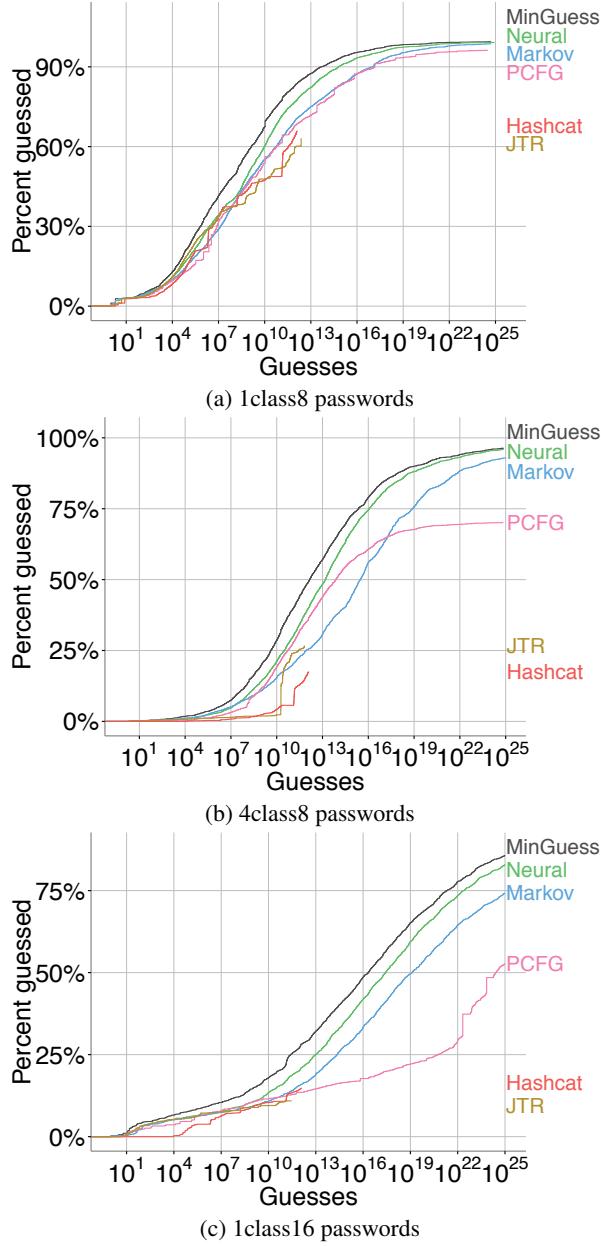

Figure 5: **Guessability of our password sets for different guessing methods using the PGS data set.** *MinGuess* stands for the minimum number of guesses for any approach. Y-axes are differently scaled to best show comparative performance.

Weight and Probability Curve Quantization Because current methods of calculating guess numbers from probabilities are too slow, taking hours or days to return results, we precompute a mapping from password probability to guess number and send the mapping to the client, as described in Section 3.3.2. Such a mapping can be efficiently encoded by quantizing the probability-to-guess-number curve. Quantizing the curve incurs safe errors—i.e., we underestimate the strength of passwords.

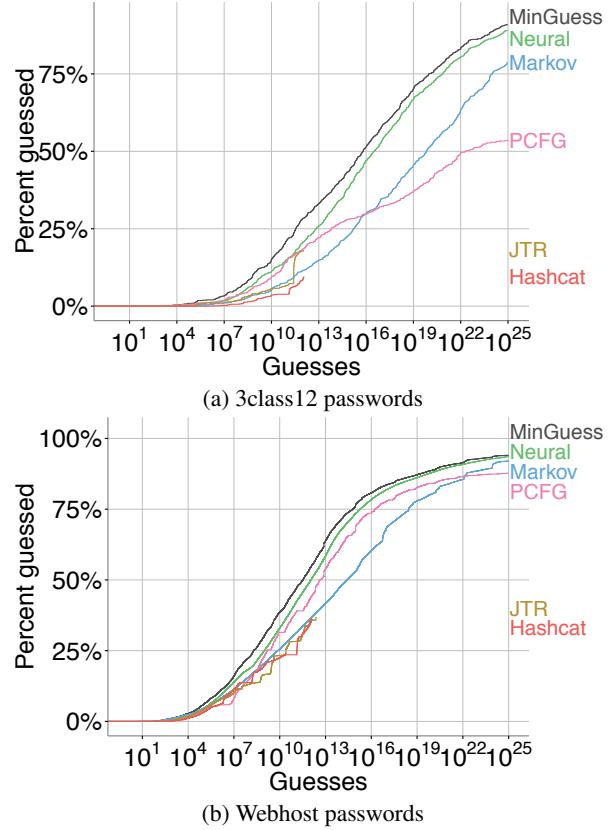

Figure 6: **Guessability of our password sets for different guessing methods using the PGS data set (continued).**

We also quantize the model’s parameters in the browser implementation to further decrease the size of the model. Both weight and curve quantization are lossy operations, whose effect on guessing we show in Figure 9. Curve quantization manifests in a saw-tooth shape to the guessing curve, but the overall shape of the guessing curve is largely unchanged.

Evaluating Feedback Speed Despite the large amount of computation necessary for computing a password’s guessability, our prototype implementation is efficient enough to give real-time user feedback. In general, feedback quicker than 100 ms is perceived as instantaneous [72]; hence, this was our benchmark. We performed two tests to measure the speed of calculating guess numbers: the first measures the time to produce guess numbers with a semi-cached password; the second computes the total time per password. The semi-cached test measures the time to compute a guess number when adding a character to the end of a password. We believe this is representative of what a user would experience in practice because a user typically creates a password by typing it in character by character.

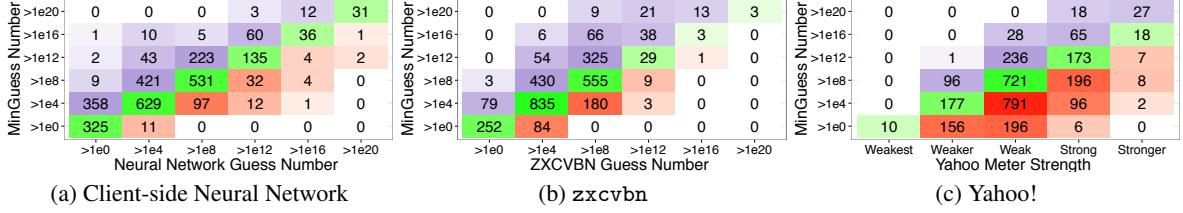

Figure 10: **Client-side guess numbers compared to the minimum guess number of all server-side methods.** The number in the bin represents the number of passwords in that bin. For example, neural networks rated 358 passwords as being guessed with between 10^0 and 10^4 guesses, while server-side approaches rate them as taking between 10^4 and 10^8 guesses. The test passwords are our 1class8 set. The Yahoo! meter does not provide guess numbers and, as such, has a different x -axis. Overestimates of strength are shown in shades of red, underestimates in shades of purple, and accurate estimates in shades of green. Color intensity rises with the number of passwords in a bin.

Pipeline stage	Size	gzip-ed Size
Original JSON format	6.9M	2.4M
Quantization	4.1M	716K
Fixed point	3.1M	668K
ZigZag encoding	3.0M	664K
Removing spaces	2.4M	640K

Table 1: **The effect of different pipeline stages on model size.** This table shows the small model that targets the 1class8 password policy, with 682,851 parameters. Each stage includes the previous stage, e.g., the fixed-point stage includes the quantization stage. We use gzip at the highest compression level.

		Total	Unsafe
1class8	Neural Network	1311	164
	zxcvbn	1331	270
	Yahoo!	1900	984
4class8	Neural Network	1826	115
	zxcvbn	1853	231
	Yahoo!	1328	647

Table 2: **The number of total and unsafe misclassifications for different client-side meters.** Because the Yahoo! meter provides different binning, we pre-process its output for fairer comparison, as described in Section 5.3.

We perform both tests on a laptop running OSX with a 2.7 GHz i7 processor and using the Chrome web browser (version 48). We randomly selected a subset of 500 passwords from our 1class8 training set for these tests. In the semi-cached test, the average time to compute a guess number is 17 ms (stdev: 4 ms); in the full-password test, the average time is 124 ms (stdev: 48 ms). However, both the semi-cached test and the uncached test perform fast enough to give quick feedback to users.

Comparison to Other Password Meters We compared the accuracy of our client-side neural network implementation to other client-side password-strength es-

timators. Approximations of password strength can be under- or overestimates. We call overestimates of password strength unsafe errors, since they represent passwords as harder to guess than they actually are. We show that our meter can more precisely measure passwords’ resistance to guessing with up to half as many unsafe errors as existing client-side models, which are based on heuristics. Our ground truth for this section is the idealized MinGuess method, described in Section 5.2.

Prior work found nearly all proactive password-strength estimators to be inconsistent and to poorly estimate passwords’ resistance to guessing [33]. The most promising estimator was Dropbox’s zxcvbn meter [94, 95], which relies on hand-crafted heuristics, statistical methods, and plaintext dictionaries as training data to estimate guess numbers. Notably, these plaintext dictionaries are not the same as those used for our training data, limiting our ability to fully generalize from these comparisons. Exploring other ways of configuring zxcvbn is beyond the scope of this evaluation. We compare our results to both zxcvbn and the Yahoo! meter, which is an example of using far less sophisticated heuristics to estimate password strength.

The Yahoo! meter does not produce guess numbers but bins passwords as weakest, weaker, weak, strong, and stronger. We ignore the semantic values of the bin names, and examine the accuracy with which the meter classified passwords with different guess numbers (as computed by the MinGuess of all guessing methods) into the five bins. To compare the Yahoo! meter to our minimum guess number (Table 2), we take the median actual guess number of each bin (e.g., the “weaker” bin) and then map the minimum guess number for each password to the bin that it is closest to on a log scale. For example, in the Yahoo! meter, the guess number of $5.4 \cdot 10^4$ is the median of the “weaker” bin; any password closer to $5.4 \cdot 10^4$ than to the medians of other bins on a log scale we consider as belonging in the “weaker” bin. We intend for this to be an overestimate of the accuracy of

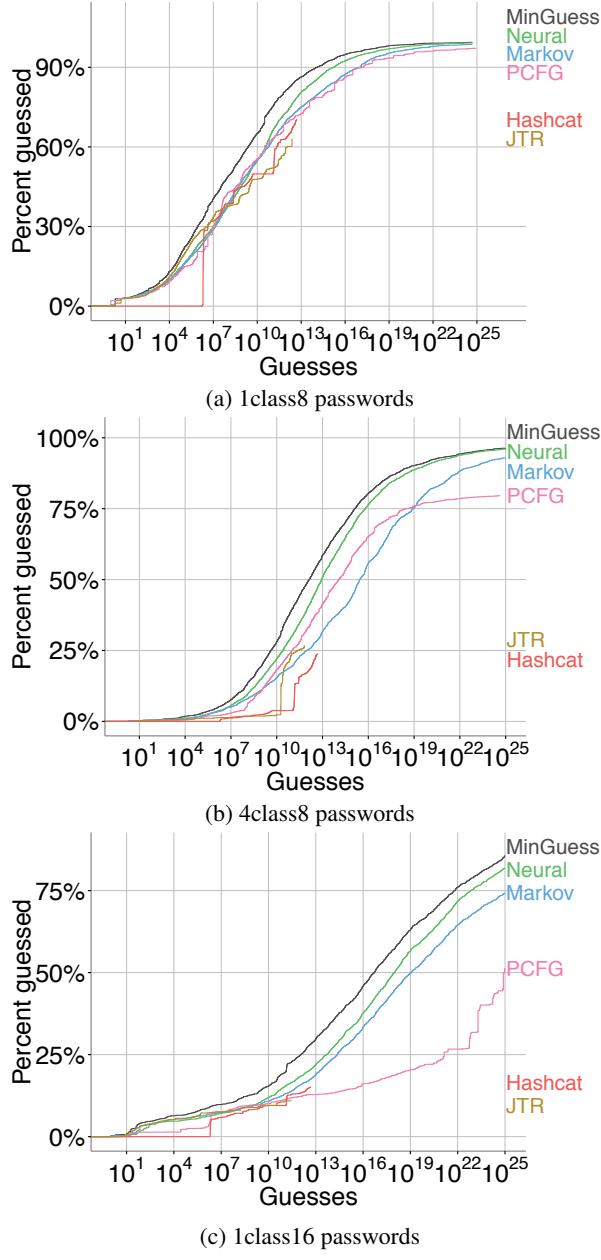

Figure 7: **Guessability of our password sets for different guessing methods using the PGS++ data set.** *MinGuess* stands for the minimum number of guesses for any approach.

the Yahoo! meter. Nonetheless, both our work and prior work [33] find the Yahoo! meter to be less accurate than other approaches, including the `zxcvbn` meter.

We find that our client-side neural network approach is more accurate than the other approaches we test, with up to two times fewer unsafe errors and comparable safe errors, as shown in Figure 10 and Table 2. Here, we used our neural network meter implementation with the tuning described in Section 3.4. We performed the 1class8

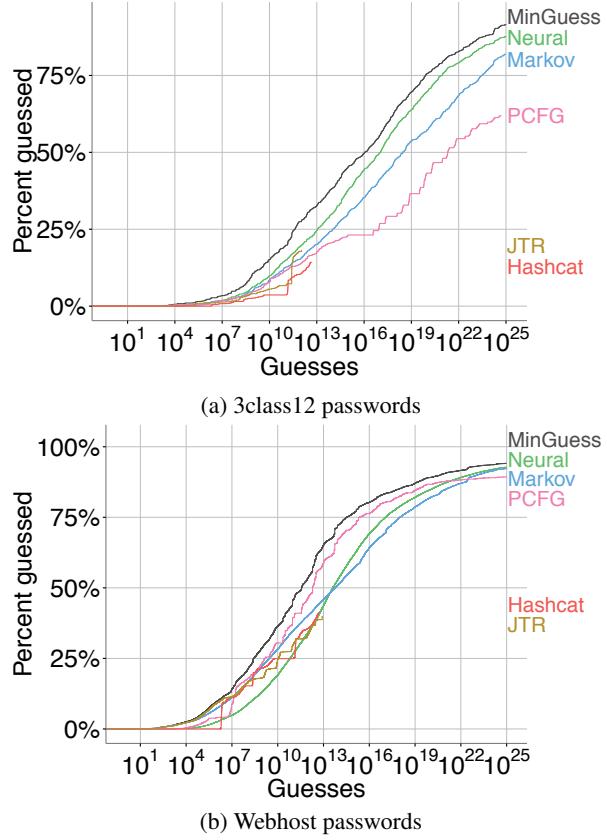

Figure 8: **Guessability of our password sets for different guessing methods using the PGS++ data set (continued).**

test with the client-side Bloom filter, described in Section 3.3.1, while the 4class8 test did not use the Bloom filter because it did not significantly impact accuracy. Both tests scale the network output down by a factor of 300 and ignore case to give more conservative guess numbers. We chose the scaling factor to tune the network to make about as many safe errors as `zxcvbn`. In addition, we find that, compared to our neural network implementation, the `zxcvbn` meter’s errors are often at very low guess numbers, which can be particularly unsafe. For example, for the 10,000 most likely passwords, `zxcvbn` makes 84 unsafe errors, while our neural network only makes 11 unsafe errors.

Besides being more accurate, we believe the neural network approach is easier to apply to other password policies. The best existing meter, `zxcvbn`, is hand-crafted to target one specific password policy. On the other hand, neural networks enable easy retargeting to other policies simply by retraining.

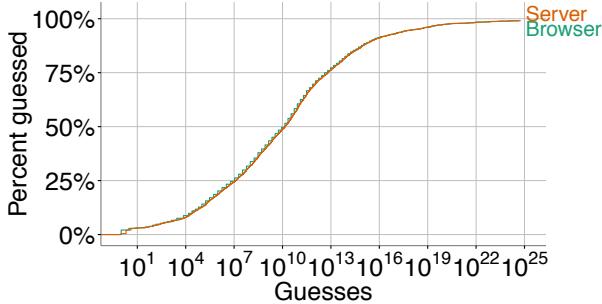

Figure 9: **Compressed browser neural network with weight and curve quantization compared an unquantized network.** *Browser* is our browser network with weight and curve quantization. *Server* is the same small neural network without weight and curve quantization.

6 Conclusion

This paper describes how to use neural networks to model human-chosen passwords and measure password strength. We show how to build and train neural networks that outperform state-of-the-art password-guessing approaches in efficiency and effectiveness, particularly for non-traditional password policies and at guess numbers above 10^{10} . We also demonstrate how to compress neural network password models so that they can be downloaded as part of a web page. This makes it possible to build client-side password meters that provide a good measure of password strength.

Tuning neural networks for password guessing and developing accurate client-side password-strength metrics both remain fertile research grounds. Prior work has used neural networks to learn the output of a larger ensemble of models [24] and obtained better results than our network tutoring (Section 5.1). Other work achieves higher compression ratios for neural networks than we do by using matrix factorization or specialized training methods [51, 96]. Further experiments on leveraging natural language, tokenized models, or other neural-networks architectures might allow passwords to be guessed more effectively. While we measured client-side strength metrics based on guessing effectiveness, a remaining challenge is giving user-interpretable advice to improve passwords during password creation.

Abstract

Many security protocols still rely on manual fingerprint comparisons for authentication. The most well-known and widely used key-fingerprint representation are hexadecimal strings as used in various security tools. With the introduction of end-to-end security in WhatsApp and other messengers, the discussion on how to best represent key-fingerprints for users is receiving a lot of interest.

We conduct a 1047 participant study evaluating six different textual key-fingerprint representations with regards to their performance and usability. We focus on textual fingerprints as the most robust and deployable representation.

Our findings show that the currently used hexadecimal representation is more prone to partial preimage attacks in comparison to others. Based on our findings, we make the recommendation that two alternative representations should be adopted. The highest attack detection rate and best usability perception is achieved with a sentence-based encoding. If language-based representations are not acceptable, a simple numeric approach still outperforms the hexadecimal representation.

1 Introduction

Public key cryptography is a common method for authentication in secure end-to-end communication and has been a part of the Internet throughout the last two decades [7, 11]. While security breaches have shown that systems based on centralized trusted third parties such as Certificate Authorities and Identity Based Private Key Generators are prone to targeted attacks [42], decentralized approaches such as Web of Trust and Namecoin struggle with being adopted in practice due to usability issues [7, 13, 30]. Certificate transparency systems, such as CONIKS and others [24, 39, 27], aim to solve a subset of these issues by providing an auditable directory of all

user keys. Still, manual key verification, i. e., the link between public keys and the entities, such as hostnames or people, remains a challenging subject, especially in decentralized systems without pre-defined authorities, such as SSH, OpenPGP, and secure messaging [12, 41].

Many traditional authentication systems still rely on manual key-fingerprint comparisons [17]. Here, key-fingerprints are generated by encoding the (hashed) public key material into a human readable format, usually encoded in hexadecimal representation. A variety of alternatives such as QR Codes, visual fingerprints, Near Field Communication (NFC), and Short Authentication Strings (SAS) have been proposed. Most of these systems offer specific benefits, e. g., QR codes and NFC do not require users to compare strings, but they also come with specific disadvantages, e. g., they require hardware and software support on all devices. While advances are being made in these areas, the text-based representation is still the dominant form in most applications.

However, due to the recent boom of secure messaging tools, the debate of how to best represent and evaluate textual fingerprints has opened up again and there are many very active discussions among security experts [28, 33]. In April 2016, WhatsApp serving over one billion users enabled end-to-end encryption as default by implementing the Signal protocol. Key verification is optional and can be done by using QR codes or comparing numeric representations, in their case 60-digit numbers [43]. However, it is not clear whether their solution is more usable than traditional representations.

In this paper, we present an evaluation of different textual key-fingerprint representation schemes to aid in the secure messenger discussion. The requirements posed to the developers are as follows:

- The fingerprint representation scheme should provide offline support and work asynchronously. One reason for this is that fingerprints are often printed on business cards or exchanged by third parties.

- The fingerprint should be transferable via audio channels, e.g., it should be possible to compare fingerprint over the phone.
- The representation scheme should be as technically inclusive as possible. No special hardware or software should be required to verify the fingerprints; both require a concerted and coordinated effort between many actors to get enough coverage for a comparison mechanism to be worthwhile for users to adopt.
- The representation should be as inclusive as possible, i.e., excluding as few people with sensory impairments (visual, color, audio, etc.) as possible.

The above requirements exclude many proposed representation schemes and offer an explanation why they have not seen any adoption outside of academia. For this reason, we focus exclusively on textual fingerprint representations in our study. Textual key-fingerprints do not require hardware support and work in synchronous and asynchronous scenarios, i.e., they can be compared via voice or printed on business cards. Depending on the scheme, they even could be recalled from memory and exchanged over a voice channel.

This paper presents our study testing the usability of various textual key-fingerprint representation schemes. Our study consists of two parts: (1) an experiment where we measured how fast and accurate participants perform for different schemes, and (2) a survey about their perception and sentiment. These also contained a direct comparison between the representations.

Our findings suggest that the most adopted alphanumeric approaches such as the Hexadecimal and Base32 scheme perform worse than other alternatives: under a realistic threat model, more than 10% of the users failed to detect attacks targeting Hexadecimal representations, whereas our best system had failure rates of less than 3%. While the best system for accuracy is not the fastest, it is the system which received the highest usability rating and is preferred by users.

In the following sections, we discuss related work followed by an analysis of current implementations deploying in-persona key-fingerprint representation techniques and discuss our evaluated representation schemes. Then, we describe our experiment evaluating text-based key-fingerprint verification techniques with regards to their attack-detection accuracy and speed. Our experiment was conducted as an online study with 1047 participants recruited via the Amazon Mechanical Turk (MTurk) platform. We consider the scenario outlined above, where a user compares two key-fingerprint strings encoded by the different representation schemes. In addition to the implicit measurements of accuracy and speed, we also

evaluate the self-reported user perception to get feedback about which systems are preferred by end users. Finally, we present our results, discuss their implications and takeaways, and conclude our work.

2 Related Work

Various key-fingerprint representations have been proposed in academia and industry. Various cryptographic protocol implementations still rely on manual fingerprint comparisons, while the hexadecimal representation is used in most of them. However, previous work suggests that fingerprint verifications are seldom done in practice [17, 37].

2.1 Key-Fingerprint Representations

Previous work has shown that users struggle with comparing long and seemingly “meaningless” fingerprints and it is suspected that they even might perform poorly in this task [19]. While most previous work has focused on the family of visual fingerprints [35, 32, 19, 10], to our knowledge, none of those focused on the differences between various different textual fingerprint representations.

Hsiao et al. have conducted a study with some textual and visual representation methods for hash verification [19]. They compared Base32 and simple word list representations with various algorithms for visual fingerprints and hash representation with Asian character sets (a subset of Chinese, Japanese Hiragana, and Korean Hangul, respectively). A within-subjects online study with 436 participants revealed that visual fingerprints score very well in both accuracy and speed, together with the Base32 text representation. Hsiao et al. conclude that depending on the available computation power and display size, either Base32 or one of the visual fingerprinting schemes should be used. They explicitly did not evaluate hexadecimal representation or digits

“because that scheme is similar to Base32 and known to be error-prone” [19]. However, our work shows that numeric representations actually perform significantly better than Base32 and is less error prone. In addition, our results suggest that language-based schemes, e.g., generated sentences achieve excellent results comparable to visual schemes. At the same time, textual approaches are more flexible (can be read out loud) and do not exclude people with sensory impairments.

Another study by Olembo et al. also focused mainly on the topic of visual fingerprints [32]. They developed a new family of visual fingerprints and compared them against a Base32 representation. The Base32 strings were twelve characters long and displayed without chunking. The participants performed better with the visual fingerprints than with Base32, regarding both accuracy and speed. Olembo et al. conclude that the Base32 representation is far away from optimal when it comes to manual key-fingerprint verification. We test this claim by comparing Base32 representation with other textual key-fingerprint representation and eventually prove it wrong.

Regarding chunking, Miller et al. have published *The magical number seven* and succeeding work that shows that most people can recall 7 ± 2 items from their memory span [29]. It has been shown that although there are slight differences between numbers, letters and words (numbers perform slightly better than letters, and letters slightly better than words), they perform similar in studies. More recent studies have shown that human working memory easily remembers up to 6 digits, 5.6 letters and 5.2 words [1, 6, 8]. Adjusting chunk sizes to these numbers can help users when comparing hashes.

While all of the above studies offer interesting insights into different (mainly visual) fingerprint representations, to the best of our knowledge there is not work focusing on which textual representation performs the best. However, this knowledge would be extremely important to help in the current debate in the secure messaging community. The representations currently being put forward and implemented are far from optimal and the results of our study can help improve the accuracy and usability of fingerprint representations. Unlike the above studies we conduct our study with a more realistic attacker strength, as presented in subsection 4.1).

2.2 Passwords and Passphrases

A passphrase is basically a password consisting of a series of words rather than characters. In academic literature, passphrases are often considered as a potentially more memorable and more secure alternative to passwords and are often recommended by system administrators [23, 40]. In contrast to most passphrase-

Scheme	Example

Peerio	bates talking duke rummy slurps iced farce pound day
Sentences	Your line works for this kind power cruelly. That lazy snow agrees upon our tall offer.

Table 1: Examples for different textual key-fingerprint representations for the same hash value

based systems, key-fingerprints cannot be chosen by the end-user and thus are more related to the system-assigned passphrases field: Bonneau et al. have shown that users are able to memorize 56-bit passwords [4]. miniLock¹ and its commercial successor Peerio² use system-assigned passphrases to generate cryptographic key pairs easing key backup and synchronization among multiple devices.

Contrary to widespread expectations, Shay et al. were not able to find any significant recall differences between system-assigned passphrases and system-assigned passwords [40]. However, they reported reduced usability due to longer submission times due to typing.

Similar to passphrases, the usage of language-based key-fingerprint representations is claimed to provide better memorability than just an arbitrary series of character strings despite the lack of empirical evidence. In our study, we measure the performance of the different approaches and also collect perception and feedback from end users.

3 Background

In the past years, various textual key-fingerprint representations have been proposed. In this section, we analyze currently practised in-persona key verification techniques in well-known applications. For comparison, Table 1 lists the approaches we used in our evaluation generated from the same hash value.

Only applications requiring manual key-fingerprint

¹<https://minilock.io>

²<https://peerio.com>

verification are considered. In mechanisms like S/MIME or X.509, fingerprints play only a secondary role because certificates are verified via certificate chains.

In the following, $SHA-1(x)$ ¹⁶ defines the execution of 16 rounds of nested $SHA-1$ on x , a truncation to the left-most 16 bits is defined by $x[0, \dots, 16]$, and pk is used as an abbreviation for the values of a public key (differs for RSA, DSA, or ECC).

3.1 Numeric

Numeric representation describes the notation of data using only numeric digits (0-9). The primary advantage of a such system is that Arabic numerals are universally understood, and in addition, numeric key-fingerprints show a similarity to phone numbers. The encoding is achieved by splitting a binary hash into chunks of equal length and expressing each chunk as a decimal number, e.g., by simply switching the representation base from 2 to 10.

The messaging and data exchange application SafeSlinger³ implements this as a fallback scheme for unsupported languages [14]. A 24 bit SAS in SafeSlinger (cf. Figure 2a) can be expressed by three decimal encoded 8-bit numbers.

In the messaging platform WhatsApp, a fingerprint is calculated by $SHA-256(pk)^{5200}[0, \dots, 240]$. This fingerprint is split up into six chunks, where each chunk is represented by a five digits long number modulo 100,000 [43]. Concatenating this fingerprint with the fingerprint of the communication partner results in the displayed representation, e.g.,

```
77658 87428 72099 51303
34908 23247 95615 27317
09725 59699 62543 54320
```

3.2 Alphanumeric

Alphanumeric approaches use numbers and letters to represent data. Depending on the representation type and its parameters, the letters can be presented either in lower-case or in upper-case. The string can be chunked into groups of characters, which are usually of equal length. Chunking does not alter the information contained, while changing lower-case letters to upper-case letters (and vice versa) may does, depending on the coding scheme. Commonly used representations are Hexadecimal, Base32, and Base64.

3.2.1 Hexadecimal

Hexadecimal digits use the letters A-F in addition to numerical digits and are a common representation for key-fingerprints and primarily used in SSH and OpenPGP.

³<https://www.cylab.cmu.edu/safeslinger>

Note that the case of the letters do not make any difference. Regarding chunking, both spaces (cf. Figure 1b) and colons (cf. Figure 1a) are commonly used as separation characters.

Key fingerprints in OpenPGP version 4 are defined in RFC 4880 [7] by

```
Hex(SHA-1(0x99 || len || 4 || creation_time || algo || pk))
```

where len is the length of the packet, $creation_time$ is the time the key has been created and $algo$ is unique identifier for the public-key algorithm. While the inclusion of $creation_time$ makes sure that even two keys with the same key material have different fingerprints, it allows an attacker to iterate through possible past times to generate similar fingerprints skipping the key generation step [5]. The actual representation of OpenPGP fingerprints is not defined in RFC 4880, but most implementations chose to encode them in hexadecimal form, e.g., GnuPG displays them uppercase in 16 bit blocks separated by whitespaces with an additional whitespace after 5 blocks (cf. Figure 1b), e.g.,

```
73EE 2314 F65F A92E C239 0D3A 718C 0701 0001 2282
```

Other implementations, such as OpenKeychain, deviate only slightly, for example by displaying them lowercase or with colored letters to ease comparison but still provide compatibility with GnuPG.

SSH fingerprint strings, as defined in RFC 4716 and RFC 4253 [15, 44], are calculated by

```
Hex(MD5(Base64(algo || pk)))
```

where $algo$ is a string indicating the algorithm, for example “ssh-rsa”. Fingerprints are displayed as “hexadecimal with lowercase letters and separated by colons” [15] (cf. Figure 1a), e.g.,

```
6f:85:66:da:e3:7a:02:c6:5e:62:3f:36:b7:d9:b4:2c
```

3.2.2 Base32

Base32 uses the Latin alphabet (A-Z) without the letters O and I (due to the confusion with numbers 0 and 10). There is no difference between lower-case letters and upper-case letters. In addition, a special padding character “=” is used, since the conversion algorithm processes blocks of 40 bit (5 Byte) in size. The source string is padded with zeroes to achieve a compatible length and sections containing only zeroes are represented by “=” [20, 21].

The ZRTP key exchange scheme for real-time applications is based on a Diffie-Hellman key exchange extended by a preceding hash commitment that allows for very short fingerprints, called Short Authentication

Strings (SAS) without compromising security [45]. The Base32 encoding used in ZRTP uses a special alphabet to produce strings that are easier to read out loud. VoIP applications such as CSipSimple⁴ use this Base32 option, usually named “B32” inside the protocol. Here, the leftmost 20 bits of the 32 bit SAS value are encoded as Base32. , e. g.,

5 e m g

3.2.3 Base64

There exist a number of specifications for encoding data into the Base64 format, which uses the Latin alphabet in both lower-case and upper-case (a-z, A-Z) as well as the digits 0-9 and the characters “+”, “/”, and “=” to represent text data. Again, the character “=” is used to encode padded input [20]. Starting with OpenSSH 6.8 a new fingerprint format has been introduced that uses SHA-256 instead of MD5 and Base64 instead of hexadecimal representation. In addition the utilized hash algorithm is prepended, e. g.,

SHA256:mVPwvezndPv/ARoIadVY98vAC0g+P/5633yTC4d/wXE

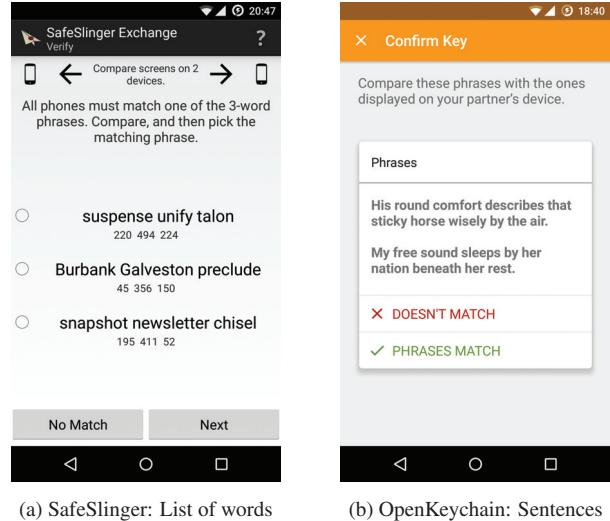

3.3 Unrelated Words

Instead of (alpha)numeric representation, fingerprints can be mapped to lists of words. Here, the binary representation is split into chunks, where each possible value of a chunk is assigned to a word in a dictionary. To increase readability, such a dictionary usually contains no pronouns, articles, prepositions and such. Word lists, such as the PGP Word List [22] and the Basic English word list compiled by K.C. Ogden [31], are primarily used for verification mechanisms based on SAS. Key-Fingerprints represented by words have been implemented for VoIP applications based on the ZRTP key exchange and other real-time communication protocols. Examples are Signal⁵, and the messaging and contact sharing application SafeSlinger [14] (cf. Figure 2). Besides their use in SAS based mechanisms, miniLock and Peerio utilize unrelated words for passphrase generation.

An example for a modern VoIP implementation that utilizes ZRTP for key exchange over Secure Real-Time Transport Protocol (SRTP) is Signal’s private calling feature, previously distributed as Redphone. The developers chose to implement only a specific subset of the ZRTP specification [45], namely Diffie-Hellmann key exchange via P-256 elliptic curves using “B256” SASs, i. e., Base256 encoding that maps to the leftmost 16 bits of the 32 bit SAS values to the previously introduced PGP Word List [22], e. g.,

⁴<https://github.com/r3gis3r/CSipSimple>

⁵<https://github.com/WhisperSystems/Signal-Android>

(a) SafeSlinger: List of words (b) OpenKeychain: Sentences

Figure 2: Language-based fingerprint representations

quota holiness

The messaging application SafeSlinger is based on a Group Diffie-Hellman protocol [14] implementing a key verification with SASs for up to 10 participants. In SafeSlinger the leftmost 24 bits of a SHA-1 hash is used to select 3 words from the PGP Word List, e. g.,

suspense unify talon.

Besides this, two other 3 word triples are selected to force users to make a selection before proceeding (cf. Figure 2a).

In contrast to Signal and SafeSlinger, Peerio (based on miniLock) does not use any SAS based verification mechanism. It uses pictures for verification and word lists for code generation. The word list is generated from most occurring words in movie subtitles. Besides key verification, these are also used to generate so called passphrases, which are used to derive their ECC private keys.

3.4 Generated Sentences

The words from the previous dictionaries can also be used to generate syntactically correct sentences as proposed by previous research: Goodrich et al. proposed to use a “syntactically-correct English-like sentence” representation for exchanging hash-derived fingerprints over audio by using *text-to-speech* (TTS) [16]. Michael Rogers et al. implemented a simple deterministic sentence generator [16, 38]⁶ Though the sentences from both approaches rarely make sense in a semantic fashion, they are syntactically correct and are claimed to pro-

⁶<https://github.com/akwizgran/basic-english>

vide good memorability. In our study, we used Michael Roger’s approach for our sentence generator.

We implemented this method for PGP fingerprints in OpenKeychain 3.6⁷ (cf. Figure 2b). To the best of the authors’ knowledge, to this date, it is the first integration of key verification via sentences although other projects are considering to change their fingerprint encoding scheme [38, 36].

4 Methodology

In order to evaluate the effect and perception of the different textual key-fingerprint representations, we conducted an online study on Amazon’s Mechanical Turk (MTurk) crowdsourcing service. Our Universities do not have an IRB, but the study conformed to the strict data protection law of Germany and informed consent was gathered from all participants. Our online study is divided into two parts: The experiment for performance evaluation followed by a survey extracting self-reported data from users. The survey ended with demographic questions.

4.1 Security Assumptions

In this section, we define the underlying security assumptions of our study, such as fingerprint method, length, and strength against an adversary. The fingerprint method and parameters are utilized consistently for all experiments in our study to offer comparability between all possible fingerprint representations. This attack model is important for the usability since an unrealistically strong or weak attacker could skew the results. Obviously, if the fingerprint strength is not kept equal between the systems this would also skew the results.

4.1.1 Fingerprint Method

To decide upon a fingerprint method for humanly verifiable fingerprints in our study, we first have to differentiate between human and machine verification to illustrate their differences. While a full fingerprint comparison can be implemented for machine verification, humans can fall for fingerprints that match only partially. Additionally, machine comparison can work with long values, whereas for human verification the length must be kept short enough to fit on business cards and to keep the time needed for comparison low.

For machine comparison, full SHA-256 hashes should be calculated binding a unique *ID* to the public key material. The probability of finding a preimage or collision attack is obviously negligible, but the fingerprints can still be computed fast in an ad-hoc manner when needed.

⁷<https://www.openkeychain.org>

It is important to note that collision resistance is not required for our scenarios. It is required for infrastructure-based trust models such as X.509, where certificates are verified by machines and trust is established by authority. In these schemes, a signature generated by a trusted authority can be requested for a certificate by proving the control over a domain, but then reused maliciously for a different certificate/domain. This is already possible with a collision attack, without targeting a full preimage. In contrast, the direct human-based trust schemes considered in this study only need to be protected against preimage attacks, because no inherently trusted authority is involved here.

While machine comparison needs to be done fast, e. g., on key import, manual fingerprint verification by humans is done asynchronously in person or via voice. Thus, we can use a key derivation function to provide a proof-of-work, effectively trading calculation time for a shorter fingerprint length. Secure messaging applications such as Signal or OpenPGP-based ones could pre-calculate the fingerprints after import and cache these before displaying them for verification later.

Thus, modern memory-hard key derivation functions such as *scrypt* [34] or *Argon2* [3] can be utilized to shorten the fingerprint length. These key derivation functions are parametrized to allow for different work factors. Suitable parameters need to be chosen by implementations based on their targeted devices and protocol.

As discussed in Section 3.2.1, while the generation of new fingerprints consists of the creation of a new key pair and the key derivation step, an attacker can potentially skip the key creation. Thus, in the following we only consider the key derivation performance as the limiting factor for brute force attacks.

When utilizing a properly parametrized key derivation function for bit stretching, the security of a 112 bit long fingerprint can be increased to require a brute force attack comparable to a classical 2^{128} brute force attacker. Consequently, a fingerprint length of 112 bit is assumed throughout our study.

4.1.2 Attacker Strength for Partial Preimages

In our user study, we assume an average attacker trying to impersonate an existing *ID* using our fingerprint method. Thus, an attacker would need to find a 112 bit preimage for this existing fingerprint using a brute force search executing the deployed key derivation function in each step. Due to the work factor, we consider this to be infeasible and instead concentrate on partial preimages. For comparability and to narrow the scope of our study, an attacker is assumed that can control up to 80 bits of the full 112 bit fingerprint.

Attackers might aim to find partial preimages where

the uncontrolled bits occur at positions that are more easily missed by inattentive users. First, the bits at the beginning and the end should be fixed as users often begin their comparison with these bits. Thus, we assume that, for any representation method, the first 24 and last 24 bits are controlled by the attacker and thus the same as in the existing fingerprint. Based on the feedback from our pre-study participants and reports from related work, this can be considered best-practice [17, 37]. Second, of the remaining 64 bits in the middle of our 112 bit fingerprint, we assume that 32 bits are controlled by the attacker in addition to the first 24 and last 24 bits. In total, we assume that 80 bits are controlled by the attacker, i. e., are the same as in the existing fingerprint, and 32 bit are uncontrolled.

The probability of finding such a partial preimage for a fingerprint when executing 2^{49} brute force steps is calculated approximately by

$$1 - \left(\frac{2^{112} - \sum_{k=1}^{32} \binom{64}{k}}{2^{112}} \right)^{2^{49}} \approx 0.66.$$

The inner parentheses of this equation define the probability that no partial preimage exists for one specific bit permutation. Instead of using $\binom{64}{32}$, a sum over 32 variations has been inserted to include permutations with more than the uncontrolled 32 bit that are also valid partial preimages. Finally, the probability to find a partial preimage is defined by the inverse of the exponentiation. Assuming the scrypt key derivation function parametrized with $(N, r, p) = (2^{20}, 8, 1)$, Percival calculates the computational costs of a brute force attack against 2^{38} ($\approx 26^8$) hashed passwords with \$610k and 2^{53} ($\approx 95^8$) with \$16B [34]. These costs can be considered a lower and upper bound for our attacker, which we assume to have average capabilities and resources. While 2^{38} has a probability of finding a partial preimage of only 0.05%, with 2^{42} the probability reaches nearly 1%, and with 2^{49} , as in our example, a partial preimage is found with over 50%.

In our study, we simulate attacks by inverting the bits from the existing fingerprint which are uncontrolled by the attacker, while the controlled bits are unchanged. For our theoretical approximation, we assume that the first 24 and last 24 bits should be controlled as well as 32 bits from the middle. In our study, we simulate an even more careful selection of appropriate fingerprints from the ones that an attacker would brute force. A general criteria here is to minimize the influence of uncontrolled bits on the entire fingerprint: For numeric and alphanumeric representations all bits affecting a character or digit are inverted together. For unrelated words, all bits affecting a word are changed. Sentences are never changed in a way that would alter the sentence structure.

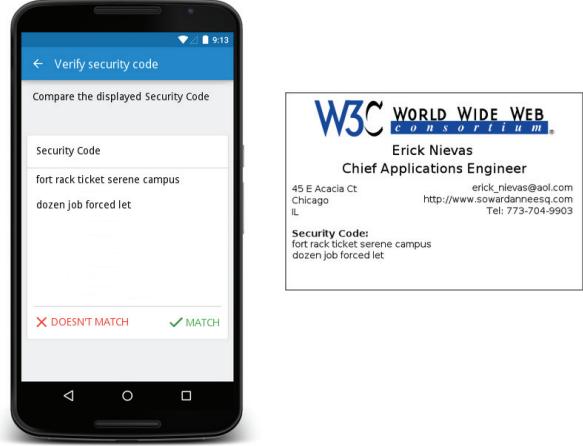

Figure 3: A screenshot of the actual task a user had to perform in the experiment. A user rates whether the *security codes* match, in this case with the Peerio word list approach, by clicking on the corresponding buttons shown on the phone.

4.2 Pre-Study

To get additional feedback from participants and evaluate our study design for flaws and misunderstandings, we conducted two small pre-studies: A lab study with 15 participants and an MTurk experiment with 200 participants, all required to perform 10 comparisons for each representation scheme (totally 60 comparisons in a randomized order). In our lab-study, we mainly focused on qualitative feedback, whereas the main goal of the MTurk pre-study was to find flaws in the presentation and task descriptions, as well as to check whether our proposed methodology is received as expected.

The biggest problem we found regarding the study design was that participants were uncertain if they should check for spelling mistakes in the words and sentence-based representation or if the all attacks would change entire words. To clarify this, a speech bubble was included in the task description that the participants do not have to look for spelling mistakes for language-based approaches.

We tested different rates of attack during the pre-study. The results showed that participants who were exposed to frequently occurring attacks were more aware and had a much higher attack detection rate. For our main study, we reduced the number of attacks to 40 comparisons with 4 attacks to have a good balance between true positives and false negatives. We received feedback that attacks on anchor parts of the strings, i. e., in the beginning, end, and at line breaks could be easily detected. Many users had problems with distinguishing the hexadecimal from the Base32 representation as well as distinguishing different word list approaches (Peerio vs. OpenPGP word list). Thus, we opted for a mixed factorial study

design where users test *only one* scheme of each type. We grouped the hexadecimal and Base32 scheme for the alphanumeric type and the PGP and Peerio for the word-list type together. These two groups were tested between-subjects in a split-plot design, i. e., the participants test either hexadecimal or Base32 for the alphanumeric type. See Table 2 for a graphical representation of our condition assignment design.

4.3 Experiment Design

The main part of our online study is the experiment part where users perform actual fingerprint comparisons. Here, we conducted two separate experiments with a distinct set of participants: (1) our main experiment testing different textual high-level representation schemes against each other and (2) a secondary experiment testing different chunk sizes for the hexadecimal representation. We opted for two distinct experiments due to the exponential growth of experiment conditions, as described in Section 4.3.1.

Before letting the participants start our experiment, we explained the scenario:

“With this HIT, we are conducting an academic usability study followed by a short survey about different types of security codes used in the IT world. Security codes are often used in encrypted communications to identify the participants in a communication. If the security codes match, you are communicating securely. If they don’t match, an eavesdropper may be intercepting your communication”.

On MTurk, the term *Human Intelligence Task*, or *HIT* stands for a self-contained task that a worker can work on, submit answers, and get a reward for completing. Since our participants might not be familiar with the *key-fingerprint representation* term, we replaced it with *security codes* for the sake of the study.

We opted not to obfuscate the goal of the study since our research aims at finding the best possible representation for the comparison of key-fingerprints in a security context. This is closest to how users interact with fingerprints in the real world — their secure messaging applications also ask them to compare the strings for security purposes. The question how to motivate users to compare fingerprints is an entirely different research question. So in our case, we believe it was not necessary or desirable to use deception and since deception should be used as sparingly as possible we opted for the “honest” approach.

After agreeing the terms, participants are shown a fictitious business card next to a mobile phone, both displaying a security code (as shown in Figure 3). To become more familiar with the task, the experiment is

Type (Within-Group)	Scheme (Between-Group)
Alphanumeric	Hexadecimal XOR Base32
Numeric	Numeric
Unrelated Words	PGP XOR Peerio
Generated Sentences	Generated Sentences

Table 2: To avoid confusion between too similar approaches (cf. Section 4.2), in our condition assignment, scheme types (left column) can consist of multiple representation schemes (right column). Each participant tests *only one* randomly assigned scheme of each type in a randomized order. .

started with 4 training tasks (each method once) not considered in the evaluation. The user’s only task is to rate whether the shown fingerprints match by clicking on *Match* or *Doesn’t Match* on the phone. Based on the condition assignment, participants see different approaches in a *randomized order*. We measure whether their answer was correct and their speed, i. e., the amount of time spent on the comparison. The experiment is concluded with a survey collecting feedback on the used approaches and the tasks and demographic information discussed in the “Results” section.

4.3.1 Variables and Conditions

In the main experiment, the used *representation scheme* is our controlled independent variable whereas its values define our experiment conditions. In our additional chunking experiment, the *chunking size* is our controlled independent variable instead of the representation algorithm. During all tasks, we measure how fast participants perform with their given conditions and whether they are able to detect attacks by rating “incorrect” (*speed* and *accuracy* as our measured dependent variables).

In both experiments, each user had to perform 46 comparisons in total. To detect users clicking randomly, 2 obviously distinct comparisons were added to test a participant’s attention. Training comparisons and attention tests are not included in the evaluation. Based on the feedback in our pre-study, we added tooltips during the training comparisons giving hints for language-based approaches telling the user that spelling attacks would not occur. We set the number of attacks to six: two obvious attacks where all bits are altered serving as control questions and 4 actual attacks with partial 80-bit preimages (one for each representation scheme). Participants failing at the control attacks are not considered in the evaluation but still received a payment if finishing all tasks. The major challenge in the study design is a high attack detection rate in general: most users perform comparisons correctly for the given attacker strength.

To avoid side effects, we chose fixed font size, color

Figure 4: A screenshot showing a statement rating in the post-experiment survey. Since the participants might not distinguish the different types, we have provided an example from their previous task.

and style, i. e., the same typeface for all fingerprint representations. In addition, we set fixed line breaks for sentences and word lists. In the main experiment, the same chunking style was used for all representations: For (alpha)numeric approaches a chunk consists of four characters separated by spaces. For word lists, we opted for a line break every four words. In the generated sentences representation, one sentence per line is displayed. We are aware that all these design decisions can have an effect on the comparison of the representations. However, our pre-study results show a significantly lower effect size. More importantly, we are mainly interested in comparing the concepts, therefore we did not vary any of the visual attributes like font size or style. In particular, differences resulting from the font's typeface have not been evaluated. Lund showed in his meta-analysis that there are no significant legibility differences between serif and sans serif typefaces [25].

Chunk-Size Testing A question was raised whether the chunking of a hexadecimal string plays a greater role in comparison to the different approaches. Thus, in addition to the main experiment testing different representation types, we conducted a second experiment with new participants testing different chunk sizes for the hexadecimal representation. Here, we used chunk-sizes ranging from 2 to 8 in addition to “zero-chunk size” (8 cases). The zero-chunk size means that no spaces have been included. To make the results more comparable, we opted for a similar design as done in the major experiment, i. e., we required the same amount of comparisons, used the same font settings, and had the same amount of attacks. For each participant, we assigned 4 out of 8 different chunk-sized randomly. Same as in the major experiment, all participants had to compare 46 fingerprints whereas the first 4 are considered as training comparisons, 4 attacks (one for each chunk size), and 2 control attacks with obviously distinct fingerprints.

The major experiment is followed by a survey fo-

cusing on self-reported user perception and opinions about the different approaches. This is the main reason we opted to compare as much as possible in a within-groups fashion and only selected a small number of conditions in total. Since users might not notice the difference between the various dictionary or alphabet approaches, we designed a mixed factorial design where the users would only get one of the alphabets/dictionaries (between-subjects) but they would test all different high-level systems (within-group) as depicted in Table 2. The between-group conditions have been assigned randomly with a uniform distribution. Since participants from our pre-study had difficulties to distinguish the different chunking approaches, we skipped the survey part in the chunk-size experiment.

4.3.2 Online Survey

The experiment was followed by an online survey gathering self-reported data and demographics from participants. To measure perception, we asked the participants whether they agreed with statements discussed in subsection 5.2 on a 5 point Likert scale: from strongly disagree to neural strongly agree as shown in Figure 4. Participants had to rate each representation type for all statements. Since users might not distinguish the different representation schemes, we provide an example from their previously finished task.

4.3.3 Statistical Testing

We opted for the common significance level of $\alpha = 0.05$. To counteract the multiple comparisons problem, we use the Holm-Bonferroni correction for our statistical significance tests [18]. Consequently, all our p-values are reported in the corrected version.

We test the comparison duration with the Mann-Whitney-Wilcoxon (MWW) test (two-tailed). We opt for this significance test due to a few outliers, consequently a

Scheme	Speed				Accuracy			Total		
	mean [s]	med [s]	stdev	p-val	fail-rate	p-val	f-pos	fails	attacks	tests

Table 3: Our experiment results showing the differences between the representation schemes. The top rows of each row group separated by a rule, show the raw performance of a baseline scheme, followed by italic rows showing a direct comparison delta. Greyed-out values are not backed by statistical significance. The columns *fail-rate* (undetected attacks) and *false-pos* (same string rated as an attack) display percentage values.

slightly skewed normal distribution, and a large amount of collected data. The *common language effect size* is shown by mean and median comparisons [26].

The attack detection rate is tested with a pairwise Holm-Bonferroni-corrected Barnard’s exact test (Exakt package in R) achieving one of highest statistical power for 2x2 contingency tables [2].

Survey ratings are, again, tested by using the MWU significance test (two-tailed test). As has been shown in previous research [9], it is most suitable for 5-point Likert scales, especially if not multimodal distributed as in our survey results. In case two fingerprint representation schemes are statistically tested against each other, only participants encountering both schemes were considered.

5 Results

In this section, we present our results: our online study with 1047 participants has been conducted in August and September 2015. The study for testing the chunk size has been conducted in February 2016 with 400 participants. Starting with our online experiment evaluation showing the raw performance of users, we then present user perception results from the follow-up survey. Finally, we discuss the demographics of our participants.

5.1 Online Experiment

Participants who have not finished all comparisons or failed the attention tests were excluded from our eval-

Scheme	Speed			Accuracy			Total		
	mean [s]	med [s]	p-val	fail-rate	p-val	false-pos	fails	attacks	tests
Hexadecimal (4)	12.3	10.4		6.78		0.38	16	236	2360
<i>hex (4) – hex (0)</i>	-2.4	-2.6	<0.001	0.33	1.000	-0.28	-2	-17	-170
<i>hex (4) – hex (2)</i>	-0.3	-0.9	<0.001	1.37	1.000	0.00	-3	3	30
<i>hex (4) – hex (3)</i>	-0.3	0.1	0.362	-0.64	1.000	0.09	2	8	80
<i>hex (4) – hex (5)</i>	-1.4	-1.2	<0.001	1.01	1.000	-0.40	-2	5	50
<i>hex (4) – hex (6)</i>	-1.9	-1.8	<0.001	2.43	1.000	0.09	-5	8	80
<i>hex (4) – hex (7)</i>	-1.7	-1.8	<0.001	3.35	1.000	0.19	-8	-1	-10
<i>hex (4) – hex (8)</i>	-2.8	-3.2	<0.001	1.35	1.000	-0.12	-4	-10	-100

Table 4: Comparison of the chunking experiment results showing the differences between the representation schemes. The top row shows the raw performance of the hexadecimal scheme with a four-character chunking, followed by italic rows showing a direct comparison delta. Greyed-out values are not backed by statistical significance. The columns *fail-rate* (undetected attacks) and *false-pos* (same string rated as an attack) display percentage values.

uation: all participant compared 46 security codes in a randomized order, whereas 40 (10 of each scheme) were considered in the evaluation. The four training samples and the control questions are excluded. Few comparisons done in less than 2 seconds and more than one minute have been excluded. The reason for such can either be multiple clicks during the page load, or external interruptions of the participants. None of the attack could be successfully detected in under 4 seconds.

Our experiment results, summarized in Table 3, show the raw performance of all schemes regarding their speed, accuracy and false-positive rate. The top rows of each row group, separated by a rule, show the raw performance of a representation scheme as baseline (negative values indicate lower values than the baseline). The following rows show a direct comparison delta between between two schemes. The speed column group consists of the mean and median (in seconds), the standard deviation and the according p-values for a direct comparison. The fail-rate column shows the rate of the undetected attacks with the according p-values for a direct comparison. The total column group simply shows the total numbers of tests, attacks and undetected attacks.

The results show that the average time spent on comparisons plays only a minor role among the schemes: 4.3 s difference between the best and the worst scheme. Note that the Peerio word-list scheme performed best with 8.7 s mean whereas the PGP word list performed worst with 13 s mean ($p < 0.001$).

However, there is a clear effect regarding the attack detection rate (see Table 3). All alternative key-fingerprint representations performed better than the state-of-the-art hexadecimal representation, where 10.1% of attacks have not been detected by the users. Previous work shows similar numbers for Base32 [19]. To our surprise, the numeric approach performs better in both categories: it features an attack detection rate of 93.57% ($p < 0.01$) and an average speed of 10.6s ($p < 0.001$). Generated sentences achieved the highest attack detection rate of

97.97% with a similar average speed as the hexadecimal scheme. On the downside, this scheme has produced a slightly higher false-positive rate. We found that the false positives occurred mostly with longer sentences where there has been a line break on the phone mock-up due to portrait orientation. This is a realistic problem of this system if used with portrait orientation and not a problem with our mock-up in itself. Improvements on making the sentences shorter could mitigate this situation.

Chunk-Size Experiment

Table 4 summarizes the results of our secondary chunk-size experiment. As can be seen, no statistically significant results have been achieved for the *attack detection fail-rate* (undetected attacks by end users). However, we observed that the chunk sizes with 3 and 4 characters performed best in speed, even though the effect sizes were minor: only 3.3 seconds difference with similar standard deviations between the best and worst chunk size setting.

Firstly, we notice that despite the same attack strength as in our major experiment, participants were able to detect more attacks. We suspect that the higher attack detection rate is based on (1) a higher learning effect due to the same scheme for all comparisons and (2) in contrast to our major study, participants had a slightly higher drop-out rate and thus only more motivated participants were considered. This is supported by the numbers in the total tests column of Table 4: here, we can see that for the zero-chunking and chunking with 8 characters less tests have been performed. This is based on the fact that although the chunk sizes have been assigned almost uniformly, participants assigned with harder chunk settings often dropped out before even finishing their entire task.

More importantly, our results also support the claim from our pre-study: The chunking parameter in hexadecimal strings plays only a minor role in the *attack detection fail-rate*.

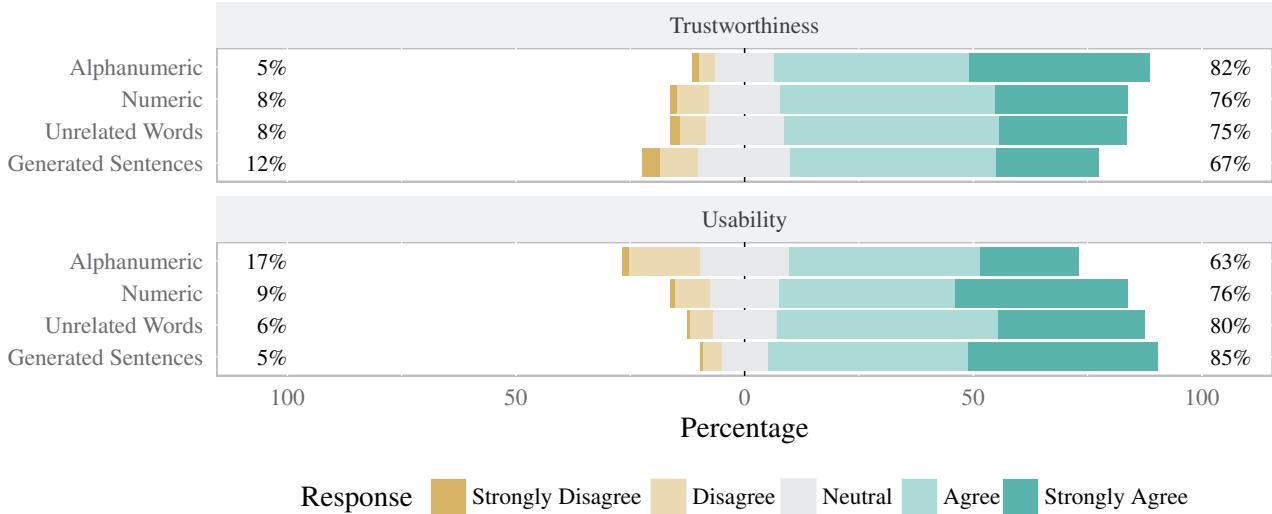

Figure 5: Aggregated survey results for statement rating regarding the usability and trustworthiness.

5.2 Online Survey

To measure the usability and trustworthiness of all representation schemes, we asked our participants whether they agreed with the following statements:

- S_1 The comparisons were easy for me with this method
- S_2 I am confident that I can make comparisons using this method without making mistakes
- S_3 I think making comparisons using this method would help me keep my communications secure
- S_4 I was able to do the comparisons very quickly with this method
- S_5 I found this method difficult to use
- S_6 Overall, I liked this method

We mixed positive and negative statements, e.g., S_1 and S_5 , to create a more robust measure. S_6 is used to calculate the overall ranking of the different representation schemes.

Figure 5 shows the aggregated results where the usability statements are grouped to one usability feature and the trustworthiness derived from the rating on the statement S_3 . Negative statement ratings have been inverted for a better comparison. Figure 6 shows the rating results for each specific statement in the survey. The order of the tested schemes has been chosen randomly, but was kept consistent across all statements. Same as in our online experiment evaluation, the pairwise statistical

tests are Holm-Bonferroni corrected. In case of a direct statistical test between two schemes, only users encountering both schemes have been considered. All in all, the usability perception of the participants is almost consistent with the performance results from the experiment.

To measure the perception of the task difficulty, we asked the participants whether they agreed with the statements S_1 , S_2 and S_3 respectively. As illustrated in Figure 6 in the Appendix A, the effect size between the different approaches is low. However, the participants were more likely to agree that language-based representation schemes are easier to use. For instance, we see that in comparison to the alphanumeric schemes (average rating of 3.4), word list (average rating of 3.9, $p < 0.001$) and generated sentence schemes (average rating of 4.2, $p < 0.001$) are rated to be easier by our participants (S_1 , S_5). While the experiment results of the sentence generators clearly outperformed all other approaches, they also were rated better by the participants. Same applies for the low-performing hexadecimal and Base32 schemes which clearly received lower ratings. Consistently with the surprising performance results in the experiment, the numeric scheme is also considered to be easier by many participants: average rating of 3.9 and $p < 0.001$.

The sentence generator scheme achieved the highest user confidence rating “making comparisons without any mistakes” (S_2 , $p < 0.001$ for all pairwise comparisons). The participants’ perception is consistent with the experiment results where the word-list-based and sentence generator schemes lead to higher attack detection rates.

The ratings for S_4 illustrate that more complex representation schemes from the user’s point of view, such as hexadecimal and Base32, are considered to be more secure by participants, even though all approaches provide the same level of security.

5.3 Demographics

A total of 1047 users participated in the online study while only 1001 have been considered in the evaluation due to our two control questions. Out of the evaluated participants, 534 participants were male, 453 were female, 4 chose other while the rest opted to not give any information. No significant difference between genders could be found, with a subtle trend of a higher accuracy for women and higher speed among men. The median age was 34 (34.4 average) years, while 34 participants chose not to answer (no statistically significant differences between ages).

A total of 39 people reported to have “medical conditions that complicated the security code comparisons (e.g., reading disorders, ADHD, visual impairments, etc.)” with a slightly higher undetected attack rate (statistically insignificant due to small sample size and thus low statistical power).

The majority of the participants stated to have a Bachelor’s degree (399 of 1047) as their highest education whereas 34% chose not to answer. 931 participants have started our HIT but stopped early during the experiment (mostly after the first few comparisons). 160 users reported the general task to be annoying.

6 Discussion

The results of our study show that while there are subtle speed variations among all approaches, the attack detection rate and user perception for the current state-of-the-art hexadecimal key-fingerprint representation is significantly lower than those of most alternative representation schemes. Language-based representations (with the exception of the PGP word list) show improved user behaviour leading to a higher detection rate of attacks. To improve the usability of key-fingerprints, we propose the following takeaways based on our study results.

6.1 Takeaways

Our results show that all representation schemes achieve a high accuracy (high attack detection rate) and can be performed quickly by users. As expected, language-based fingerprint representations are more resilient against attacks (higher attack detection rate) and achieve better usability scores. Among all conditions, alphanumeric approaches performed worse and have been out-

performed. For instance, the *numeric* representation was more suitable than hexadecimal and Base32. The raw performance results suggest a similar speed for the numeric representation with a higher attack detection rate, and it also has received better usability ratings from end-users.

Our chunking experiment has shown that chunk-sizes play only a minor role in improving attack detection rates (we could not find statistically significant differences). However, if a hexadecimal representation is used chunks of 3 and 4 characters perform best.

As shown by the word list representations, the comparison speed can be increased by larger dictionaries leaving room for improvement in this area. Even though all representation schemes provide the same level of security, exotic looking solutions are considered to be more secure by end users.

6.2 Limitations

Most importantly, our study design *does not test* whether end users *are actually willing to compare any fingerprints* in practice. We only aim to study how easy different representations are to compare from the users’ point of view.

As with any user study conducted with MTurk, there is concern about the external validity of the results: users in the real world might show different behaviour. This is mainly because of two reasons: (1) in practice fingerprint comparisons will seldom occur in a such frequency, and (2) when performed in practice play a more important role than just participating in an anonymous online study. Additionally, MTurkers have been shown to be more tech-savvy and are better in solving textual and visual tasks in comparison to the average population. Thus, they could have performed better in most of the comparison conditions than the average population. It is also known that some MTurkers just “click through” studies to get the fee and thus distort study results. Our counterbalanced study design with included control questions and statistical significance tests mitigate this effect. For instance, we excluded 46 out of 1047 participants from our main study part based on these questions being answered incorrectly.

Due to the within-group part of our factorial design, many parameter choices such as different fonts, font sizes, attack rates, etc. could not be considered. These are, however, interesting avenues for future work. As shown in our additional chunking experiment, another challenge in testing different parameters is the high attack detection rate, where subtle changes would require a high amount of users to produce statistically significant results.

Due to the anonymous nature of online studies, it is

also impossible to reliably tell which languages a participant is fluent in. We specified that we only wanted participants from English-speaking countries, however we had no way of checking compliance except by relying on self-reported data. Language-based representation approaches might induce additional barriers for non-native speakers, e. g., due to unknown or unfamiliar words.

7 Conclusion and Future Work

We evaluated six different key-fingerprint representation types with regards to their comparison speed, attack detection accuracy and usability, which encompasses attack detection but also resilience against human errors in short-term memory. An online study with 1047 participants was conducted to compare numeric, alphanumeric (Hexadecimal and Base32), word lists (PGP and Peerio), as well as generated sentences representation schemes for key-fingerprint verification. All fingerprint representations were configured to offer the same level of security with the same attacker strength.

Our results show that usage of the large word lists (as used in Peerio) lead to the fastest comparison performance, while generated sentences achieved highest attack detection rates. In addition, we found that additional parameters such as chunking of characters plays only a minor role in the overall performance. The widely-used hexadecimal representation scheme performed worst in all tested categories which indicates that it should be replaced by more usable schemes. Unlike proposals which call for radically new fingerprint representations, we studied only textual fingerprint representations, which means that the results of our work can be directly applied to various encryption applications with minimal changes needed. Specifically, no new hardware or complex software is required: applications merely need to replace the strings they output to achieve a significant improvement in both attack-detection accuracy and usability.

There are various interesting areas of future work. Firstly, we chose to study only a selected sample from the design space of fingerprint representations in a within-subjects design, so we could facilitate a direct comparison between the different classes of fingerprints. Further work exploring line breaks, font settings, dictionaries, different attacker strengths, etc. will likely lead to further improvement possibilities.

While this work shows that there are better ways to represent key-fingerprints than currently being used, it does not explore what can be done to motivate more users to actually compare the fingerprints in the first place. Follow-up studies to research this important question are naturally an interesting and vital area of research.

Abstract

In this paper, we report a subtle yet serious side channel vulnerability (CVE-2016-5696) introduced in a recent TCP specification. The specification is faithfully implemented in Linux kernel version 3.6 (from 2012) and beyond, and affects a wide range of devices and hosts. In a nutshell, the vulnerability allows a blind off-path attacker to infer if any two arbitrary hosts on the Internet are communicating using a TCP connection. Further, if the connection is present, such an off-path attacker can also infer the TCP sequence numbers in use, from both sides of the connection; this in turn allows the attacker to cause connection termination and perform data injection attacks. We illustrate how the attack can be leveraged to disrupt or degrade the privacy guarantees of an anonymity network such as Tor, and perform web connection hijacking. Through extensive experiments, we show that the attack is fast and reliable. On average, it takes about 40 to 60 seconds to finish and the success rate is 88% to 97%. Finally, we propose changes to both the TCP specification and implementation to eliminate the root cause of the problem.

1 Introduction

TCP and networking stacks have recently been shown to leak various types of information via side channels, to a blind off-path attacker [22, 14, 12, 21, 11, 29, 5]. However, it is generally believed that an adversary cannot easily know whether any two arbitrary hosts on the Internet are communicating using a TCP connection without being on the communication path. It is further believed that such an off-path attacker cannot tamper with or terminate a connection between such arbitrary hosts. In this work, we challenge this belief and demonstrate that it can be broken due to a subtle yet serious side channel vulnerability introduced in the latest TCP specification.

The two most relevant research efforts are the following: 1) In 2012, Qian *et al.*, framed the so called

“TCP sequence number inference attack”, which can be launched by an off-path attacker [22, 23]. However, the attack requires a piece of unprivileged malware to be running on the client to assist the off-path attacker; this greatly limits the scope of the attack. 2) In 2014, Knockel *et al.*, identified a side channel that allows an off-path attacker to count the packets sent between two arbitrary hosts [21]. The limitation is that the proposed attack requires on average, an hour of preparation time and works at the IP layer only (cannot count how many packets are sent over a specific TCP connection).

In this paper, we discover a much more powerful off-path attack that can quickly 1) test whether any two arbitrary hosts on the Internet are communicating using one or more TCP connections (and discover the port numbers associated with such connections); 2) perform TCP sequence number inference which allows the attacker to subsequently, forcibly terminate the connection or inject a malicious payload into the connection. We emphasize that the attack can be carried out by a purely off-path attacker without running malicious code on the communicating client or server. This can have serious implications on the security and privacy of the Internet at large.

The root cause of the vulnerability is the introduction of the *challenge ACK* responses [26] and the global rate limit imposed on certain TCP control packets. The feature is outlined in RFC 5961, which is implemented faithfully in Linux kernel version 3.6 from late 2012. At a very high level, the vulnerability allows an attacker to create contention on a shared resource, i.e., the global rate limit counter on the target system by sending spoofed packets. The attacker can then subsequently observe the effect on the counter changes, measurable through probing packets.

Through extensive experimentation, we demonstrate that the attack is extremely effective and reliable. Given any two arbitrary hosts, it takes only 10 seconds to successfully infer whether they are communicating. If there is a connection, subsequently, it takes also only tens of

seconds to infer the TCP sequence numbers used on the connection. To demonstrate the impact, we perform case studies on a wide range of applications.

The contributions of the paper are the following:

- We discover and report a serious vulnerability unintentionally introduced in the latest TCP specification which is subsequently implemented in the latest Linux kernel.
- We design and implement a powerful attack exploiting the vulnerability to infer 1) whether two hosts are communicating using a TCP connection; 2) the TCP sequence number currently associated with both sides of the connection.
- We provide a thorough analysis and evaluation of the proposed attack. We present case studies to illustrate the attack impact.
- We identify the root cause of the subtle vulnerability and discuss how it can be prevented in the future. We propose changes to the kernel implementation to eliminate or mitigate the side channel.

2 Background

Security was not the primary concern in the design of TCP. There have been many security patches over the years at both the specification and implementation level. Interestingly, most new specifications are well thought out and typically improve security. Unfortunately, as we discover, one of the most recent specifications intended to improve security creates an even more serious vulnerability.

In this section, we first present the threat model that is being addressed in RFC 5961 and how the new specification is supposed to protect against blind in-window attacks. In the next section, we will show that how this specification introduces a new vulnerability.

Threat model: As illustrated in Figure 1, a realistic threat model for TCP is off-path attacks. There are three hosts involved: a victim client, a victim server and an off-path attacker. Any machine might act as the attacker in this model as long as its ISP allows the off-path attacker to send packets to the server with the spoofed IP address of the victim client. Alternatively, as shown in Figure 2, the off-path attacker is able to send packets to the client with the spoofed IP address of the victim server.

Blind in-window attacks: Under the above threat models, the most common attacks considered are “blind in-window attacks” where an off-path attacker sends spoofed TCP packets with guessed sequence numbers in an attempt to achieve DoS or data injection attacks. To succeed in such an attack, it is necessary to first know the target 4-tuple <src IP, dst IP, src port, dst port> of an

ongoing TCP connection between a client and a server¹. Once the correct 4-tuple is known, if the guessed sequence number of the spoofed packet happens to fall in the receive window, (called an in-window sequence number), one can in fact reset or inject *acceptable* malicious data into the connection. To be more precise, an in-window sequence number is one that satisfies the following condition, ($RCV.NXT \leq SEG.SEQ \leq RCV.NXT + RCV.WND$), where $SEG.SEQ$ is the guessed sequence number, $RCV.NXT$ and $RCV.WND$ are the sequence number of the next byte that the receiver expects to receive, and the receive window size, respectively. To carry out a blind attack, one typically needs to blast the entire sequence number space by sending a large sequence of spoofed packets. In this sequence, the sequence number of a packet is larger than that of its predecessor by a window size.

To defend against such attacks, RFC 5961 proposes several modifications on how TCP should process incoming packets. We highlight only the necessary details below.

2.1 Mitigating the Blind Reset Attack using the SYN Bit

An attacker might tear down an existing TCP connection by injecting SYN packets (TCP packets in which the SYN flag is set). This is because a valid SYN packet will cause the receiver to believe that the sender has restarted and thus, the connection should be reset.

In the former (pre-RFC 5961) Linux kernel versions, an incoming SYN packet is processed as follows:

- If the sequence number is outside the valid receive window, the receiver will send an ACK back to sender.
- If the sequence number is in-window, the receiver will reset this connection.

It is obvious that the attacker only needs a single SYN packet with an in-window sequence number to reset an ongoing TCP connection. Instead, RFC 5961 proposes modifications in processing the SYN packets as follows:

- If a receiver sees an incoming SYN packet, regardless of the sequence number, it sends back an ACK (referred to as a challenge ACK) to the sender to confirm the loss of the previous connection.
- If the packet is indeed initiated from the legitimate remote peer, it must have truly lost the previous connection and is now attempting to initiate a new one. Upon receiving the challenge ACK, the remote peer will send a RST packet with the *correct* sequence num-

¹This can be achieved, among other methods, through brute-force attempts.

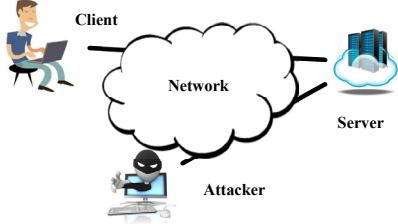

Figure 1: Threat model 1

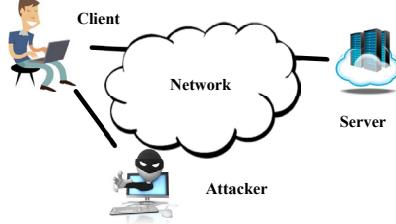

Figure 2: Alternative threat model

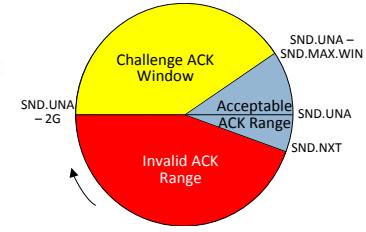

Figure 3: ACK window illustration

ber (derived from the ACK field of the challenge ACK packet) to prove that the previous connection is indeed terminated.

Hence, if the SYN packet is a spoofed one, it can no longer terminate a connection with an in-window sequence number.

2.2 Mitigating the Blind Reset Attack using the RST Bit

An attacker might also tear down the connection by injecting RST packets (TCP packets in which the RST flag is set) into an ongoing TCP connection.

In pre-RFC 5961 Linux kernels, just like in the SYN packet case, a RST packet can terminate a connection successfully as long as its sequence number is in-window. RFC 5961 suggests the following changes:

- If the sequence number is outside the valid receive window, the receiver simply drops the packet. No modifications are proposed for this case.
- If the sequence number *exactly* matches the next expected sequence number ($RCV.NXT$), the connection is reset.
- If the sequence number is in-window but does not exactly match $RCV.NXT$, the receiver must send a challenge ACK packet to the sender, and drop the unacceptable RST packet.

In the final case, if the sender is legitimate, it sends back a RST packet with the correct sequence number (derived from the ACK number in the challenge ACK) to reset the connection. On the other hand, if the RST is spoofed, the challenge ACK packet will not be observable by the off-path attacker. Therefore, the attacker needs to be extremely lucky to be able to succeed — only one out of 2^{32} sequence numbers will be accepted.

2.3 Mitigating the Blind Data Injection

An attacker might corrupt the contents of a transmission by injecting spoofed DATA packets. When a packet arrives, the receiver first checks the sequence number to

make sure it is in-window; in addition, the ACK number will be checked. Pre-RFC 5961, the ACK number is considered valid as long as it falls in the wide range of $[SND.UNA - (2^{31} - 1), SND.NXT]$; this is effectively half of the ACK number space. Here, $SND.UNA$ is the sequence number of the first unacknowledged byte. $SND.NXT$ is the sequence number of the next byte about to be sent.

RFC 5961 suggests a much smaller valid ACK number range of $[SND.UNA - MAX.SND.WND, SND.NXT]$, where $MAX.SND.WND$ is the maximum window size the receiver has ever seen from its peer. This is illustrated in Figure 3. The reasoning is that the only valid ACK numbers are those that are (i) not too old (bytes that are recently sent) and (ii) not too new (receiver cannot ACK bytes that are yet to be sent). The remaining ACK values will be in the range of $[SND.UNA - (2^{31} - 1), SND.UNA - MAX.SND.WND]$, denoted as the *challenge ACK window*. Even though ACK numbers inside this window are still considered invalid, the specification requires the receiver to generate outgoing challenge ACKs in response to packets with such ACK numbers. Overall, this more stringent ACK number check does not eliminate, but helps dramatically reduce the probability that invalid data is successfully injected. Specifically, if the $MAX.SND.WND$ is small (which is typically the case for most connections), then the acceptable ACK window will be much smaller than the half of the ACK number space (as illustrated in Figure 3).

2.4 ACK Throttling

In general, as explained earlier, RFC 5961 enforces a much stricter check on incoming TCP packets; for example, it requires the RST packets to have an exact sequence number to actually reset the connection, whereas a “good enough” in-window value only triggers a challenge ACK. In order to reduce the number of challenge ACK packets that waste CPU and bandwidth resources, an ACK throttling mechanism is also proposed. Specifically, the system administrator can configure the maximum number of challenge ACKs that can be sent out in a given interval (say, 1 second). The RFC clearly states “An implementation SHOULD include an ACK

throttling mechanism to be conservative.” Therefore, the Linux kernel has faithfully implemented this feature by storing the challenge ACK counter in a global variable shared by *all* TCP connections. This approach, unfortunately, creates an undesirable side channel, as will be elaborated. We emphasize that the RFC states that ACK throttling applies to only *challenge ACKs* and not to regular ACKs. This means that the challenge ACK counter is unlikely to be affected by legitimate ACK traffic as the conditions that trigger challenge ACKs are all considered rare or due to attacks.

3 Vulnerability Overview

The Linux kernel first implemented all the features suggested in RFC 5961, in version 3.6 in September 2012. The changes were backported to certain prior distributions as well. The ACK throttling feature is specifically implemented as follows: a global system variable `sysctl_tcp_challenge_ack_limit` was introduced to control the maximum number of challenge ACKs generated per second. It is set to 100 by default. As this limit is shared across all connections (possibly including the connections established with the attacker), the shared state can be exploited as a side channel.

Assuming we follow the threat model in Figure 1, the basic idea is to repeat the following steps: 1) send spoofed packets to the connection under test (with a specific four-tuple), 2) create contention on the global challenge ACK rate limit, i.e., by creating a regular connection from the attacker to the server and intentionally triggering the maximum allowed challenge ACKs per second, and 3) count the actual number of challenge ACKs received on that connection. If this number is less than the system limit, some challenge ACKs must have been sent over the connection under test, as responses to the spoofed packets.

Depending on the types of spoofed packets sent in step 1, the off-path attacker can infer 1) if a connection specified by its four-tuple exists; 2) the next expected sequence number (*RCV.NXT*) on the server (or client); 3) the next expected ACK number (*SND.UNA*) on the server (or client). It is intriguing to realize that the three information leakages are enabled by the three (and only three) conditions that trigger challenge ACKs as described in §2.1, §2.2, and §2.3, respectively.

We elaborate below, the intuition on how the inference can be done in each case.

Connection (four-tuple) inference. Figure 4 shows the sequence of packets that an off-path attacker can send to differentiate between the cases of (i) the presence or (ii) the absence of an ongoing connection. In both cases, the attacker sends the same sequence of packets. Dashed lines represent packets with spoofed IP addresses. In

the figure, the initial SYN-ACK packet is spoofed so that it appears to come from the client. The counter for the number of challenge ACKs that can be issued (100 initially) is tracked and depicted on the timeline of the server.

The hope is that the initial spoofed SYN-ACK packet will hit a correct four-tuple that corresponds to an active connection between the client and the server. In such a case (the left of Figure 4) the server will reply with a challenge ACK² (in accordance with the countermeasure proposed to defend against blind SYN packet injection as described in §2.1). At the same time, this will reduce the global challenge ACK count from 100 to 99. In the case where the spoofed SYN-ACK does not hit a correct four-tuple (on the right of the figure), the server will simply reply with a RST back to the corresponding client (as per TCP standards).

The attacker will then send 100 non-spoofed in-window RST packets to exhaust the challenge ACK count (this behavior is described in §2.2). In the *active connection* case, since the challenge ACK count is 99, the attacker can now observe only 99 challenge ACKs. In the *no connection* case, the attacker can observe 100. The difference in the number of challenge ACKs effectively leaks the information about whether a tested four-tuple corresponds to an active connection or not.

Sequence number inference. Assuming the attacker has already identified a four-tuple that corresponds to an active connection between the client and server, the off-path attacker now needs to guess a valid sequence number that is considered acceptable by the server. Figure 5 shows the sequence of packets that an attacker can send to distinguish between the cases of (i) *in-window* and (ii) *out-of-window sequence number*. In the first case where the spoofed RST packet has an in-window sequence number (but not the next expected sequence number), as per the countermeasure proposed to defend against blind RST packet injection as described in §2.2, a challenge ACK is triggered and this reduces the global challenge ACK count from 100 to 99. In the second case where the sequence number falls outside of the window, no challenge ACK will be generated (the global challenge ACK count remains at 100).

Similar to connection inference, the attacker will now send 100 non-spoofed in-window RST packets to exhaust the challenge ACK count. Once again, based on how many challenge ACKs are received, the attacker can tell if the guessed sequence number in the spoofed RST, is in-window or out-of-window.

ACK number inference. After an in-window sequence number of an active connection is identified, the attacker now will need to guess a valid ACK number that

²The effect is the same as sending a spoofed SYN. However, sending a SYN-ACK is generally more stealthy.

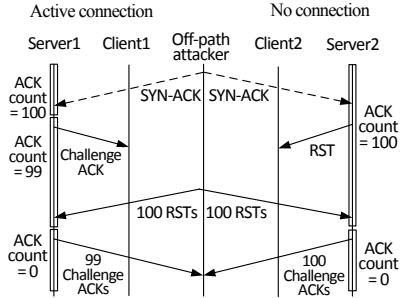

Figure 4: Connection (four-tuple) test

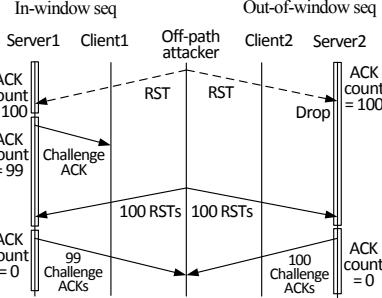

Figure 5: Sequence number test

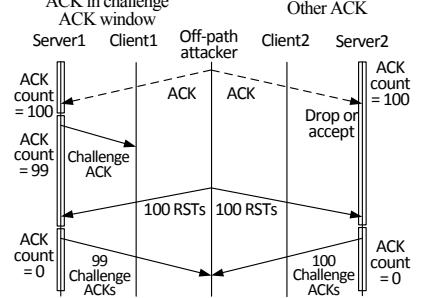

Figure 6: ACK number test

is considered acceptable by the server. Figure 6 shows the sequence of packets that an attacker can send to differentiate the cases of (i) *ACKs in challenge ACK window* and (ii) *other ACK numbers*. In the first case where the spoofed ACK packet has an ACK number in challenge ACK window (but with an in-window sequence number), the server will reply with a challenge ACK, in accordance with the countermeasure proposed to defend against blind data packet injection (as described in §2.3). Following the same procedure as before, an attacker can infer if the guessed ACK number falls in the challenge ACK window. As will be described in §5.2, this helps the attacker to eventually identify the *SND.NXT* on the server.

It is worth noting that once both the sequence number and ACK number acceptable by the server are inferred, an attacker can determine the sequence number and the ACK number acceptable by the client as well. This is because the *RCV.NXT* and *SND.NXT* on the server are basically equivalent to *SND.NXT* and *RCV.NXT* on the client [25, 18]. In practice, if the victim connection has ongoing traffic, the inferred sequence and ACK number may shift as the attack is in progress. We discuss such cases in §6.

An alternative approach for sequence number inference. In some cases a large number of RST packets observed in a short period time may be considered abnormal. Firewalls may even rate limit RST packets on a per-connection basis. In order to alleviate this, one can in fact replace RST packets with ACK packets, which are likely to stay under the radar. As shown in Figure 3, a challenge ACK will be sent when ACK number is in *challenge ACK window* while sequence number is inwindow. Since the *challenge ACK window* space is at least 1/4 of the entire 4G of the ACK number space, one can send 4 packets with ACK numbers 0, 1G, 2G, and 3G respectively and at least one packet will trigger a challenge ACK if the guessed sequence number is inwindow. To understand why the *challenge ACK window* is at least this large, we first point out that the maximum receive window size is 1G with the TCP window scaling

option (RFC 7323), which means that *SND.MAX.WIN* cannot be larger than 1G. Therefore, according to definition of the challenge ACK window described in §2.3, it is at least 1G as well. Given this, every spoofed RST packet sent earlier for sequence number inference is replaced by four ACK packets, which is less efficient but still effective. We have implemented and tested this alternative approach for sequence number inference. However, to simplify the description, we assume the use the original sequence number inference with RST packets in the subsequent sections.

4 Off-Path Connection Reset Attack

In the previous section, we illustrate how the global challenge ACK rate limit can theoretically leak information about an ongoing connection to an off-path attacker. In this section, we focus on how to construct a practical off-path connection reset attack that succeeds when a spoofed RST arrives with a matching sequence number of *RCV.NXT*. This requires an attacker to successfully carry out both *connection (four-tuple) inference* and *sequence number inference*. As will be discussed, to construct a realistic attack, several practical challenges need to be overcome. We assume the threat model to be the one in Figure 1 throughout the section, but the attack works with the alternative threat model (Figure 2) as well.

Goals and constraints. The main goal of the attack is to *quickly* and *reliably* conduct the sequence number inference and use it to reset an ongoing connection. The faster the attack succeeds, the more potent the DoS effect will be. However, the extent of the effect is subject to two practical constraining factors: (i) The bandwidth may be limited between the attacker and the victim (either server or client). (ii) Packet loss may occur between the attacker and victim, especially when they are far away. In this section, we focus only on designing fast probing schemes with given bandwidth constraints and leave the strategy to deal with packet loss to §6.

4.1 Time Synchronization

Challenge: As mentioned in §3, the challenge ACK rate limit is on a per second basis. In other words, the counter for the number of challenge ACK packets that can be issued, gets reset each second. Therefore, it is critical that in each cycle, all the spoofed and non-spoofed packets sent from the attacker arrive within the same 1-second interval, at the server.

One naive solution is that the attacker sends all those packets in a very short period (say, 10 ms), to ensure that the likelihood that they arrive within the same 1-second interval is high. Unfortunately, in practice, this solution does not work well since (i) many factors influence packet delays and thus, the gaps between packet arrival times at the receiver, might be much larger than the gaps in their transmission times, (ii) such bursts of traffic are likely going to experience congestion and packet loss. Thus, it is best for the attacker to synchronize with the clock on the server, so that the attacker can spread the traffic over the 1-second interval, without worrying that some packet arrivals may cross the boundary between two 1-second intervals.

The most common way to synchronize time between two machines is using the Network Time Protocol (NTP). But in practice, the attacker does not know if the server uses NTP, or to what NTP server it connects to; thus, it is not a reliable solution.

Solution: We propose a time synchronization strategy based on the very side channel introduced by the challenge ACK rate limit. The idea is to send more than 200 in-window RST packets spread out evenly in one second and check if we can see more than 100 challenge ACKs; if so, this indicates that we have crossed the boundary between two one second intervals (and have therefore not synced with the server yet). We then adjust the timing for next round of probing (shift it just enough) until we receive exactly the 100 challenge ACKs; in this case, we have succeeded in synchronizing with the server clock.

The reason we choose 200 packets is two-fold: 1) We are able to trigger at most 200 challenge ACKs no matter how many RST packets we send. These 200 challenge ACKs are triggered only when half of the RST packets arrive before the start of a new 1-second interval and half arrive after. 2) By evenly spreading the 200 packets over a 1-second window, i.e., sending one packet every 5ms, allows us to adjust the timing of the next round probing with the finest granularity. Specifically, we show that the time synchronization can be done in at most three rounds of probing in an ideal case (without packet losses).

Round 1: As described before, the attacker sends 200 in-window RST packets to the server evenly spread out over a 1-second window. The attacker then listens and counts the number of received challenge ACK packets.

This value is stored as n_1 . Here, the attacker listens for incoming packets for 2 seconds conservatively, before sending any additional packets to make sure a 1-second interval on the server has elapsed. Note that apart from the 200 RST packets, no other packet is sent to the server in this interval. If n_1 equals 100, it means that all 200 RST packets all arrive in the same 1-second interval on the server, thereby indicating that we have already synchronized with the server. Otherwise, it must be true that $n_1 > 100$, in which case the attacker proceeds to the next round.

Round 2: The attacker waits for 5ms (shifting the start time of the probes by 5ms) and repeats the same process as in the first step. The number of received challenge ACK this time is stored as n_2 . If n_2 equals 100, the synchronization is done. Otherwise, the attacker proceeds to round 3.

Round 3: By comparing n_1 with n_2 , the attacker can determine the final move to be synchronized. Specifically, we provide the following reasoning to support the decision. Assume that in step 1, x RST packets arrive in the first 1-second interval on the server, and y RST packets arrive in the second 1-second interval; note that $x + y = 200$. Similarly, in step 2, there are $(x - 1)$ and $(y + 1)$ RST packets arrive in the first and second 1-second intervals respectively, since in step 2 the attacker time shifts its probes by a period of 1 sub-interval. Thus, $n_1 = \min(x, 100) + \min(y, 100)$ and $n_2 = \min(x - 1, 100) + \min(y + 1, 100)$.

(i) If $n_2 \geq n_1$: Let us assume that $y \geq 100$ and $x \leq 100$; then $n_1 = \min(x, 100) + \min(y, 100) = x + 100$, and $n_2 = \min(x - 1, 100) + \min(y + 1, 100) = (x - 1) + 100 < n_1$, which contradicts the assumption that $n_2 \geq n_1$; thus $y < 100$ and $x > 100$. With these conditions, $n_2 = 100 + (y + 1) = 100 + (200 - x + 1)$, or $(x - 1) = 300 - n_2$. In step 2, $(x - 1)$ RST packets arrive in the first 1-second interval on the server; thus, the attacker has to wait for $(x - 1)$ sub-intervals, i.e., $(300 - n_2) \cdot \frac{1}{200}$ seconds to synchronize her time interval with the server.

(ii) If $n_2 < n_1$: With the same reasoning, the attacker knows that $x < 100$ and $y > 100$. In this case, $n_2 = (x - 1) + 100$; thus, the attacker has to wait $(n_2 - 100)$ sub-intervals, or $\frac{n_2 - 100}{200}$ seconds to synchronize her time interval with the server.

If no packet loss occurs (which is likely due to the small number of packets sent every second), then the three rounds are enough to complete the synchronization process. To handle the rare event that packet loss may occur, we double check that the synchronization was successful by sending another round of 200 RST packets. If it is inconsistent with the previous round, we start over. As will be discussed later, such cases were almost never seen in our experiments.

Algorithm 1: Binary search for source port number

```
1: left = left boundary of the port range
2: right = right boundary of the port range
3: while left < right do
4:   mid = (left + right) / 2
5:   for i = mid to right do
6:     Send a spoofed SYN packet with i as the client port number
7:   end for
8:   Send 100 RST packets on the legitimate connection
9:   Wait until the end of the 1-second interval, count the number of
   received challenge ACK packets
10:  if received ACK packets = 100 then
11:    right = mid - 1
12:  else
13:    left = mid
14:  end if
15: end while
16: return left; //the correct port value
```

4.2 Connection (Four-tuple) Inference

After time synchronization, the attacker can successfully launch subsequent attacks by knowing the boundaries between the 1-second intervals. The first step is “four-tuple inference”, wherein the attacker determines if a connection is established between the client and the server. As mentioned in §2.1, the receiver will send back a challenge ACK (regardless of the sequence number of the packet) when a packet with a SYN flag set, arrives.

In §3, we discussed how this behavior can be exploited to determine whether or not a specific four-tuple is currently active. Basically, for each four-tuple in question, the attacker needs to send a spoofed SYN-ACK packet (a TCP packet in which the SYN and ACK flags are set) with $\langle \text{srcIP} = \text{clientIP}, \text{dstIP} = \text{serverIP}, \text{srcPort} = X, \text{dstPort} = \text{serverPort} \rangle$. The above assumes both the client and server IP addresses are known. In addition, the server port is assumed to be publicly known according to its service type. Therefore, the only unknown is the source port the client uses. The maximum possible port range is $2^{16} = 65536$, and the default range on Linux is only from 32768 to 61000.

A naive approach is to test each port number at a time per second, as depicted in Figure 4, which, in the worst case, requires hours to complete. Therefore, a practical attack requires the attacker to test several port numbers in a second. Let us denote the maximum number of spoofed packets that can be sent in one second by n (constrained by network bandwidth). If n is large, one can search for the port number using a binary-search-like algorithm, the pseudo-code of which is shown in Algorithm 1. Specifically, assuming n is larger than 32767, in the first round the attacker can test the port range from 32768 to 65535 (the most likely half) in a 1-second interval. If the actual port number falls in the range, then the challenge ACK observed by the attacker at the end of the interval will

```
if (!tcp_sequence(tp, TCP_SKB_CB(skb)->seq,
                  → TCP_SKB_CB(skb)->end_seq)) {
...
  goto discard;
}
if (th->rst) {
  if (TCP_SKB_CB(skb)->seq == tp->rcv_nxt
      → )
    tcp_reset(sk);
  else
    tcp_send_challenge_ack(sk, skb)
      → ;
  goto discard;
}
```

Figure 7: Logic of handling an incoming packet with RST flag in latest Linux kernels

be 99 (one goes to the victim). If the actual port number *does not* fall in this range, the observed number of challenge ACKs will be 100. In either case, the attacker can narrow down the search space by half and proceed to the next round of search.

An even better strategy is to divide the search space into multiple bins and probe them together in the same round. That way, one can eliminate $\frac{n-1}{n}$ of the search space. A similar multi-bin search strategy is used for sequence number inference in (§4.3).

In cases where n is smaller than 32767 (due to bandwidth constraints), the best the attacker can do is to simply try as many port numbers as possible in each round. The binary search or multi-bin search can be applied later when the search space becomes small enough.

4.3 Sequence Number Inference

As discussed in §2.2, the receiver generates a challenge ACK in response to a RST packet that contains an in-window sequence number which does not match exactly the expected value. The related Linux kernel code is shown in Figure 7; the `tcp_sequence()` function returns true if the sequence number is in-window, and false if it is out-of-window. In the latter case, the packet will simply be dropped. When the sequence number is in-window and the packet has the RST flag set, its sequence number is analyzed further. As we can see, the connection is terminated only when the sequence number matches *RCV.NXT*; otherwise, a challenge ACK is sent.

The main difference between port number inference and sequence number inference is that the attacker does not need to check every possible sequence number to trigger a challenge ACK. Therefore, the attacker can divide the sequence number space into blocks whose sizes are equal to the receive window size, and probe with a guessed sequence number in each block to determine which sequence numbers fall in the receive window. Theoretically, an attacker can apply the same binary

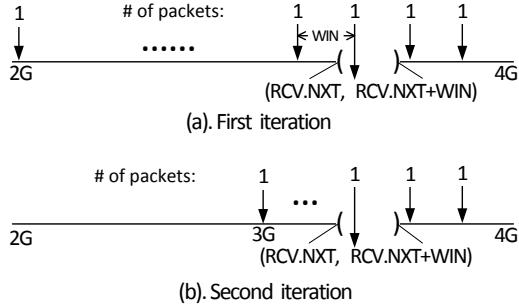

Figure 8: Binary search for sequence number illustration

search algorithm used in connection inference. This process is illustrated in Figure 8. In the first round of probing, the attacker can probe the right half of the sequence number space — (2G, 4G). If any of the spoofed RST packets triggers a challenge ACK, the attacker will observe less than 100 challenge ACKs at the end of the 1-second interval. If there are exactly 100 challenge ACKs observed, it indicates that the receive window is on the left side of the search space. In either case, in the second round, the attacker knows “which half the receive window belongs to.” Let us say that the receive window is in the right half. The attacker would then divide the search space of (2G, 4G) into (2G, 3G) and (3G, 4G). Similar to the first round, only (3G, 4G) needs to be probed in order to determine the part that contains the receive window. This search will eventually stop after 32 rounds exactly (because the sequence number is 32-bit).

However, in practice, the sequence number search space is significantly larger than port number space. Let us consider a receive window size of 12600. This leaves the attacker 340870 possible blocks to search through. If the attacker were to transmit this many packets in one second, the bandwidth requirement would be around 150Mbps, which is extremely high. Likely, the attacker will have to perform a linear search by attempting to search as many blocks as allowed by bandwidth in one second.

Dealing with unknown window sizes: Ideally, the block size should be determined by the window size of the target connection, i.e., the server’s receive window size. In reality, however, an *off-path* attacker cannot observe the window size. If the attacker chooses a smaller window size (compared to the actual window size), the attack will send more packets unnecessarily and take more time. On the other hand, if the guessed value is larger than the actual value, the attacker might miss the correct window of sequence numbers while traversing consecutive blocks. Thus, there is an inherent trade-off between the success rate and the cost incurred (in terms of time and bandwidth) of the attack. Even if the attacker can come up with a correct receive window size at one

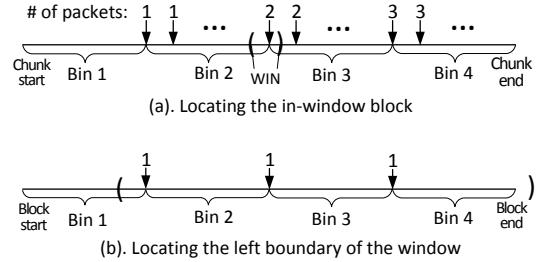

Figure 9: Multi-bin search for sequence number illustration

particular time, the size can change over time.

Our solution is to use a conservative estimate of the window size as the block size in the beginning and update it later given proper feedback. The conservative window size is determined by the initial window size advertised by the server in the SYN-ACK packet. By surveying Alexa top 100 websites, we find that the average initial receive window size is 26703. This window size is the lower bound as the window typically grows after the connection is established. To observe the initial window size, the attacker simply attempts to establish a valid (non-spoofed) TCP connection with the server. This strategy works because a server typically uses the same initial receive window size for all clients. Such a conservative estimate of window size may force the attacker to send more packets, but it at least will guarantee success. We will also discuss how to update the window size dynamically during the search process.

Next, we elaborate the design of sequence number inference:

- **Step 1 – Identify the approximate sequence number range.** Let us assume that the attacker, in n blocks, can send n spoofed packets per second (n is on the order of thousands in our experiments). We call such n consecutive blocks a chunk. The guessed sequence number is always chosen to be the first sequence number within a block. If at the end of the 1-second interval, the attacker observes 100 challenge ACKs, then the attacker proceeds to the next chunk, i.e., the next n consecutive blocks. If the attacker observes less than 100 challenge ACKs, it indicates that the receive window is within the chunk that was just probed. The attack can now proceed to step 2. Note that if the number of observed challenge ACKs is less than 99, it indicates that the initially estimated window size (block size) is too small.

For example, as illustrated in Figure 10(a), if there are two blocks whose beginning sequence numbers are inside the actual receive window, then the number of observed challenge ACKs will be 98; this indicates that the actual window size should be approximately twice the estimated window size (initial block size). We there-

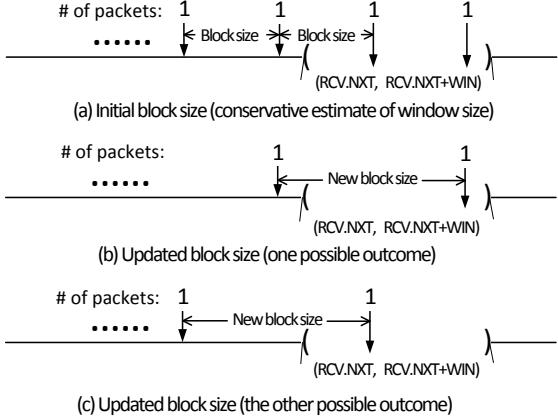

Figure 10: Window size estimate and adjustment

fore update the block size to be twice as much in the subsequent search steps. The two possible outcomes are shown in Figure 10(b) and Figure 10(c).

- **Step 2 – Narrow down the sequence number space to a single block.** From step 1, we know that the receive window is within a chunk. We now further narrow down the search space to an exact block within the chunk. Note that we have now updated the block size so that there will be one and only one block that can trigger challenge ACKs. To locate the exact block, the same binary search strategy outlined in Figure 8 can be used except that the search space now is dramatically reduced after step 1.

The located block has a beginning value which, is an in-window sequence number; therefore, one of the following is true: (i) its beginning value is the correct sequence value; or (ii) the correct sequence value is in its left neighboring block. In the first case, since the sequence number matches the $RCV.NXT$, the spoofed RST packet can already terminate the connection. In the second case, the attacker performs an additional search in the left neighboring block (see Step 3).

- **Step 2 (optimized version) – Identify the correct sequence block using multi-bin search.** With the previous assumption that the attacker can send n spoofed packets per second, with a binary search, the first round requires only $\frac{n}{2}$ packets (as we divide a chunk into two halves initially). The second round requires only $\frac{n}{4}$ packets and so on. As we see, the number of packets sent in each round reduces quickly. This is not an efficient use of the network bandwidth. We show that it is possible to speed up the search process by sending more packets per round (still at most n per round).

The idea is, instead of dividing the search space into two halves in each round, we can divide the space into multiple bins and probe them simultaneously. This is illustrated in Figure 9(a) where 4 bins are present in a chunk. Each bin here holds an equal number of blocks. To determine which bin the receive window falls in, the

attacker sends a different number of spoofed RST packets in each bin. In the example, he sends 1 RST packet per block in the 2nd bin, 2 RST packets per block in the 3rd bin, and 3 RST packets per block in the 4th bin. Since the receive window can fall into one and only one of the bins, the attacker can determine which bin it is in, by observing how many challenge ACKs are received at the end of the 1-second interval. If there are 100 challenge ACKs received, it indicates that the receive window is in the 1st bin (since no RST packets were sent in the 1st bin). Receipt of 99 challenge ACKs indicates that the receive window is in the 2nd bin, etc.

Note that the more bins we have, the faster we can narrow down the sequence number space. However, the number of bins chosen for each round is constrained by n . The larger the n , the more the bins that can be created. The number of bins is also capped at 14, given that the number of spoofed packets may already exhaust the 100 challenge ACK counter in one round ($0 + 1 + 2 + \dots + 13 = 91$).

- **Step 3 – Find the correct sequence number using binary search.** Now we are sure that $RCV.NXT$ is within a specific block, we need to locate its exact value. To achieve the goal, another modified binary search strategy is used here. The observation is that the correct sequence number ($RCV.NXT$) is the highest value in the block, such that any spoofed RST packet with a sequence number less than it will not trigger a challenge ACK packet. It is worth noting that we may not realize which value is the correct sequence number until the connection is terminated, as all the probing packets are RST packets.

- **Step 3 (optimized version) – Find the correct sequence number using multi-bin search.** Similar to the previous multi-bin search, the attacker can divide the single block into many small bins and probe them simultaneously. All bins before the left boundary of the receive window ($RCV.NXT$) will not trigger any challenge ACKs; the ones after will. Thus, in this step attacker only sends one spoofed packet per bin and accumulates all the challenge ACKs received from right to left (See Figure 9). If the attacker sees (100-X) challenge ACKs at the end of the 1-second interval, it indicates that X probed bins are after $RCV.NXT$. In Figure 9, let us say we divide the block into 4 bins. After probing them, the number of observed challenge ACK will be 97 because 2nd, 3rd, and 4th bins turn out to be after $RCV.NXT$. Note that if the observed challenge ACK is 100, it indicates that the correct sequence number is somewhere inside the 4th bin (but not its beginning value).

Similar to the previous multi-bin search, the number of bins chosen for each round is constrained by n . In addition, the number of bins is always capped at 100, as the spoofed packets may exhaust the limit of 100 challenge ACK count.

The RST off-path TCP attack is successfully launched after the above three steps. The exact number of probing rounds depends on the available bandwidth, and will determine the time it takes to finish the attack. We will evaluate this in §7.

5 Off-Path Connection Hijacking Attack

In this section, we discuss how an off-path attacker can hijack an ongoing connection and inject spoofed data. The methodology used to inject data into the client or to the server are similar; thus, without loss of generality, we exemplify the attack targeting the server. First, we describe the challenges that the attacker will need to overcome; subsequently, the entire attack process is described in detail.

5.1 Challenges and Overview

The attacker will experience obstacles that are similar to those associated with launching an off-path reset attack. In addition, the following additional challenges need to be addressed.

Preventing unwanted connection reset. As described in §4.3, the RST packets with in-window sequence numbers are leveraged towards identifying the next expected sequence number on the connection. However, with that process, sending a RST packet with the exact, expected sequence number ($RCV.NXT$) to the server will terminate the TCP connection; this is not the goal of the hijack attack. The challenge is thus, to infer $RCV.NXT$ without causing connection termination.

Identifying both the sequence number and ACK number. In order to trick the server into believing that the injected data is valid, and sent from the server, the attacker needs to know both the correct sequence number ($RCV.NXT$) and the acceptable ACK range on the server side of the connection. The latter is typically a fairly small range as discussed in §2.3.

At a high level, our design of the attack consists of the following steps: First, the attacker finds an in-window sequence number on the server using the techniques described in §4.3. Based on this, the attacker will be able to guess the range of acceptable ACK values that trigger challenge ACKs. The range of these acceptable values (ACK window) can be used to identify the highest acceptable ACK number, i.e., $SND.NXT$, on the server. We will show next that obtaining this ACK number then allows the attacker to infer the exact expected sequence number on the server without resetting the connection.

5.2 Inferring Acceptable ACK Numbers

Assuming an in-window sequence number is already inferred, we now discuss how an attacker can infer the

next ACK number, $SND.UNA$, which is expected by the server. As illustrated in Figure 3, an incoming data packet is accepted if the ACK number is in the range of $[SND.UNA - MAX.SND.WND, SND.NXT]$. If not, the receiver will respond with a challenge ACK packet, if the ACK number is in the range of $[SND.UNA - (2^{31} - 1), SND.UNA - MAX.SND.WND]$; this range is called the *challenge ACK window*. It is obvious that $SND.UNA$ can be computed if one can successfully infer the left boundary of the challenge ACK window, $SND.UNA - (2^{31} - 1)$. This in turn can be found using the following approach.

Step 1: Identify the challenge ACK window position. According to RFC 1323, by using the window scaling option, the maximum receive window size can be extended from 2^{16} to a maximum of $2^{30} = 1G$. Thus, the $MAX.SND.WND$ cannot be larger than 1G. Accordingly, the *challenge ACK window* size is between 1G and 2G, which is one quarter of the entire ACK space size. Because of this, we divide the entire ACK space into 4 bins and probe each bin to check which bin(s) the *challenge ACK window* falls in. In our implementation, we probe the first value of each bin, i.e. 0, 1G, 2G, 3G. We know for certain that either one or two bins can trigger challenge ACK packets. Therefore, we need to send different number of packets for each bin to differentiate the resulting cases. A simple strategy is to send one packet at ACK number 0, two packets at 1G, four packets at 2G, and 8 packets at 3G. For instance, if the number of observed challenge ACKs is 94 (6 missing), then we can infer that both ACK number 1G and 2G have triggered challenge ACKs. If the number of observed challenge ACKs is 96 (4 missing), then only ACK number 2G has triggered challenge ACKs. We can then easily determine the “left-most” bin whose beginning value falls in challenge ACK window.

Step 2: Find the left boundary of the challenge ACK window Now the problem is, given the bin located in the previous step, we need to identify an ACK number in the left neighboring bin, such that it is the “left-most” value (in the circular sense) that can still trigger challenge ACKs. This is a problem that can be solved in a similar way to the last step of sequence number inference using multi-bin search (§4.3).

Finally, when the left boundary of the challenge ACK window ($SND.UNA - (2^{31} - 1)$) is found, an acceptable ACK value ($SND.UNA$) is trivially computed.

5.3 Identify the Exact Sequence Number

To locate $RCV.NXT$ without resetting a connection, we leverage the knowledge learned about the various ACK number ranges. The idea is that, instead of sending spoofed RST packets (which may terminate a connec-

tion), the attacker can send spoofed *data* packets with ACK numbers that fall in the challenge ACK window and thus, intentionally trigger challenge ACKs (if the sequence number is in-window). Combined with the fact no challenge ACK will be triggered if the guessed sequence number is before *RCV.NXT* (considered old packet and dropped), *RCV.NXT* can be located as the “left-most” value that can trigger challenge ACKs. The search process is in fact similar to the last step in sequence number inference except that we now use spoofed data packets.

Now that the attacker knows both the *RCV.NXT* and *SND.UNA* on the server, it is trivial to inject legitimate-looking data packets that will be accepted by the server. Further, it is also trivial to inject legitimate-looking data packets to the client because the *RCV.NXT* on the server is effectively the *SND.UNA* on the client, and the *SND.UNA* is the *RCV.NXT* on the client (assuming no traffic is in flight). In §7.2, we will present a case study on how a web service can be hijacked by a completely blind off-path attacker.

6 Other Practical Considerations

We have fully implemented the attacks described in §4 and §5. In §7, we will evaluate the effectiveness and efficiency of the attacks extensively. In this section, we outline a few practical considerations that need to be handled.

Detecting and handling packet loss. So far, we have assumed that spoofed connections will not incur packet loss and the challenge ACK side channel has no noise. However, in reality, even if the number of packets sent per second is chosen conservatively (well below bandwidth constraints), there is still no guarantee that packet loss will not occur, and a host may legitimately generate challenge ACKs that are not triggered by the attack. They exhibit the same effect to the attacker — the number of observed challenge ACKs will be smaller than expected. In this paper, we call them both packet loss for convenience. We address packet loss based on the two following principles: 1) when in doubt, repeat the probes; 2) add redundancy in the probing scheme to proactively detect packet loss.

In the initial step of the sequence number search, if packet loss occurs, the number of observed challenge ACKs may reduce to 99; the attacker thus, may incorrectly conclude that a chunk that contains the receive window is located. This will affect all subsequent search steps. Therefore, every time when a “plausible” chunk is detected, we repeat the probe on the same chunk. The search will proceed to step 2 only when both rounds return exactly 99 challenge ACKs (no more, no less).

In step 2 and step 3 of the sequence number search,

we add redundancy to actively detect packet loss so that we repeat only the round of probing that experienced packet loss. The idea is similar to using parity bits. In each round, instead of allowing the number of observed challenge ACKs to be any value equal to or below 100, we can construct the probing packets such that only odd number of challenge ACKs will be considered a valid outcome. If an even number of challenge ACKs is received, packet loss must have happened. This strategy can be visualized by referring to Figure 9(a). Instead of sending 1, 2, or 3 packets per block for each bin, we will send 1, 3, and 5 packets per block for each bin. This means that if the receive window falls in 2nd bin, the number of challenge ACKs will be 99; if the receive window is in 3rd bin, the number of challenge ACKs will be 97, etc.

Both schemes are implemented and shown to be very effective in cases where the network conditions between the attacker and the victim are poor.

Moving receive window and challenge ACK window. So far, we have assumed that the connection is relatively idle, and the window does not change while the inference is in progress. This is likely to be the case in many real world scenarios, especially with long-lived connections. One example is the push notification connections on mobile platforms [2]. They are idle most of the time until a new push notification arrives. Even when a connection is not idle at one point, it is likely to become idle at some point and become more susceptible to the attack. Moreover, the traffic activity will mostly be concentrated on either uplink and downlink, rarely both. Typically, downlink traffic dominates; therefore, the attacker targeting at resetting the connection on the server side will experience less difficulty (client’s sequence number increases very slowly). Tor network connections are also candidates as the end-to-end throughput is typically very low.

To support sequence number inference against (slow) moving receive windows, we implement a simple strategy which conducts a brute-force style sequence number guessing. Specifically, once a “left-most” in-window sequence number is inferred (which may become invalid in the next interval due to the ongoing activities), we send 20,000 RST packets with sequence numbers, with offset 1, 2, ..., 20,000 to the valid sequence number. As will be shown in §7.1.2, for low-activity connections, this strategy works well. We leave the exercise to come up with a strategy to target connections with heavier traffic to future work.

Per-connection rate limit. Since the Linux kernel version 4.0 (released in Apr 2015), in addition to the global challenge ACK rate limit, a per-connection rate limit was introduced. The idea is to reduce the impact of potential ACK loops [3] that may occur if client

and server are de-synchronized. Theoretically, the per-connection rate limit provides an isolation between the victim connection and the attacker connection, and the side channel should be eliminated completely. For instance, even if the challenge ACK count limit is reached for the victim connection, it does not affect the limit on the attacker connection at all.

However, interestingly, the per-connection rate limit only applies to SYN packets or packets without any payload. The comment in the Linux kernel states “Data packets without SYNs are not likely part of an ACK loop”, hinting that such packets do not need to be governed by the per-connection rate limit. It is evident that the developers assumed a benign scenario instead of an adversarial one. To get around this restriction, we simply send spoofed packets with a single byte of payload. For the spoofed SYN-ACK packets though, it is impossible to bypass the per-connection rate limit. Unfortunately, upon a closer look at the implementation, when a per-connection challenge ACK is sent out, it is also counted towards the global challenge ACK limit. Therefore, it is still possible to infer that the four-tuple of an ongoing connection has been guessed correctly by observing only 99 challenge ACKs at the end of the 1-second interval. In practice, the per-connection rate limit is 1 packet every 0.5 second, which does allow the attacker to proceed with the binary search approach outlined in §4.2. We have verified experimentally that it does work against the latest Linux kernels with per-connection rate limit.

Configurable maximum challenge ACK count. For simplicity, throughout the paper, we assume the challenge ACK count to be 100, which is the default value. Our test on a variety of Linux operating systems also confirmed the result. However, as proposed in RFC 5961, this value is configurable by a system administrator. According to the specification, the flexibility is provided to allow the tradeoff between resource (bandwidth and CPU) utilization and how fast the system cleans up stale connections. Fortunately, the exact configured value can be inferred quite easily with some simple steps (as long as it is not excessively large). After establishing a legitimate connection to the server, the attacker can send many RST packets, e.g., 1000 packets which is much larger than default value of 100, with in-window sequence values to trigger as many challenge ACKs as possible. The packets are sent in a very short period of time (say, 100 or 200 ms) to increase the likelihood that they end up in the same 1-second interval. The attacker then counts the total number of challenge ACKs returned. Finally, the attacker can wait for a short amount of time and repeat the process one more time to verify the number of received challenge ACK packets is the same; that value would be the actual limit set by the server. Note that this is only a one-time effort for each target.

7 Evaluations

To showcase the effectiveness of our attacks, we next evaluate them in terms of metrics such as success rate and the time to succeed.

7.1 Connection Reset Case Studies

There are two sets of experiments reported in this section viz., where (i) we reset an SSH connection and (ii) perform a Tor connection reset.

Experimental setup. For the SSH experiments, we use a Ubuntu 14.04 host on the University of California - Riverside campus as the victim client. The victim SSH server is one of the instances we create on Amazon EC2 in different geographic locations, worldwide. The attack machine is a Ubuntu 14.04 host in our lab. For the Tor experiments, we target the connection between a Tor relay (set up in our campus) and a random peer relay. Our Tor relay is also a Ubuntu 14.04 host and has been running the service for several months. The attack machine is the same host as the one in the SSH experiments.

In both the SSH and Tor experiments, the attacker attempts to reset the connection on the server end by connecting to it and performing the inference attacks. The diversity of servers and the corresponding network paths help test the robustness of the attack. We assume that the 3-tuple <client IP, server IP, and server port> is known. Further, the attack machine is capable of spoofing the IP address of both the victim client and server.

7.1.1 SSH Connection Reset

Location	Success Rate	Avg # of rounds with loss	Avg % of rounds with loss	BW (pkts)	Time Cost (s)
US West 1	10/10	0	0	5000	48.00
US West 2	9/10	1.0	1.91%	5000	58.00
US East	10/10	0	0	5000	32.00
EU German	9/10	0.3	0.67%	5000	48.00
EU Ireland	10/10	0	0	5000	35.20
Asia 1	10/10	0	0	5000	51.00
Asia 2	9/10	1.7	5.34%	5000	36.67
South America	10/10	0	0	5000	45.70

Table 1: SSH connection reset results

Summary. We run the reset attack against 8 different Amazon EC2 servers in different geographical locations. They are all micro instances set up for our experiments only. We establish a connection from the victim client to each server, and have the attacker perform the off-path connection reset attack. For each server, we repeat the experiment 10 times and report the average. As shown in Table 1, the attack is highly effective: the average success rate is 97% over all runs, with an average time cost of 44.3s. Note that the overall time excludes the time for synchronization (recall §4.1) as it is a one-time effort for a server and can be done a priori. The bandwidth cost

here is 5000 spoofed packets per second, which translates to 4Mbps. Note that the probing scheme has already built in packet loss detection using “parity bits” as described in §6. To show that the packet loss detection scheme works, we report the number of rounds and the percentage of rounds on average, when packet loss is detected. For instance, even when packet loss between the attack node and “Asia 2” server is frequent, we still manage to succeed 9 times out of 10.

Failures may still occur since the detection scheme is rudimentary and may fail to detect packet loss. In some cases, the failure can also be the result of the attacker and server becoming out-of-sync due to network delay variance. The success rate can be further improved by adding more redundancy and using better error detection schemes. However, we argue that the current success rate is already good enough to carry out effective DoS attacks.

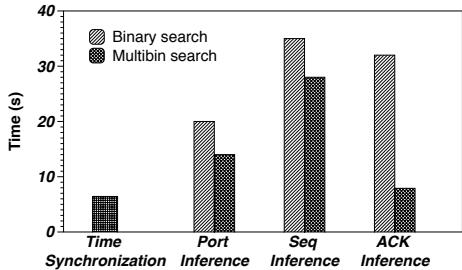

Figure 11: Time breakdown

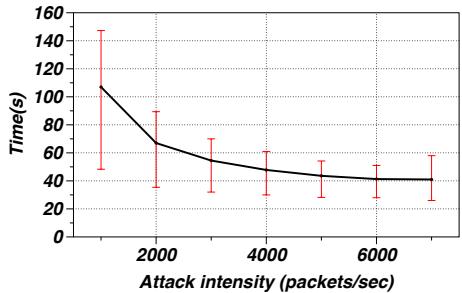

Figure 12: Attack intensity impact on time to succeed

Time breakdown. To understand where the time is spent in our attacks, we conduct another benchmark experiment against one of the SSH servers with both sequence number and ACK number inference. As shown in Figure 11, we break down the time spent into time synchronization and the three search phases of port number inference, sequence number inference, and ACK number inference. We also compare the optimized multi-bin search versus the regular binary search in each phase. Time synchronization takes around 7 seconds (optimization is not applicable). As discussed, it is only a one-time

effort and therefore not on the “critical path”. We see that with the optimized multi-bin search, the time spent on port search is fairly short (around 14 seconds). The time spent on sequence number search takes the most time due to the fact that the sequence number space is much larger. The time spent on ACK number inference is also fairly short (around 8 seconds) due to the fact that the challenge ACK window is extremely large and easy to locate.

Compared to the results with binary search, we see that the optimized multi-bin search has greatly improved the search speed by more than 30 seconds overall. This is due to the fact that binary search significantly underutilizes the bandwidth resources and significantly increases the number of rounds of probes. The reason why the sequence number search does not benefit as much is because most of the time is spent on the initial linear search of the huge sequence number space. This step cannot be optimized with the multi-bin search.

Attack intensity vs. Time to succeed. Using the same experimental setup as before, we vary the attack intensity, i.e., the number of packets sent per second and show how this affects the time it takes to succeed. As shown in Figure 12, we plot the average, min, and max time to successfully conduct sequence number inference only (reset attack), as well as with the ACK number inference added (hijacking attack). Clearly, the higher the attack intensity the faster the attack. When the intensity is only \approx 512 Kbps (1000 packets per second), the time to succeed is over 100 seconds, on average. When the intensity is \approx 4 Mbps, (5000 packets per second), the average time reduces to \approx 50 seconds for hijacking and only 30 seconds for reset. Note that an intensity $>$ 4 Mbps does not substantially improve the time to succeed because we begin to observe more packet losses, which cause additional rounds of probing. Of course, this is experienced on the specific network environment between the attack host and the server, which could differ elsewhere; if the network conditions are even better, the time to succeed can be further improved.

7.1.2 Tor Connection Reset

Node	Target	Success Rate	Avg # of rounds with loss	Avg % of rounds with loss	BW (pkts)	Time Cost(s)
62.210.x.x	FR	8/10	1.9	4.58%	4000	46.36
89.163.x.x	DE	9/10	4.0	7.97%	4000	49.08
178.62.x.x	GB	7/10	3.2	4.20%	4000	53.00
198.27.x.x	NA	10/10	0.8	1.45%	4000	59.86
192.150.x.x	NL	8/10	4.1	5.64%	4000	68.03
62.210.x.x	FR	6/10	2.5	5.85%	4000	49.57
89.163.x.x	DE	8/10	1.7	3.06%	4000	52.51
178.62.x.x	GB	8/10	6.0	8.15%	4000	78.35
198.27.x.x	NA	7/10	2.1	3.64%	4000	72.49
192.150.x.x	NL	6/10	5.5	7.14%	4000	79.42

Table 2: Tor connection reset results (first half under browsing traffic and second half under file downloading traffic)

To conduct a realistic experiment, we use a Tor relay set up in our campus and have a user using it as an entry relay. The entry relay establishes connections with an arbitrary middle relay (anywhere in the world). For ethical reasons, we do not perform attacks against arbitrary relay nodes that are not connected to our node.

To understand how the attack performs against mostly idle connections, we test it against connections between our own Tor relay and 40 other Tor relays throughout the world. The attack node has to connect to these Tor relays that are far away to perform attacks. In each case, we repeat the reset experiment 10 times. First, we discover that 16 of them do not appear vulnerable to the side channel attacks, even though they appear to be Linux hosts. We suspect that this is because of certain firewalls that drop our spoofed packets. For the remaining 24 hosts, the average success rate is 88.8% and the average time to succeed is 51.1s. We find these results to be slightly worse than those in the SSH experiments because of higher packet loss rates.

In addition, we pick 5 random relays and simulate background traffic with browsing and file downloading, and conduct the same experiment as above. Here, to deal with moving windows, we use the simple brute-force strategy described in § 6. The results are shown in Table 2. The average success rate is now down to 77% and the average time to succeed is 60.9s. Upon further inspection, the increased failure rate is exactly due to the moving window problem i.e., it interferes with the sequence number search. Nevertheless, we think the result is acceptable as we have not designed a robust solution specifically for dealing with a moving window (this is left for future work).

In general, we believe that a DoS attack against Tor connections can have a devastating impact on both the availability of the service as a whole and the privacy guarantees that it can provide. The default policy in Tor is that if a connection is down between two relay nodes, say a middle relay and an exit relay, the middle relay will pick a different exit relay to establish the next connection. If an attacker can dictate which connections are down (via reset attacks), then the attacker can potentially force the use of certain exit relays.

7.2 TCP Hijacking Case Study

Our attack does not require any assistance from client-side or server-side malware or puppet (which are required in prior studies [23, 14]). Therefore, our target is any long-lived TCP connection that does not use SSL/TLS. There are several attractive targets: video, advertisements, news, and Internet chat rooms (e.g., IRC). Depending on the implementation, one can envision the following possibilities: 1) the client periodically initiates a request and asks for responses, or 2) the server proac-

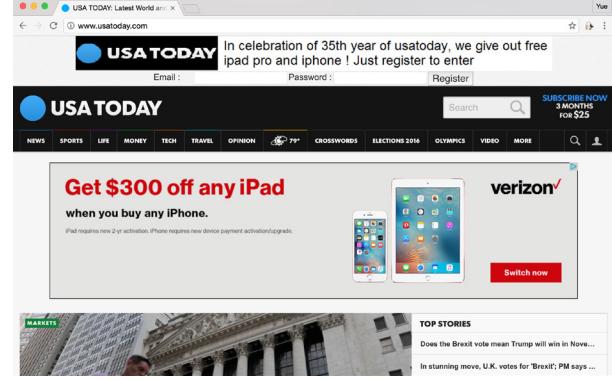

Figure 13: USAToday screenshot with phishing registration window

tively pushes notification messages. In both cases, our attack can inject malicious messages to the client and induce a variety of classic attacks such as phishing or cross-site scripting.

Here, we pick a news website www.usatoday.com which has a long-lived TCP connection that periodically retrieves news updates every 30 seconds. This gives ample idle time for our sequence number and ACK number inference. The attacker machine and the victim client are Ubuntu 14.04 hosts in our lab (as in the other case studies). Once the numbers are inferred, we perform a de-synchronization attack [4] by sending a spoofed request to the server that will force it to send a response to the client. Since the request was never sent by the client, it will not accept the response as the response packet contains an invalid ACK number (acknowledging data that have not been sent). Later, when the client itself initiates a real request, the server would no longer accept it as the packet is considered to be data with an old sequence number. Now that the client and server become de-synchronized, the attacker no longer needs to worry about a race condition where the response to the victim client is sent back by the server first. During all this, the attacker simply sends spoofed responses periodically every few seconds with ACK numbers properly acknowledging the client’s requests. If such spoofed responses arrive before the client sends a request, they will simply be dropped without any adverse effect (because the ACK numbers are acknowledging data that has not been transmitted yet).

We implement the attack end to end, and successfully hijack the connection and inject a phishing registration window to solicit email and passwords at the top of the webpage as shown in Figure 13. We repeat the experiment 10 times and summarize our results in Table 3. The attack first infers sequence and ACK numbers before injecting the malicious payload. Success rate 2 quantifies the rate of inferring the sequence and ACK numbers correctly. However, USAToday occasionally switches the

Success rate 1	Success rate 2	Avg # of rounds with loss	Avg % of rounds with loss	BW (pkts)	Time (s)	Cost
7/10	9/10	2.22	3.63%	5000	81.05	

Success rate 1 = success rate of injecting the phishing registration window
 Success rate 2 = success rate of inferring the correct sequence and ACK number

Table 3: USAToday injection results

HTTP request from one type to another and therefore the injected payload will not match the request. Success rate 1 quantifies the rate of injecting the response that matches the request, which is strictly lower than success rate 2, but is still reasonable in our experiments. In addition, the time to succeed is longer than in the case of SSH and Tor experiments mostly because of the extra steps of ACK number inference and data injection.

8 Discussion and Defenses

Vulnerabilities in other OSes: We examine if the studied vulnerability exist in the latest Windows and FreeBSD OSes (The latter TCP stack is also used by Mac OS X). In brief, these OSes are not vulnerable to the attack. First of all, neither Windows nor FreeBSD has implemented all three conditions that trigger challenge ACKs according to RFC 5961. More importantly, the ACK throttling is not found for Windows or MAC OS X. Ironically, not implementing the RFC fully, in fact is safer in this case.

Defenses. As highlighted earlier, the root cause of all the attacks described is the side channel associated with the global challenge ACK count. This side channel can leak various types of information about an ongoing TCP connection. In general, as asserted in previous studies [21], network protocols are not designed rigorously to guarantee the non-interference property. In our study, we discover that the design and implementation of RFC 5961 has actually introduced an information flow that leaks TCP connection state through the shared challenge ACK counter, and is highly exploitable.

The best defense strategy is to eliminate the side channel (the global challenge ACK count) altogether. One can still enable the per-connection rate limit as long as each connection has a completely separate counter that does not interfere with those of other connections. The downside of this strategy is that if the number of connections in a system increases, the aggregate challenge ACK count can go up without any bound. There is currently no evidence to suggest that this worst case scenario is likely to ever happen. However, if one is really concerned about wasting resources on sending challenge ACKs, we suggest a second solution which is adding noise to the channel. This is a common defense strategy in mitigating side channel attacks [10, 27]. Specifically, instead of having a fixed global challenge ACK count of 100 in all intervals, we can add random values (either positive or nega-

tive) for each interval. This will essentially confuse the attacker during the search process. In fact, even if the attacker repeats the probe many times, the result will always differ over time. To ensure that the added randomness is theoretically sound, one can even apply differential privacy to systematically introduce noise, as was done recently in [28]. We leave the design of the exact scheme to add randomness to future work. We also plan to propose the defenses to the Linux community.

9 Related Work

Previous work on off-path TCP sequence number inference heavily relies on executing malicious code on the client side [22, 23, 14, 16, 17, 1], either in the form of malware [22, 23] or malicious javascript [14, 16, 17]. They share the same scheme of “guess-then-check” based on some side channels observable by the malicious code on the client side. They include OS packet counters [22, 23, 9], global IPID [14, 1], and HTTP responses [16]. In contrast, our off-path TCP attack eliminates the requirement completely, which makes the attack much more dangerous. The only prior study that shares the same threat model is the one reported by lkm in phrack magazine in 2007 [1]. The authors exploit the well-known global IPID side channel on Windows hosts to perform such attacks. Unfortunately, the IPID side channel is extremely noisy and the attack can take close to 20 minutes to succeed, as reported by the authors. Furthermore, as reported in [14], the success rate of such an attack is very low, unless the attacker has a low latency to the victim (e.g., on the same LAN). In comparison, our newly reported attack finishes much faster and is significantly more reliable.

Besides the TCP sequence number, it has been shown that other types of information can be inferred by an off-path or blind attacker [12, 21, 11, 29, 5, 15]. For instance, Ensafi *et al.* [12] show that, by leveraging the SYN cache and RST rate limit on FreeBSD, one can infer if a port is open on a target host through bouncing scans off of a “zombie” FreeBSD host. Knockel *et al.* [21] demonstrate the use of a new per-destination IPID side channel that can leak the number of packets sent between two arbitrary hosts on several major operating systems with a bootstrapping time of an hour on average. Alexander *et al.* [5] can infer the RTT between two arbitrary hosts with reasonable accuracy within minutes. Gilad *et al.* [15] are also able to infer if two hosts have established a TCP connection identified by a specific four-tuple, by utilizing the same noisy global IPID side channel. Compared to the newly discovered side channel, it has the following limitations: 1) requires the presence of stateful firewall or NAT which may not be universally present; 2) has a low success rate even when the

tests are repeated multiple times (e.g., for more than a minute). Utilizing the new side channel, we can do this much faster.

Many of the side channels can be abused and cause unwanted information leakage. However, in some cases, they can also be used legitimately for network measurements. For instance, the global IPID side channel has been used to infer a network’s port blocking policy [24]. The same side channel has also been used to count how many hosts are behind a NAT [6]. In addition, even though commonly considered a vulnerability, ISPs that allow IP spoofing are still prevalent according to the latest reports in 2009 [7] and 2013 [8]. Further, very recently, IP spoofing has also been used in legitimate applications such as reverse traceroute [20], detecting Inter-domain Path changes [19], and detecting routing policy violations [13].

10 Conclusions

To conclude, we have discovered a subtle yet critical flaw in the design and implementation of TCP. The flaw manifests as a side channel that affects all Linux kernel versions 3.6 and beyond and may possibly be replicated in other operating systems if left unnoticed. We show that the flaw allows a variety of powerful blind off-path TCP attacks. Finally, we propose changes to the design and implementation of TCP’s global rate limit to prevent or mitigate the side channel.

Website-Targeted False Content Injection by Network Operators

Gabi Nakibly^{1,3}, Jaime Schcolnik², and Yossi Rubin¹

¹Rafael – Advanced Defense Systems, Haifa, Israel

²Computer Science Department, Interdisciplinary Center, Herzliya, Israel

³Computer Science Department, Technion, Haifa, Israel

Abstract

It is known that some network operators inject false content into users' network traffic. Yet all previous works that investigate this practice focus on edge ISPs (Internet Service Providers), namely, those that provide Internet access to end users. Edge ISPs that inject false content affect their customers only. However, in this work we show that not only edge ISPs may inject false content, but also non-edge network operators. These operators can potentially alter the traffic of *all* Internet users who visit predetermined websites. We expose this practice by inspecting a large amount of traffic originating from several networks. Our study is based on the observation that the forged traffic is injected in an out-of-band manner: the network operators do not update the network packets in-path, but rather send the forged packets *without* dropping the legitimate ones. This creates a race between the forged and the legitimate packets as they arrive to the end user. This race can be identified and analyzed. Our analysis shows that the main purpose of content injection is to increase the network operators' revenue by inserting advertisements to websites. Nonetheless, surprisingly, we have also observed numerous cases of injected malicious content. We publish representative samples of the injections to facilitate continued analysis of this practice by the security community.

1 Introduction

Over the last few years there have been numerous reports of ISPs that alter or proxy their customers' traffic, including, for example, CMA Communications in 2013 [7], Comcast in 2012 [19], Mediacom in 2011 [10], WOW! in 2008 [31], and Rogers in 2007 [36]. Moreover, several extensive studies have brought the details of this practice to light [20, 34, 28, 39]. The main motivations of ISPs to alter traffic are to facilitate caching, inject advertisements into DNS and HTTP error messages, and compress or

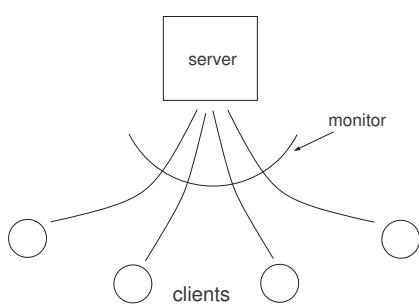

transcode content.

All of these reports and studies found that these traffic alterations were carried out exclusively by *edge ISPs*, namely, retail ISPs that sell Internet access directly to end customers, and are their "first hop" to the Internet. This finding stems from the server-centric approach the above studies have taken. In this approach, one or a handful of servers are deployed to deliver specific content to users, after which a large number of clients are solicited to fetch that content from the servers. Finally, an agent on the clients – usually a JavaScript delivered by the server itself – looks for deviations between the content delivered by the server and that displayed to the user. Figure 1(a) illustrates the traffic monitored in this server-centric approach.

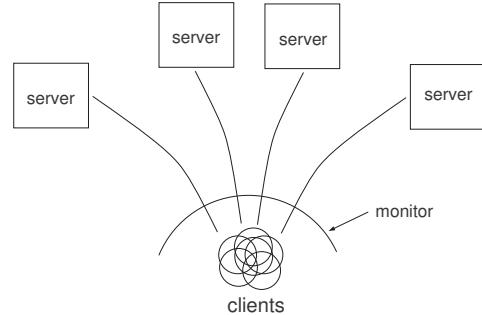

Such an approach can be used to inspect the traffic of many clients from diverse geographies who are served by different edge ISPs. The main disadvantage of this approach is that the content fetched by the clients is very specific. All clients fetch the same content from the same web servers. This allows only the detection of network entities that aim to modify all of the Internet traffic¹ of a predetermined set of users and are generally oblivious to the actual content delivered to the user. Such entities indeed tend to be edge ISPs that target only the traffic of their customers.

In this work we show that the above approach misses a substantial portion of the on-path entities that modify traffic on the Internet. Using extensive observations over a period of several weeks, we analyzed petabits of Internet traffic carrying varied content delivered by servers having over 1.5 million distinct IP addresses. We newly reveal several network operators that modify traffic not limited to a specific set of users. Such network operators alter Internet traffic on the basis of its content, primarily by the website a user visits. The traffic of *every* Internet

¹In some cases these network entities modify all internet traffic originating from very popular websites such as google.com, apple.com, and bing.com or all Internet traffic originating from .com.

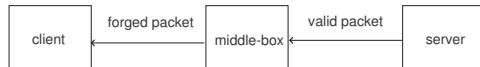

(a) Depiction of monitored traffic in the server-centric approach (of past works). One server with specific content serves many clients in many edge networks.

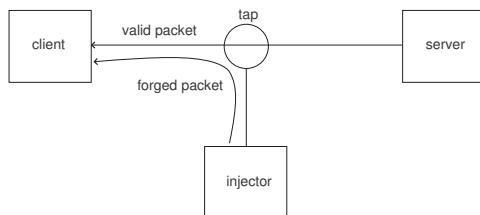

(b) Depiction of monitored traffic in the client-centric approach (of the current work). Many servers with varied content serve many clients in a few edge networks.

Figure 1: Server-centric approach versus client-centric approach to monitoring traffic. The lines between clients and servers illustrate the monitored traffic.

(a) In-band alteration of packet by a middle-box. Only a single packet arrives at the client.

(b) Out-of-band injection of a forged packet. Two packets arrive at the client.

Figure 2: In-band versus out-of-band alteration of content

user that traverses these network operators is susceptible to alteration. This is in contrast to the case of edge ISPs that alter the traffic of their customers only. Although a primary focus of these network operators is to inject advertisements into web pages, we also identified injections of malicious content.

Our analysis is based on the observation that network operators alter packets *out-of-band*: all traffic is passively monitored, and when the content of a packet needs to be altered, a forged packet is injected into the connection between the server and the client. The forged packet poses as the valid packet. If the forged packet arrives at the client before the valid one, the client will accept the forged packet and discard the valid one. Such an approach has considerable advantages to the network operators since it does not introduce new points of failure to their traffic processing and there is no potential for a per-

formance bottleneck. Figure 2 illustrates the differences between in-band alteration of traffic and out-of-band alteration. Note that both in-band and out-of-band traffic alteration is possible only on unprotected traffic, e.g., traffic that is not carried by TLS [12] or authenticated using TCP authentication [32].

The out-of-band operation has a crucial characteristic that enables our analysis: the client receives two packets – the forged one and the valid one – that claim to be the same response from the server. However, they carry different content. This characteristic allows us to detect traffic alteration events while monitoring the traffic at the edge network. We can thus monitor and analyze traffic in a client-centric manner in which the traffic is not destined to a specific set of servers but to all servers contacted by the users at the edge network. Figure 1(b) illustrates the traffic monitored in our work. In this paper we specifically focus our analysis on alteration of *web* traffic, i.e., HTTP traffic over port 80.

An example of out-of-band injection To illustrate how content is altered using out-of-band injection, we describe in the following one of the injections we identified during our observations. In this example the user’s browser sends the following HTTP GET request to cnzz.com (a Chinese company that collects users’ statistics):

```
GET /core.php?show=pic&t=z HTTP/1.1
User-Agent: Mozilla/5.0 (Windows NT 6.1; WOW64)
Host: c.cnzz.com
Accept-Encoding: gzip
Referer: http://tfkp.com/
```

In response the user receives two TCP segments having the same value in the sequence number field. The segments include different HTTP responses. One segment

carries the legitimate HTTP response that includes the requested resource (a JavaScript code) from cnzz.com:

```
HTTP/1.1 200 OK
Server: Tengine
Content-Type: application/javascript
Content-Length: 762
Connection: keep-alive
Date: Tue, 07 Jul 2015 04:54:08 GMT
Last-Modified: Tue, 07 Jul 2015 04:54:08 GMT
Expires: Tue, 07 Jul 2015 05:09:08 GMT

!function(){var p,q,r,a=encodeURIComponent,c=...
```

The other segment includes a forged response that directs the user via a 302 status code to a different URL that points to a different JavaScript code:

```
HTTP/1.1 302 Found
Connection: close
Content-Length: 0
Location: http://adcpc.899j.com/google/google.js
```

Our analysis shows that this JavaScript redirects the user through a series of affiliate ad networks ending with Google’s ad network, which serves the user an ad. In this injection event the forged segment arrived before the legitimate one, which means that the user sees the injected ad instead of the original content.

Relation to censorship Website-targeted false content injection is similar in some ways to content blocking for the purpose of state-sponsored censorship. There is a substantial body of work that studies the mechanisms and characteristics of censorship worldwide [33, 37, 22, 9]. In many cases this blocking of content is also website-targeted. Moreover, blocking is often done by injecting false traffic segments, which in some cases is done out-of-band [33, 11, 8]. In contrast to previous works on censorship, in this work we study the practice of false content injection by commercial network operators, rather than state entities. Such injections primarily serve financial gains rather than political agenda, with the goal of *altering* the web content rather than blocking it. In this work we study and analyze the practice of financially-motivated false content injection by network operators. In Section 7 we discuss in more detail related work on censorship. During this work we observed numerous occurrences of censorship-aimed injections. We do not report on them in this paper.

Our contributions can be summarized as follows:

1. The observation that network operators inject false web content out-of-band.
2. Investigation of the identities of network operators that practice website-targeted content injection.

3. Thorough analysis of the characteristics of the injections and the purpose of the injecting operators.

The paper’s structure is as follows. In Section 2 we present technical background pertaining to injection of forged TCP and HTTP packets. Section 3 details our methodology for monitoring web traffic and identifying injections of forged packets. Section 4 details the sources of traffic we monitored. In Section 5 we present our analysis of the injection events and our investigation as to the identities of the network operators behind them. Section 6 proposes effective and efficient client-side mitigation measures. Section 7 discusses related work and Section 8 concludes the paper.

2 Background

2.1 Out-of-band TCP Injection

A TCP [27] connection between two end nodes offers reliable and ordered delivery of byte streams. To facilitate this service, every sent byte is designated a sequence number. Each TCP segment carries a Sequence Number field that indicates the sequence number of the first data byte carried by the segment. The following data bytes in the segment are numbered consecutively. A third party that wishes to send a forged TCP segment as part of an existing TCP connection must correctly set the connection’s 4-tuple in the IP and TCP header, i.e., the source’s port number and IP address as well as those of the destination. In addition, for the forged segment to be fully accepted by the receiver, the sequence numbers of the forged data bytes must fully reside within the receiver’s TCP window. Forging such a TCP segment is trivial for an on-path third party, since it can eavesdrop on the valid segments of the connection and discover the 4-tuple of the connection as well as the valid sequence number.

In some circumstances an injected TCP segment may trigger an undesirable “Ack storm”. An “Ack storm” occurs when the injected segment causes the receiver to send an acknowledgment for data bytes having sequence numbers that were not yet sent by the peer. Appendix A details how an “Ack storm” is formed. Nonetheless, as long as the injecting third party ensures that the injected TCP segment is no larger than the valid TCP segment sent by the peer, no “ACK storm” will be triggered. If this is not the case, the injector could send a TCP reset right after the injection in order to forcibly close the connection. This will also eliminate the possibility of an “Ack storm”. The latter option is used only if the connection is expected to close right after the valid response is received. Indeed, in all our observations either of these alternatives took place and no “Ack storms” were observed.

Nonetheless, the fact that the injected TCP segment aims to displace an already sent or soon to be sent valid TCP segment poses a different obstacle for the injecting third party. According to the TCP specification [27], the first data byte received for a given sequence number is accepted. A subsequent data byte having the same sequence number is always discarded as a duplicate regardless of its value. Thus, the injected segment must arrive at the receiver *before* the valid TCP segment in order to be accepted. Note that the TCP specification does not consider the receipt of bytes with duplicate sequence numbers as an error but rather as a superfluous retransmission.

2.2 HTTP Injection

In this work we focus in particular on the injection of false HTTP responses received by a web client. HTTP [15] is a stateless client-server protocol that uses TCP as its transport. An HTTP exchange begins by a client sending an HTTP request, usually to retrieve a resource indicated by a URI included in the request. After processing the request the server sends an HTTP response with a status code. The status codes we later refer to in this paper are:

- 200 (Successful): The request was successfully received, understood, and accepted. Responses of this type will usually contain the requested resource.
- 302 (Redirection): The requested resource resides temporarily under a different URI. Responses of this type include a Location header field containing the different URI.

An HTTP client will receive only one HTTP response for a given request even when a false HTTP response is injected because, as mentioned above, the TCP layer will only accept the first segment that it receives (be it the false or the valid segment). When the forged response is shorter than and arrived before the valid response, the client then receives the byte stream that includes the forged response, followed by the tail of the valid response. The tail includes the data bytes having sequence numbers that immediately follow those of the forged response. By default, the response message body length is determined by the number of bytes received until the TCP connection is closed. This might be a problem for the injecting entity as the client will eventually receive a mixed HTTP response, which might yield unintended consequences. To avoid this problem, the injected response will usually include Content-Length or Transfer-Encoding headers that explicitly determine the end of the response. Thus, even if the TCP layer delivers the tail of the valid response to the HTTP layer, it will not be processed by the client.

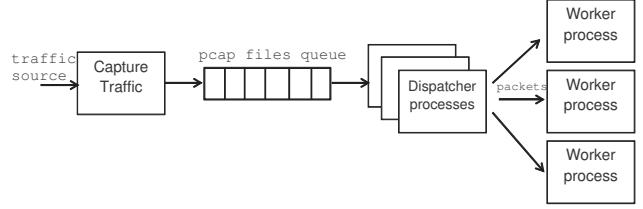

Figure 3: Depiction of the design of the monitoring system

3 Methodology

We now describe our methodology for collection and identification of TCP injection events.

3.1 Monitoring System

At the core of the collection of injection events was a monitoring system that eavesdropped on Internet traffic and identified these events. The monitoring system was deployed at the entry points of large networks (detailed in Section 4) and analyzed the bidirectional traffic that flowed in and out of those networks. The monitoring system was comprised of the following three stages (depicted in Figure 3). First, we captured the traffic using the 'netsniff-ng' tool [3] along with a Berkeley packet filter [25] to capture only HTTP traffic. The tool iteratively produced files comprising 200,000 packets each. These files were fed into a queue for processing by the next stage. To avoid explosion of the queue when the traffic rate exceeded the throughput of the next stages, the queue's length was bounded. Once the queue reached its limit, the capturing process was halted until the queue length decreased.

At the next stage each capture file was processed by a dispatcher process that read each packet in the file, removed the Ethernet header, and computed a hash on the IP addresses and TCP ports in such a way that packets of the same TCP session would have the same hash result. A packet's hash result was then used to choose one of several worker processes to handle that packet. In this way all packets of the same session were delivered to the same worker.

At the final stage each worker process grouped the packets it received into TCP sessions and stored each session in a data structure. For each received packet a worker checked all the packets of that session to determine whether the conditions for a packet race were met (the conditions are detailed in Section 3.2). If so, the last 30 packets of the session were written to a file, including their payload, for later analysis. See Section 3.3 for the ethics and privacy issues pertaining to the storage and analysis of packets.

The packet sessions were stored by each worker in a

data structure that is a least-recently-used cache with a fixed size. Once the cache reached the maximum number of sessions it can store, the session that was idle the longest was evicted from the cache. To simplify packet processing we did not use TCP signaling (SYN and FIN flags) to create a new session in the cache or evict an existing one. This design choice gave rise to the possibility that a session would be evicted even if still active. Nonetheless, as our experiments show, the caches were large enough so that the minimum idle time after which a session was evicted did not drop below 10 minutes — long enough to make the occurrences of active session evictions negligible. Note that even if such an eviction were to occur, packet races could still be detected in that session, since we treated the packets sent after the idle period as a new session and stored them in the cache. In this case, however, the packets of the session prior to the eviction would not be available for analysis.

3.2 Injection Detection

The detection logic of packet injection events is relatively straightforward. Our goal was to detect packet races within the session, namely, two packets that carry different payloads, but correspond to the same TCP sequence numbers. Usually these packets will arrive in quick succession. To make our code more efficient we checked for a race only between pairs of packets that were received within a time interval that does not exceed the parameter *MaxIntervalTime*. Throughout our data collection process we set *MaxIntervalTime* = 200msec. We believe that this value captures the vast majority of injection events as almost all round trip times on the Internet are below 400msec [18]. Indeed, nearly all of the time differences we observed between raced packets were below 100msec (see Section 5). Algorithm 1 in Appendix B details the procedure for race detection.

The procedure we used to identify packet races should, in theory, flag only events in which a third party injected rogue packets into the TCP session. However, interestingly, we observed numerous events which fulfill the above conditions but are not the result of a packet injection. We detail such occurrences in Appendix C.

3.3 Ethics and Privacy

As explained above, the monitoring system captures Internet user traffic. To minimize concerns about user privacy, the system stores only TCP sessions in which a packet race was detected. All other sessions are only cached briefly in the workers’ caches, after which they are permanently erased. Moreover, for each stored session, only the last 30 packets (at most) are saved. Earlier packets are dropped. This is in order to store only those

packets that are relevant to the analysis of the injection events while minimizing the chance that user privacy will be breached. Indeed, during our analysis no identifiable personal information was found in the stored sessions.

Throughout our research we were supervised by the networks’ administration teams, who reviewed and approved the code of the monitoring system and procedures for the analysis of the stored sessions. During the analysis the location and identity of users associated with IP addresses were never disclosed to us. Finally, we note that our monitoring system passively collected information; it never interfered or tampered in any way with the traffic.

3.4 Limitations

Our monitoring system cannot detect content alterations in which there is no race between the legitimate packet and the forged one. In particular, we cannot detect the following cases:

1. In-band changes in which the legitimate packet is changed in-place. In such cases the client only sees a forged packet.
2. Additions to the response in which an extra forged packet is sent such that it extends the HTTP response, but does not replace any legitimate part.
3. Drops of packets that are part of a valid HTTP response.

We monitored a large volume of traffic originating from diverse networks having tens of thousands of users (see Section 4). Nonetheless, as in any other study that involves uncontrolled traffic, our findings are only as diverse as the traffic we monitor. Namely, we cannot identify an injecting entity on the Internet if we do not monitor traffic that triggers an injection by that entity. Furthermore, the types of injections we have observed are dependent on the web traffic originating from the networks we monitored.

4 Data Sources

During our study we monitored the network traffic of four institutions. For each institution we monitored the Internet traffic (incoming and outgoing) of all its users. In all cases the same monitoring mechanism was used: traffic was copied to the monitoring system using a SPAN port out of a border switch. In all cases, we only monitored HTTP traffic, namely traffic having source port or destination port that equals 80.

Table 1 lists the characteristics of the monitored traffic sources. For each institution we list the number of users

Institution	User base	Monitoring period [week]	Traffic volume [Tb]	Number of sessions [Million]
University A	20,000	2	80	8
University B & University C	50,000	16	1400	120
Enterprise D	5,000	3	24	0.8

Table 1: Monitored traffic sources

who may use Internet connectivity in that institution. For a university this is the number of students and staff, and for an enterprise this is the number of employees. In addition, we list the length of time we monitored the traffic as well as the total volume traffic and number of sessions the monitoring system processed. In aggregate, we monitored the traffic of more than 75,000 users, while processing 1.4 petabits carried by 129 million HTTP sessions contacting servers having more than 1.5 million distinct IP addresses. The details of University B and C are displayed together since we monitored their traffic jointly on the same border switch. Enterprise D represents the main branch of a large hi-tech company. The monitored branch includes an extensive R&D division as well as the headquarter offices and the international marketing and sales divisions. All institutions wish to remain anonymous.

5 Injection Analysis

In this section we present an analysis of the injection events. In Section 5.1 we present an overview of the injections and highlight a few of them. Section 5.2 describes ways to automatically distinguish between the valid and forged packets. In Section 5.3 we explore the time differences between the raced packets. Section 5.4 characterizes the recurrence of injection events. Finally, Section 5.5 presents an investigation aimed at unveiling the entities behind the injection events.

5.1 Initial Investigation

In this section we refer to a TCP session into which a forged packet was injected as an *injected session*. We manually analyzed each injection event. We detected around 400 injection events that aim to alter web content². Although this is not a negligible number, it pales in comparison to the total volume of traffic we monitored to extract these events. This is attributed to the fact that most of the injected sessions were destined to web servers in the Far East, a region to which relatively

²We have also found hundreds of additional events that do not aim to alter web content; these events were related to caching and censorship.

little traffic is destined from the networks we monitored. Thus the relatively small number of injections. Nonetheless, these events were sufficient to gain substantial indications as to the different entities that practice forged content injection (Section 5.5).

We grouped the injection events into 14 groups based on the resource that was injected into the TCP session. In other words, two injections that forged the same content are placed in the same group. Representative (and anonymized) captures of the injected sessions can be found in [4]. For each injection group we publish up to 4 captures of injected sessions that are representative of their respective group. To preserve the anonymity of the users, in each capture we zeroed the client’s IP address as well as the IP and TCP checksum fields.

Table 2 lists the groups. For each group we list the following details:

1. Group name – an identifier that was given by us to that group. We selected the name either by the name of the site whose content was forged or by the name of a server the forged content directed us to.
2. Destination site(s) – the website(s) of the requested resource that was forged. There may be several such sites for a single group.
3. Site type – the category of the destination site(s)
4. Location – the country of the IP address of the destination server³
5. Injected resource – the type of forged content that was injected
6. Purpose – the aim of the injection

It is evident from Table 2 that the majority of injected sessions we observed were to web servers located in China. We note that the networks we monitored are *not* located in China or the Far East, but in a Western country. The proportion of HTTP traffic destined to China in the monitored networks is only about 2%. This is a first indication that the majority of entities that injected the forged

³Note that this country might be different than the nationality of the entity that owns the destination site.

Group name	Destination site(s)	Site type	Location	Injected resource	Purpose

Table 2: Injection groups and their characteristics

content we observed reside in China (we investigate the injectors’ identity in Section 5.5).

Seven injection groups are aimed at injecting advertisements to web pages. An analysis of the injected resources shows similarities between the various groups. These similarities might indicate that the injections are done by the same entity or at least by different entities that use the same injection mechanism or product. The injection groups ‘icourses’, ‘uyan’, and ‘jiathis’ all used the HTML meta refresh tag to redirect the user to a different URL. In all cases, the redirection was to Baidu (a Chinese search engine) using the URL `www.baidu.com/?tn=95112007_hao_pg`. The URL includes a referral tag that identifies `hao123.com` – a well-known adware-related site – as the referring site. The referral tag is possibly used by Baidu to pay `hao123` for referring traffic to it. In one case, the redirected URL included a search keyword for a clothing chain store. Interestingly, another injection group, ‘hao’, referred the user to `hao123.com` itself, but using a different mechanism – an HTTP 302 response.

Surprisingly, five injection groups showed strong indications that the aim of the injector was malicious. One such group is ‘gpwa’. The injections in this group target the traffic to `gpwa.org`. The forged content here includes a JavaScript that refers to a resource having the same name as the one originally requested by the user, but the forged resource is located at `qpwa.org`, a domain that is suspiciously similar to the legitimate domain. The forged domain is registered to a Romanian citizen, who appears to be unrelated to the organization that registered the domain `gpwa.org`. These are strong indications of malicious intent. As of May 2016 the web server of `qpwa.org` is still active at a web hosting provider based in the US, however we have not been able to retrieve from it the malicious script.

The injections in the ‘duba’ group add to the original content of a website a colorful button that prompts the user to download an executable from a URL at the domain `duba.net`. The executable is flagged as malicious by several anti-virus vendors.

Another malicious injection group is ‘mi-img’. In these injected sessions the client, which appears to be an Android device, tries to download an application. The injected response is a 302 redirection to another IP address (no domain name is specified). According to BotScout [2] – an online bot database – this forged IP address is known to be a bot. We retrieved the application from this IP address. The downloaded apk file is flagged by Fortinet’s antivirus as a malware called ‘Android/Gepew.A!tr’.

Another injection group worth mentioning is ‘server erased’. In this group injections were identical to the legitimate response but instead of original value of

the Server HTTP header, e.g., `nginx/1.2.7`, the string ‘*****’ appeared. This is as if to prevent identification of the web server’s software. We assume that this injection is due to a security measure at the network operator. The HTTP specification [14] indeed recommends that Server header be configurable.

5.2 Distinguishing the Forged Response from the Valid One

Identifying a race between two packets is a relatively straightforward task. However, without a priori knowledge of the legitimate content expected from the server, automatically distinguishing the forged packet from the legitimate one is not trivial. Nonetheless, in the following we list a few rules that worked well for this difficult task.

IP identification In many operating systems, such as Windows and Linux [16], the IP identification value equals a counter that is incremented sequentially with each sent packet. In some operating systems there is a single global counter for all sessions. In others, there is a separate counter for each destination. Indeed, our observations show that in most injected sessions the IP identification values of the packets sent by the web server are either monotonically increasing (when the counter is global) or consecutively increasing (when there is a counter per destination). In most of the injection events we observed that the injecting entity made no attempt to make the identification value of the forged packet similar to the identification values of the other packets sent by the server. In Appendix D we detail a few of the (failed) attempts of the injecting entity to mimic the Identification field of the legitimate packet it aims to displace.

We formulate the following rule to determine which of the two raced packets is the forged one: the forged packet is the one that has the largest absolute difference between its identification value and the average of the identification values of all the other packets (except the raced one).

For all injection events, we manually identified the forged packet according to its content and compared it to the corresponding identification that used the above rule. The comparison reveals that the rule is accurate about 90% of the time. This is a fairly accurate measure considering that it is not based on the payload of the raced packets.

IP TTL The IP TTL value in a received packet is dependent on the initial value set by the sender and the number of hops the packet has traversed so far. Thus, it is unusual for packets of the same session to arrive at the

client with different TTL values. Therefore, if the raced packets have different TTL values we can use them to distinguish between the two packets. From our observations, the injecting entity often made no attempt to make the TTL value of the forged packet similar to the TTL values of the other packets sent by the server. Similarly to the case of the IP identification rule above, we identify the forged packet using the following rule: the forged packet is the one that has the largest absolute difference between its TTL value and the average of TTL values of all the other packets (except the raced one).

Manual analysis of the injection events reveals that the TTL rule correctly identified the forged packet in 87% of all injection events. The TTL rule concurs with the IP identification rule above in 84% of all injection events. We thus conclude that the TTL and identification values can serve to effectively distinguish the forged packet from the valid packet.

We note that our finding that the TTL and Identification fields of the forged packets have abnormal values generally agrees with findings on censorship-related injections which also show that censoring entities do not align the TTL and Identification values with those of the legitimate packets (e.g., [8]).

5.3 Timing Analysis

The race between the forged and legitimate packets can also be characterized by the difference in their arrival times. By arrival time we mean the time at which the packet was captured by the monitoring system. Since the system captures traffic at the entrance to the edge network close to the client, it is reasonable to assume that these times are very close to the actual arrival times at the end client. For each injection event we calculate the difference between the arrival time of the legitimate packet and the arrival time of the forged packet. A negative difference means that the forged packet “won” the race, and a positive difference means that the legitimate packet “won”. The histogram of the time differences of all the injection events we observed are shown in Figure 4.

It is evident from Figure 4 that in most injection events the forged packet wins the race. In only 32% of the events does the legitimate packet arrive first. This result strengthens our initial assumption that the decision to inject a forged packet is made according to the HTTP request sent by the client. This means that the injecting entity can send the forged packet well before the server sends the legitimate packet, as the client’s request still needs to travel to the server. Still, even in such a case, in a non-negligible portion of events, the forged packet loses the race. This may indicate injections that occurred very close to the server. Alternatively, it may indicate that

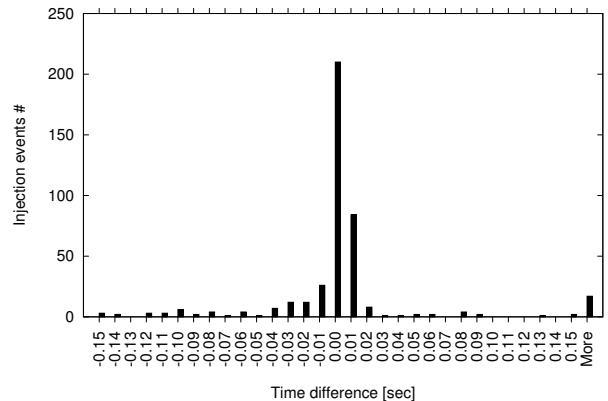

Figure 4: Arrival time difference between the forged and legitimate packets

in some cases the decision to inject the packet is made at the time the response from the server is encountered. In the latter case, the forged packet is at a distinct disadvantage as it starts the race lagging behind the legitimate packet. In many cases in which the forged packet won the race, the legitimate packet arrived very soon after, in less than 10msec.

5.4 Repeatability

All injection groups were observed for only a short period of time, usually one to three days, after which they were not detected again by our monitoring system. A few injection types were even encountered only once. No long-term (3 days or more) injections were observed by our monitoring system⁴.

We next tried to reproduce the injection events we observed. This attempt was made several weeks after the initial observations of the injections. For each injection event we extracted the HTTP request that triggered the injection. We then sent from the edge network in which the injection originally occurred the same HTTP request (following a proper TCP 3-way handshake) to the destination web server. We sent each request 1000 times. This is with the aim to reproduce the injections even if they do not occur for every request. We captured the resulting TCP sessions and searched for injections. We were not able to reproduce any of the injection groups.

Following the initial publication of this work an effort independent of our own to reproduce the injections had more success [17]. The ‘gpwa’ and ‘hao’ injections were successfully reproduced. However, the author of [17] has

⁴The only long-term injections we did observe were related to censorship and caching. These injections were the only ones we were able to reproduce.

not been able to reproduce those injections again in a second attempt made a few weeks later. Moreover, when the injections were observed by [17] they were not always reliable. For one of the resolved IP addresses (for the destination site’s domain name) the injections were observed only 30% of the time (this information was given to us via personal communication by the author of [17]).

From the above findings we surmise that, in general, injections by on-path entities may be intermittent; namely, the injecting entity injects forged content to a particular site for only a short period of time before moving on to other sites. Moreover, when an injector is active for a web site it may target only a portion of the HTTP requests. This might be motivated by the desire of the injector to stay “under the radar”. It is plausible that injecting forged content to a site for only a short period of time might go unnoticed by the users and site owners, or at least would not cause them to expend effort investigating the forged content’s origin.

The injections we found were triggered by an HTTP request to specific resources which in most cases were not the main page of the site. This leads us to assume that an effort to actively seek other sites for possible injections may be computationally too expensive as we would need to crawl those entire sites.

5.5 Who is Behind the Injections?

We finally turn our attention to the culprits behind these injection events. In general, it is difficult to unveil these entities as there is no identifying information in the injected content. Nonetheless, we can get indications as to the identity of the injecting entities by trying to detect the autonomous system from which the forged packet originated. We assume that the entity that operates this autonomous system is the entity responsible for the injection.

Note that the analysis thus far shows strong indications that the injections do not originate at the web servers themselves. First, the injected responses had anomalous IP ID and TTL values. To bring this about an injecting rogue software on the end server would need to circumvent the standard TCP/IP stack as it sends packets. While this is possible it would require the injecting software elevated privileges and more complex logic to send the injected responses. Such elevated privileges would have also allowed the injector to block the valid response and eliminate the possibility of a race altogether. Second, most of the injected packets “win” the race. An attacker injecting packets from the end server does not have a distinct advantage to win the race. Therefore it is reasonable to assume that in such a case the race would have been more even. Third, to the best of our knowledge there is no malware that injects packets out-of-band. All known

malware that aim to alter traffic on the machine they reside alter the the actual packets to be sent (usually by simply injecting code to the sending process or hooking the suitable system services).

We note that we ruled out the possibility that the edge network operators serving the networks we monitored are responsible for the injections. We verified this by speaking directly with the network operators’ administrators and sharing with them the injections we found.

Since the injections were not reproducible during this analysis, we cannot employ the oft-used traceroute-like procedure to locate the injector [22, 8, 24]. In this procedure the packet triggering the injection is repeatedly sent with increasing TTL values until the forged response is triggered, thereby revealing the location of the injector. To identify the injecting entities we resort to the following procedure:

1. Estimate the number of hops the forged packet traversed: this estimation relies on the packet’s TTL value. Specifically, it relies on there being a significant difference between the default initial TTL values set by the major operating systems [29]: in general, the differences between those initial values are larger than the length of most routes on the Internet. The default initial TTL values of the major operating systems are 32, 64, 128 and 255. This means, for example, that if a packet is received with a TTL value of 57, the initial TTL value of that packet was likely to be 64 and the number of hops traversed was likely to be 7. If the estimated number of hops is larger than 30 or smaller than 3⁵, we assume the estimation is incorrect and stop the analysis.
2. Identify the path from the destination server to the client: the actual path from the server to the client cannot be known without an agent in the server’s network. Instead, we use the path from the client to the server while assuming that the routing on this path is symmetric. We identify the path from the client to the server by using a ‘traceroute’ tool. The traceroute used a TCP syn packet with destination port 80. We found that such a packet triggers responses from most routers and servers.
3. Infer the hop along the above path from which the forged packet was injected: using the estimated number of hops the forged packet traversed and the estimated path it traversed, we can now infer the hop on the path from which the packet was sent.

⁵Nearly all routes on the Internet are shorter than 30 hops [21]. Additionally, it is very unlikely that the injecting third party resides less than 3 hops away since the first couple of hops reside within the edge networks we were monitoring.

Injection group	Web server's AS number	Suspected injecting AS number
xunlei	17816	17816
szzhengan	4134	4134
taobao	4837	4837
uvclick	38182	38182
adcpc	38182	38182
server erased	4134	4134
GPWA	6943	6943
tupian	4812	4812

Table 3: The autonomous system numbers in which the injected web servers reside and in which the suspected injecting entities reside

4. Identify the autonomous system the injecting hop belongs to: given the IP address of the hop, we can now identify the autonomous system to which it belongs in order to reveal the entity responsible for injecting the packet. To this end we leveraged public databases that hold current BGP advertisements: this allows us to identify the autonomous system that advertises the given IP address. BGP advertisements for mapping of IP addresses to autonomous systems are known to be more precise and up-to-date than Internet route registries [23].

It should be noted that this procedure has the following caveats:

1. The initial TTL value of the injected packet may not be one of the common default values. In such cases, this analysis can not be carried out. In particular, based on the TTL values of the injected packet, we conclude that this is indeed the case for the injections in the groups 'jiathis', 'uyan', 'mi-img', and 'icourses'.
2. Not all routes on the Internet are symmetric. If the path from the client to the server is not symmetric, the analysis will produce an incorrect result. We address this issue in the next subsection.
3. The implicit assumption of this procedure is that the injecting machine resides on-path. Strictly speaking, this need not be the case. An on-path machine monitoring the traffic can trigger the injection from a remote machine. In such a case the forged packet will travel on an entirely different path than the legitimate packets.

In Table 3 we list the results of the above analysis. For each injection group, we list the autonomous systems

AS number	Operator
17816, 4837	China Unicom
4134, 4812	China Telecom
38182	Extreme Broadband (Malaysia)
6943	Information Technology Systems (US)

Table 4: The operators for each suspected injecting autonomous system

in which the destination sites reside and the autonomous systems suspected of the injections. The table lists only injection groups for which the analysis can be performed; namely, the estimated number of hops the injected packet traversed is not larger than 30 and not smaller than 3, and it is also not larger than the path between the client and server.

In all cases where the above analysis succeeded, it indicated that the forged content was injected 2-5 hops away from destination site. Since the injection groups are largely independent we believe that this is a signal that the assumptions we made throughput the above analysis are not far off. In all cases the injector is located in the very same autonomous system where the destination site resides. Indeed, this is the most reasonable location for an injector to be in order to alter content for all web users accessing the targeted site.

Table 4 lists for each suspected injecting autonomous system the organization that operates it. It is worth noting that two of the largest network operators in China – China Unicom and China Telecom – are suspected of practicing content injections. Moreover, the autonomous systems of these operators originate injections of different groups. This might imply that more than one injector mechanism is deployed in these autonomous systems.

The operator of the suspected autonomous system for the 'gpwa' group is Information Technology Systems. In this particular case, this is the organization that is responsible for the content of the destination site for these injections – gpwa.org. Since there are strong indications that the injections of this group are malicious (see discussion in Section 5.1), we assume that the attacker compromised a router in the suspected autonomous system.

Using a traceroute from the server-side

As noted above, a caveat of the above analysis is that we used traceroutes from the client to the server while assuming this route is symmetric. This is a necessity since we cannot execute a traceroute to the client from the actual server. To address this caveat we leveraged RIPE Atlas [26]. This is a global network comprised of thousands of probes hosted throughout the Internet. Each probe can

AS number	Injection groups
4812	tupian
4134	szzhengan, server erased
4808	uyan, icourses, jiathis

Table 5: Autonomous systems which host RIPE Atlas probes and the corresponding injection groups that forged traffic of web servers residing in those autonomous systems

be instructed to execute a measurement out of a predetermined set that includes ping, DNS query, HTTP request and traceroute. RIPE Atlas hosts 6 probes in 3 autonomous systems that host destination sites the content of which was forged. The autonomous systems and the corresponding injection groups that forged content for destination sites residing in each autonomous system are listed in Table 5.

For each of the 6 probes we executed a traceroute from it to the edge network where the corresponding injection events were identified. We then employed the procedure we described above on these new traceroutes. We note that using these traceroutes may still not be without error. The probes indeed reside in the autonomous systems that host the destination site; however, we cannot guarantee that their route to the client is the same as the route from the destination site. Specifically, the traffic from the probe may exit the autonomous system through a different point than the traffic originated from the site.

The traceroute from each of the 3 autonomous systems to the corresponding edge network were *different* than the opposite routes from the edge networks to those autonomous systems. Nonetheless, in all cases, a pair of routes in opposite directions traversed the same autonomous systems with the exception of one Tier-1 autonomous system; namely, each route traversed a different Tier 1 operator (for example, the route between the client and the server traversed Level 3’s AS while the route in the opposite direction traversed Cogentco’s AS). The other autonomous systems on the routes were the same; this is why the outcome of the analysis with these routes was the same as for the routes in the opposite direction. The analysis for the ‘szzhengan’ and ‘server erased’ injections yielded the same suspected autonomous system – 4134, while the analysis for the ‘tupian’ injections yielded a different autonomous system – 4134 instead of 4812 found by the previous analysis. Nonetheless, these autonomous systems are siblings operated by the same company – China Telecom.

The injecting groups that correspond to destination sites residing in autonomous system 4808 – ‘uyan’, ‘icourses’, and ‘jiathis’ – were set with an unknown ini-

tial TTL value (namely the estimated number of hops was larger than 30 or smaller than 3); hence the analysis cannot be performed on them.

6 Proposed Mitigation

The best mitigation against TCP injection attacks is simply to use HTTPS. Unfortunately, this is not always subject to the discretion of the user. Many web sites still do not support HTTPS [5]. A user wishing to access a website that does not support HTTPS must resort to the unprotected HTTP. Moreover, about 17% of the Alexa Top 500 websites still serve a login page over HTTP but submit the users password over HTTPS [30]. This setup allows an on-path entity to steal a user’s login credentials by injecting a false login page. In this section we present a client-side mitigation measure that monitors the incoming HTTP traffic and blocks injected forged TCP segments, thereby defending the user even if he must use HTTP.

A naive mitigation measure is to simply apply the procedure described in Algorithm 1 on the monitored traffic in order to identify packet races. Nonetheless, such an approach means that every incoming packet must be delayed for 200msec. Such a delay is necessary in order to make sure a given packet is not an injected packet forging a legitimate one. Only after 200msec have passed with no race detected can we accept the packet. Such an approach incurs noticeable delay on the incoming traffic and degrades the user’s browsing experience. This approach, however, by definition, ensures that all injected packets will be identified and blocked. In Section 6.1 we detail our experimental results with such an approach. We use these results as a benchmark for the next mitigation approach.

An improved approach is to take advantage of the insights we presented in Section 5.2, where we showed that for the vast majority of the injected packets, the values of the TTL and Identification fields in the IP header do not correspond to the respective values of the legitimate packets of the session. This insight can be leveraged to improve the naive mitigation measure such that only packets with abnormal TTL or Identification values will be delayed for 200msec, and only for those packets will we try to detect a race. This way only suspicious packets are delayed.

Algorithm 2 in Appendix E details the improved mitigation algorithm. Note that this algorithm will be effective only if the forged packets exhibit anomalous TTL or Identification values as compared to the legitimate packets in the injected session. We note that it is possible for an injector to inject a packet with values that will not appear anomalous, as in most likelihood it can also inspect the traffic sent by the web server. Anomalous TTL

and identification values have also been observed in the censorship-related state-sponsored injections [8]. This indicates that aligning the TTL and identification values to the legitimate values might not be trivial to implement. Indeed, aligning the identification value requires that injector keep track of the identification values of packets sent by the web server for every potential session that may be injected, well before the actual injection decision is made. This may require a substantial addition of memory space and computational overhead. If the injector does align the TTL and identification values, the improved mitigation algorithm we propose will not be effective and the naive approach must be used.

6.1 Experiments

We now detail our experiments to evaluate the two mitigation algorithms – the naive and improved algorithms. We evaluate the algorithms using two measures:

1. Web page load time increase – this measure shows the increase of time it takes to load a web page as compared to the case where no mitigation measure is employed. This measures the extent to which the algorithm degrades the user’s experience.
2. False negatives – this measure counts how many injections are not identified. This measures the effectiveness of the algorithm.

We evaluated the algorithms against two data sets:

1. Benign data set – this data set includes traffic of benign web browsing having no content injection. We used the 200 most popular sites from Alexa’s list [1]. From these sites we used the ones for which majority of their objects are fetched using HTTP (rather than HTTPS). There are 136 of these sites that met this criterion.
2. Injected data set – This data set includes the injected sessions we captured throughout our observations.

The two algorithms were evaluated on the benign data-set to measure the web page load time increase. We browsed each website using PhantomJS. We inspected the incoming traffic while leveraging the NFQUEUE target of Linux iptables [6]. We measured the load time of each website 5 times and recorded the smallest load time value to disregard intermittent network delays. We compared these load times to the load times where no mitigation algorithm is deployed.

The two algorithms were evaluated on the injected data set to measure the false negative events, i.e., the injections that were missed. Table 6 summarizes the findings. It is evident that the naive algorithm imposes

Algorithm	Load time increase	False Negative
naive	120%	0%
improved	12%	0.3%

Table 6: The performance of the two mitigation algorithms.

a considerable increase in page load time – 120%. In contrast, the improved algorithm incurs a mere 12% increase, while having a negligible false negative rate of 0.3%.

7 Related Work

The practice of Internet traffic alteration has been studied in several works [20, 34, 28, 39], all of which have employed the server-centric approach described in the Introduction.

In [20, 34] the authors deployed a website that directs users to about 20 back-end servers that deliver a Java applet. The applet runs a series of tests which try to fetch predetermined content. The analysis found many web proxies of several categories, the most popular of which are anti-virus software installed on the end clients, HTTP caches and transcoders deployed by ISPs, and security and censor proxies deployed by enterprises and countries. Ref. [34] identifies two ISPs that employ HTTP error monetization, and one that injects advertisements into all HTTP connections.

In [28] the authors set up a web server that delivers the same content from a handful of different domains. The content includes a JavaScript code that runs when the page is loaded in the client’s browser and reports any detected changes to the web page. It found that most changes to the content were made indiscriminately regardless of the originating domains. Most of the content modifications were due to software installed locally on the end clients or due to security gateways deployed at enterprises. Other modifications were due to ISPs that compressed content delivered to their users. Additionally, 4 ISPs and a company that provides free wireless service were identified as injecting advertisements to web pages their customers visit.

In [39] the authors leveraged the online advertising infrastructure of several ad networks to spread a specially crafted Flash-based advertisement that runs a JavaScript code and retrieves a preconfigured measurement page while reporting back any change made to it. Almost 1000 page alteration events were detected; however, the portion of events for which ISPs are responsible is unknown.

The authors of [38] investigate inflight modifications of traffic from an unnamed popular Internet search ser-

vice. In contrast to the abovementioned works, here the changes were detected by the IP address the client contacted, which was different than the addresses owned by the search service. This work found 9 ISPs that proxy their customers' traffic destined to the search service. The redirection to the proxy is done by resolving the DNS name of the service to the IP address of the proxy.

A considerable body of work deals with censoring countries and the mechanisms they use to censor Internet traffic. The authors of [33] have categorized the mechanisms of the censorship employed by different countries. It is noted that China and Thailand use out-of-band devices to send forged packets, which are usually HTTP 302 redirection, or a TCP reset.

In [35] it was shown that several ISPs enforce usage restrictions of their networks by actively terminating undesirable TCP connections. The authors note that this is done by sending forged TCP resets out-of-band. They then leverage this insight – much as we do in the current work – to identify these forged resets. Nonetheless, the detection conditions are different than the ones we used since the forged TCP reset has no payload to spoof; hence, the detection conditions mainly revolve around the arrival time and sequence number of the reset segment as compared to those of other segments in the connection.

The authors of [13] discuss attacks that employ out-of-band injection of forged DNS responses. To mitigate the effects of such attacks it is suggested that the resolver wait after receiving an initial reply to allow a subsequent legitimate reply to also arrive. In particular, the resolver should wait for another reply if the first reply arrived sooner than half of the expected RTT since the query was issued or if the TTL field in the IP header does not have the expected value. If indeed two replies eventually arrive, this indicates an attack.

8 Conclusions

In this work we reveal a new side to the practice of false content injection on the Internet. Previously, discussion on this practice focused on edge ISPs that limit their misdeeds to the traffic of their customers. However, we discovered that some network operators inject false content to the traffic of predetermined websites, regardless of the users that visit them. Our work leverages the observation that rogue content injection is done out-of-band. It can hence be identified while monitoring an edge network in which the victim clients reside. Our analysis is based on extensive monitoring of a large amount of Internet traffic. We reveal 14 groups of content injections that primarily aim to impose advertisements or even maliciously compromise the client. Most of the financially-motivated false content injection we observed originated

from China. Our analysis found indications that numerous injections originated from networks operated by China Telecom and China Unicom – two of the largest network operators in Asia.

Acknowledgments

We would like to thank Hank Nussbacher and Eli Beker, whose cooperation made this research possible. We also thank Erik Hjelmvik for his efforts to independently reproduce the injections.

A “Ack storm” due to TCP Injection

An “Ack storm” occurs when the injected segment causes the receiver to send an acknowledgment for data bytes having sequence numbers that were not yet sent by the peer. This acknowledgment is dropped by the peer, triggering it to respond by resending an earlier Ack, which may in turn trigger a retransmission by the receiver. The retransmitted segment will include again an acknowledgment for the yet to be sent sequence numbers and so forth. Such a “ping-pong” exchange, if run long enough, will cause the connection to timeout and reset. In many cases this is undesirable for the injector as it will interfere with the flow of traffic on the connection. An “Ack storm” can subside if the peer eventually sends data bytes having sequence numbers that correspond to those of the forged data bytes injected by the third party.

B Injection Detection Algorithm

Algorithm 1 details the procedure for detecting packet races. This algorithm is executed by each worker process upon the receipt of a new packet. In the following, CP denotes the currently received packet and S denotes the set of packets received so far as part of the session of CP . $P(f)$ denotes the value of parameter f of packet P . If parameter f is a field of TCP or IP, it is denoted by the protocol and field names, e.g., $P(IP_total_length)$ denotes the value of the field Total Length in the IP header of packet P . The algorithm returns True if and only if a race is detected.

In Algorithm 1, line 1 iterates over the previously received packets of the current session. Line 2 verifies that the two considered packets have been received within a time interval that does not exceed the parameter $MaxIntervalTime$. Lines 5 and 6 compute the total lengths of the TCP and IP headers of each of the two packets. Lines 7 and 8 compute the payload size of each of the two packets. Lines 9 and 10 compute the TCP sequence number of the last byte delivered in the payload in each of the two packets. Lines 11 and 12 check for a sequence number overlap between the two packets. Line 15 checks whether the overlapped payload is different. If it is, a race is detected and the algorithm returns True.

To avoid false positives, we did not consider the following packets (not shown in Algorithm 1):

1. Checksum errors – packets that have checksum errors either in the TCP or IP headers will clearly have

```

Input: CP, S
1 foreach  $OP$  in  $S$  do
2   if  $CP(t) - OP(t) > MaxIntervalTime$  then
3     | continue;
4   end
5    $CP(headers\_size) = CP(IP\_header\_length) + CP(TCP\_data\_offset)*4;$ 
6    $OP(headers\_size) = OP(IP\_header\_length) + OP(TCP\_data\_offset)*4;$ 
7    $CP(payload\_size) = CP(IP\_total\_length) - CP(headers\_size);$ 
8    $OP(payload\_size) = OP(IP\_total\_length) - OP(headers\_size);$ 
9    $CP(top\_sequence\_number) = CP(TCP\_sequence\_number) + CP(payload\_size);$ 
10   $OP(top\_sequence\_number) = OP(TCP\_sequence\_number) + OP(payload\_size);$ 
11  if  $CP(top\_sequence\_number) > OP(TCP\_sequence\_number)$  then
12    if  $OP(top\_sequence\_number) > CP(TCP\_sequence\_number)$  then
13       $bottom\_overlap = MAX(CP(TCP\_sequence\_number), OP(TCP\_sequence\_number));$ 
14       $top\_overlap = MIN(CP(top\_sequence\_number), OP(top\_sequence\_number));$ 
15      if  $CP(TCP\_payload)[bottom\_overlap:top\_overlap] \neq$ 
16         $OP(TCP\_payload)[bottom\_overlap:top\_overlap]$  then
17          | return True;
18        end
19      end
20    end
21  end
22 return False;

```

Algorithm 1: Race detection algorithm

a different payload than that of their retransmission.

2. TCP reset – reset packets can carry data payloads for diagnostic messages which are not part of the regular session’s byte stream.

C False Positives

There were numerous events in which the race identification algorithm (described in Appendix B) of our monitoring system identified a race that was not due to a forged packet injection. In the following we describe these events and why they occur:

Retransmissions with different content As per the TCP specification [27], the payload of retransmitted segments must have the same content as the payload of the original segment. In practice, however, this is not always the case, and retransmitted segments sometimes carry slightly different content, for the following reasons:

- Load balancing – some websites serve HTTP requests using more than one server. Usually, a front-end load balancer redirects the HTTP requests according to the current load on each web server. It is sometimes desirable that the same server serve all HTTP requests coming from the same client. To facilitate this, the first HTTP response sent to

a client sets a cookie containing the identity of the server chosen to serve the client from now on. Subsequent requests from that client will include this server ID and allow the load balancer to redirect those requests to that server. If the first HTTP response needs to be retransmitted, some load balancers might, at the time of the retransmission, choose a different web server than the one they originally chose when the response was first transmitted. This results in a different cookie value set in the retransmitted response. Examples of websites that exhibit such behavior are wiley.com and rottentomatoes.com.

- Accept-Ranges HTTP header – the HTTP 1.1 specification [15] allows a client to request a portion of a resource by using the Range header in the HTTP request. It may do so in cases where the web server has indicated in previous responses its support of such range requests. Such support is indicated by the Accept-Ranges header. We observed cases where a web server sent an HTTP response which included 'Accept-Ranges: none', indicating that the server is unwilling to accept range requests, while in a retransmission of the same response the header was replaced by 'Accept-Ranges: bytes', indicating that it is willing to accept range requests having units of bytes. This happened when the retrieved

resource spanned multiple TCP segments. Presumably, the intention of the server is to allow the client to retrieve a portion of a resource when network loss is high. Examples of websites that exhibit such behavior are `sagemath.org` and `nih.gov`. Furthermore, such behavior was exhibited by several types of web servers, including Apache, nginx and IIS.

- Non-standard HTTP headers – we have observed that in some web applications that use non-standard HTTP headers (namely, headers that begin with 'x-'), a retransmission of an HTTP response has different values for these headers than their value in the initial response. For example, Amazon's S3 service includes in every response the headers 'x-amz-id-2' and 'x-amz-request-id', which help to troubleshoot problems. These headers have a unique value for each response even if it is a retransmission.

Retransmissions with different sequence numbers
For a few websites we encountered sessions in which a retransmitted TCP segment started with a sequence number that was offset by 1 compared to the sequence number of the original segment. This might occur due to a bug that caused the unnecessary incrementation when a FIN segment was sent between the original and retransmitted segment. There were no indications in the HTTP responses as to the type of software executed by those web servers. This unnecessary incrementation might also be an artifact of a middle-box that serves the traffic to those servers. An example of a website that exhibits such behavior is `www.knesset.gov.il`.

Non-compliant TCP traffic We encountered many TCP sessions (over port 80) which do not appear to have originated from TCP-compliant nodes. There was no proper 3-way handshake to open the session, the acknowledgment did not correspond to the actual received bytes, flags were set arbitrarily, and the sequence numbers were not incremented consecutively. This last point led our monitoring system to flag many of these sessions as injected sessions. Many of these sessions included only unidirectional incoming traffic that originated from a handful of networks primarily residing in hosting providers (such as GoDaddy and Amazon). We suspect that these are communication attempts by a command and control server to its bots. However, we have no proof of this.

D Attempts to Mimic the Identification Values of the Legitimate Packet

In the following we account for some of the failed attempts we observed in which the injecting entity tried to

mimic the identification value of the legitimate packet. Note that in order to increase the chances of winning the race with the legitimate packet, the forged packet is injected well before the injecting entity has a chance to inspect it. For this reason the injecting entity can not simply copy the identification value of the legitimate packet to the forged one.

1. Duplicate ID with a packet from the server – in some cases the injecting entity tries to mimic the identification values of the packets sent by the server to make the forged packet less conspicuous. Sometimes this is done rather carelessly by simply copying the identification number of one of the packets the server already sent (not the legitimate packet the entity wishes to forge). This means that the client receives two IP packets from the server having the exact same identification number. This situation is highly unlikely to occur without the intervention of a third party in the session, as the IP layer of the server must make sure that each packet in the session has a unique identification value.
2. Duplicate ID with a packet from the client – in different attempts to, perhaps, mimic the identification values of the packets sent by the server, some injectors simply copy an identification value from the HTTP request packet that triggered the response. Since this packet is, of course, sent by the client, the injector cannot achieve its goal; the identification values of the packets sent by the client are completely independent of those sent by the server. We can use this to our advantage. It is possible but unlikely that two packets – one sent by the server and the other by the client – have the same identification value.
3. Swapped bytes of an ID in packets coming from the client – we noticed that at least one injector that aims to copy the identification value from a packet coming from the client (as described in the previous rule), does so in such a way that the two bytes of the copied values are swapped. For example, if the identification value of a packet coming from the client is 0xABCD, then the identification value of the injected packet will be 0xCDAB. This is probably due to a bug of the injector⁶. Occurrence of such an event is highly unlikely without third-party intervention.

E Improved Mitigation Algorithm

Algorithm 2 details the proposed mitigation algorithm. The algorithm is executed upon the receipt of a new in-

⁶Most likely the bug is a case of big endian/little endian confusion.

```

Input: CP, S
1 if Check_Race(CP,S(Suspicious_Queue)) then
2   | Block suspicious packet;
3 end
4 Suspicious = False;
5 if abs(CP(IP_TTL)-S(Average_TTL)) > 1 then
6   | Suspicious = True;
7 end
8 Lower_ID_Boundary = (S(Last_ID) - 10)%216;
9 Upper_ID_Boundary = (S(Last_ID) + 5000)%216;
10 if CP(IP_ID) < Lower_ID_Boundary or CP(IP_ID) > Upper_ID_Boundary then
11   | Suspicious = True;
12 end
13 if Suspicious == True then
14   | S(Suspicious_Queue).append(CP);
15 end
16 else
17   | Update S(Average_TTL) with CP(IP_TTL);
18   | S(Last_ID) = CP(IP_ID);
19   | Accept CP;
20 end

```

Algorithm 2: Mitigation algorithm

coming packet – CP . As in Algorithm 1 above, S denotes the session of CP . $P(f)$ denotes the value of parameter f of packet P . If parameter f is a field of TCP or IP, it is denoted by the protocol and field names, e.g., $P(IP_ID)$ denotes the value of the field Identification in the IP header of packet P .

The algorithm maintains a queue of packets that are suspected of being forged. The incoming packet is first checked against the suspicious packets for a race. If a race is detected, the suspicious packet is blocked. Afterward, the TTL of the incoming packet is compared against the average of TTL values of the previous packets received in the same session. If the difference is larger than 1, then the packet is marked as suspicious. The packet is also marked as suspicious if its Identification value is higher than 5000 plus the Identification value of the previously received packet of the session or lower than that value minus 10. The rationale behind this comparison is that we generally expect the Identification values of the session be monotonically increasing, except in cases of packet reordering. If the packet is marked as suspicious it is enqueued to the suspicious queue for 200ms. If the packet is not suspicious the value of the average TTL and last ID are updated and the packet is accepted.

Note that a race will not be identified if the injected packet arrives *after* the legitimate one. This is because the legitimate packet will not be delayed, and once the inject packet is received it will not be checked for a race against the legitimate one. Nonetheless, this does not

compromise the security of the client since in this case the content of the injected packet will not be accepted by the client’s TCP layer.

The Ever-changing Labyrinth: A Large-scale Analysis of Wildcard DNS Powered Blackhat SEO

Abstract

Blackhat Search Engine Optimization (SEO) has been widely used to promote spam or malicious web sites. Traditional blackhat SEO campaigns often target hot keywords and establish link networks by spamming popular forums or compromising vulnerable sites. However, such SEO campaigns are actively disrupted by search engines providers, making the operational cost much higher in recent years. In this paper, we reveal a new type of blackhat SEO infrastructure (called “*spider pool*”) which seeks a different operational model. The owners of spider pools use cheap domains with low PR (PageRank) values to construct link networks and poison long-tail keywords. To get better rankings of their promoted content, the owners have to reduce the indexing latencies by search engines. To this end, they abuse *wildcard DNS* to create virtually infinite sites and construct complicated loop structure to force search-engine crawlers to visit them relentlessly.

We carried out a comprehensive study to understand this emerging threat. As a starting point, we infiltrated a spider pool service and built a detection system to explore all the recruited SEO domains to learn how they were orchestrated. Exploiting the unique features of the spider pool, we developed a scanner which examined over 13 million domains under 22 TLDs/SLDs and discovered over 458K SEO domains. Finally, we measured the spider-pool ecosystem on top of these domains and analyzed the crawling results from 21 spider pools. The measurement result reveals their infrastructure features, customer categories and impact on search engines. We hope our study could inspire new mitigation methods and improve the ranking or indexing metrics from search engines.

1 Introduction

To most people, search engine is the entrance to all sorts of web sites on internet. The traffic volume generated through search engines is huge: the number one search engine Google receives 3.5 billion search queries per day [46] and the subsequent visits referred by the search results can account for more than 60% of the incoming traffic of a website [55]. Improving sites’ search rankings and attracting crawlers to visit them frequently are very important to their owners.

Site owners and researchers have done extensive studies and come up with a set of “golden rules” on how to improve one site’s performance in search results, which are also called *Search Engine Optimization* (SEO) techniques. Some SEO techniques aim to improve the site structure (*e.g.*, providing navigation in HTML pages) and search affinity (*e.g.*, adding descriptive keywords to titles and metadata). They are termed “whitehat SEO” techniques and are encouraged by search engine providers. However, applying these techniques usually requires great effort from site owners and the effects are not always immediate. As a shortcut, “blackhat SEO” techniques are developed, which exploit the blind side of search-engine algorithms and gain a site big advantage in search results at low cost.

Traditional blackhat SEO practices recommend stuffing keywords and injecting inbound links into reputable sites. While the first method can be achieved just by manipulating the site’s content, the second one is much more difficult because it requires changing content on other reputable sites which are not under SEOer’s control. Common approaches towards this goal include posting spam links in forums [43], compromising sites to inject links [24, 51], buying links from link exchange services [54], and constructing link network using ex-

pired domains with high PR (PageRank) value [15, 16]. These techniques, nevertheless, require big investment (*e.g.*, buying links and expired domains) and could result in severe penalties from search engines (*e.g.*, when the SEOer is found to use compromised sites).

New blackhat SEO techniques. Instead of contesting high rankings of trending keywords which are often dominated by top-brand sites, SEOers start to target the search queries containing *long-tail keywords* and tunnel the traffic to their sites [32]. Long-tail keywords are usually overlooked by big sites because the traffic towards each keyword is quite limited. However, the traffic combined from many such keywords can be substantial, which motivates SEOers to launch campaigns targeting them. The sites competing long-tail keywords usually have low PR value, leading to infrequent visits from search-engine crawlers and long waiting time before being indexed (*i.e.*, site is shown in search results) [18]. To increase the chance of being crawled, new blackhat SEO strategy is proposed to feed infinite hyperlinks to crawlers which all point to the sites under SEOer’s control. When a crawler enters SEOer’s network, it will be *trapped* and keep crawling the content fed by the SEOer.

To escape from such network, a crawler can check if it keeps visiting a fixed set of sites and exit when this happens. This is actually enforced by many search engines. As a countermeasure, SEOers can create a massive number of fresh sites for the crawlers to foil the check, and it turns out *wildcard DNS* perfectly serves this purpose. A site with wildcard DNS toggled on can redirect visits landing on its subdomains (*e.g.*, `aaaa.example.com`) to itself (*e.g.*, `example.com`). Leveraging this technique, SEOers can create unlimited number of virtual sites under only one valid domain name. This new attack clearly harms search engines, as the crawling resources are wasted and search results are manipulated.

This novel approach quickly gains popularity in the blackhat SEO community, especially in China. The infrastructure built upon wildcard DNS domains is called *spider pool* in China (“蜘蛛池” in Kanji)¹ and has been broadly discussed in underground forums. In this study, we aim to provide the first comprehensive study of this new threat in hopes of inspiring new methods for mitigation.

Our study. In order to understand the spider-pool infrastructure, we reached out to an owner of a spider pool in operation and purchased SEO service to promote a site created by us. Playing as a customer enabled us to infiltrate the spider pool and discover unique features regarding its infrastructure. In particular, we found wildcard DNS was extensively used on each site and dynamic

¹Such infrastructure may be named differently in SEO communities of other countries. We use spider pool to represent all variations for brevity.

content generation was fully automated. We also discovered a new promotion technique which has never been reported by previous research. The adversaries are able to advertise their messages through very popular sites, like `amazon.com`, without compromising or even spamming them.

Exploiting the DNS and content features of spider pool, we developed a scanner based on DNS probing and differential analysis. We used this scanner to examine 13.5 million domains under 22 TLDs and SLDs. The result is quite alarming: we identified 458K spider pool domains distributed among 19 TLDs/SLDs. In addition, we discovered a trend of misusing new gTLD domains for this type of SEO and also policy holes for domain registration process of `.ac.cn` SLD. We measured these domains in different aspects and show statistics regarding their hosted IPs, domain registrars and registrants. We found that though the domains are spread over 28K IPs, they are rather centralized on a small set of ASNs, registrars and controlled by a small group of SEOers.

Finally, we extended our study and crawled 20 new spider pools using seed domains detected by our scanner, to study their business model and impact on search engines. As a result, we identified 15.8K SEO domains, 1.4K customer domains and 7.2M URLs embedding customer messages. The study on the business model revealed new categories of customer’s business that are never reported before. Our results also suggest that spider pool is clearly effective in attracting search crawlers and manipulating search results under long-tail keywords. Baidu, the top search engine vendor in China, has acknowledged our findings and we are now collaborating with Baidu to deploy detection system to purify search results and capture spider pool services.

2 Background

In this section, we first overview the factors affecting search rankings and indexing delay of a website. Then, we survey widely used blackhat SEO techniques and their infrastructures which aim to promote a website’s ranking unethically.

2.1 Search Engine Optimization

The goal of search engine is to provide a user with a list of web pages that are *relevant* to search keywords and ranked by their *importance*. Although ranking algorithm is considered as the topmost secret by search engine providers and is never released, guidelines and techniques called *Search Engine Optimization (SEO)* are developed from white-papers published by the providers, extensive experiments and reverse engineering [17, 20, 44]. Whitehat SEO advocates improving the structure of a site to make it more friendly to search crawlers. Advices include adding targeted key-

words to webpage (document body, title, meta tags and page URLs), creating navigation page (*e.g.*, a sitemap file) to guide crawler, avoiding repeated page content, and frequent content update. Improving the site’s quality also increases the chance of being referred by other web sites, which in turn increases its *PR* (*PageRank*) value.

In addition to gaining high rankings in relevant search results, it is also important to reduce the indexing delay of a page. The more frequently a web site is visited by search crawler, the faster its pages will be indexed (*i.e.*, shown in search results). The visit frequency is mainly determined by the PR value [18], meaning that a new web site might have to wait for a long time to be indexed and displayed under search terms it targets.

While most of the web sites attempt to get good rankings under hot keywords, the cost is always high. Instead, targeting *long-tail keywords* might help the site harvest a large volume of traffic without big spending [32]. As an example, to get top ranking under the search results of “socks” is challenging, but achieving so for “socks with dogs on them” or “socks that knock my socks off” is much easier. In fact, the traffic querying long-tail keywords can account for 70% of all traffic to a search engine [10]. So, long-tail keywords are also important for web sites.

2.2 Blackhat SEO Techniques

Tuning the factors that improve site’s quality is allowed by search engine companies. However, unethical adversaries also develop techniques (*i.e.*, *Blackhat SEO*) to gain advantages in search results at low cost by gaming ranking algorithms. We describe known techniques as follows:

Content spam. Since the number of keywords contained in a web page and URLs play an important role in computing the ranking score, an adversary can either repeat the same keywords to increase the relevance to search terms of the same category, or include a spectrum of trending keywords to associate the site with many search terms of different categories (also named *search poisoning* [31]). Recently, Google starts to penalize web pages with excessively repeated contents, which forces the SEOers to use a new technique called *spinning* to generate spam texts with similar meaning but different appearances [57]. A set of SEO toolkit is developed to automate this process, like *XRumer* [6].

Link farm. To accumulate a large number of incoming links to a web site, an adversary can set up *link farm* [8, 53] which exploits the vulnerabilities of other reputable sites to inject link. We show more details about this blackhat SEO infrastructure in Section 2.3.

Cloaking. Blackhat SEO is becoming one popular channel for malware and scam delivery. Cloaking technique is leveraged to serve benign content to search engines

while malicious content to normal visitors, in order to avoid being detected [50]. User agent, *referrer* field in HTTP header, and IP address are inspected to determine if the request is from a real browser or a search engine crawler.

2.3 Blackhat SEO Infrastructures

The number and quality of incoming links are key factors for the effectiveness of a SEO campaign. The adversary needs to have a large number of incoming links at disposal to elevate the site’s popularity. Different blackhat SEO infrastructures on organizing the links have been discovered and they are described below.

Forum spam. Web forum accepts and displays posts contributed by web users, and the posts are also crawled by search engines. A forum with high reputation is prone to be abused by attackers who post links to promote their sites [37]. Moreover, blog sites allowing comments are also likely to be spammed by the similar techniques. As a mitigation strategy, a site can set the *rel* attribute of external links as *nofollow* to stop disseminating reputation score to spam links [20], or request CAPTCHA solving before comments are posted.

SEO botnet. The adversary has limited privileges in posting spams to forum/blog. To overcome such restrictions, attackers could choose to compromise vulnerable sites, turn them into botnet, and make them refer to the sites to be promoted. Later, when search engines visit the compromised sites and compute rank value, the promoted web site will get an unusual high ranking [24, 51]. Some SEO kits are developed to manage thousands of sites simultaneously, reducing attackers’ workload [2]. Knowing the existence of such infrastructure, search engine vendors are actively detecting compromised sites and removing sites promoted in this fashion. The compromised sites are also alarmed in search results to avoid being clicked by victim visitors [49].

Link exchange platform. There are also online forums and platforms helping website administrators to exchange incoming links and improve their sites’ rank mutually [54]. Examples include *sape.ru* [39] and *warriorforum.com* [52]. Link exchange through SEO forum and platform is explicitly forbidden by search engine companies like Google, which for example penalizes buyers of *sape.ru* [40]. This approach is also expensive for adversaries, because they have to buy links to maintain their faked popularity.

Private Blog Network (PBN). This is a new type of black SEO infrastructure. The adversaries first buy and set up many blog sites on a set of expired domains with high PR values, then construct link network carefully under their control, and finally inject outgoing links pointing to sites to be promoted [15, 16]. Expired domains

with high PR values are usually sold at high prices, so a large-scale and successful PBN could cost considerably [11].

3 Dissecting a Spider Pool Campaign

Since search engine vendors upgrade their ranking algorithm frequently (*e.g.*, Google updates its algorithm 500-600 times per year [42]) and demote sites engaged in blackhat SEO actively or even seize the back-end servers [49], attackers are forced to invent new ways to keep their business effective and profitable. In this section, we elaborate our study on “*spider pool*”, a new type of blackhat SEO infrastructure unreported by previous research.

3.1 Overview

All known blackhat SEO techniques ask for massive incoming links from reputable sites to increase the importance score of the promoted site under hot keywords, which are always competed by numerous sites. Inevitably, these techniques are very expensive. To reduce the cost, SEOers start to operationalize their campaigns under long-tail keywords, for which the competition is more relaxing. Though the search traffic flowing to an individual long-tail keyword is nominal, the volume accumulated for a large set is considerable.

Furthermore, new or expiring domains which are much cheaper are recruited to set up this SEO infrastructure. However, since the PR values of these domains are usually negligible, they cannot be directly used to boost the score of the customer sites they point to. This causes a big issue in indexing latency, as search engines prefer to crawl and index a page faster if it comes from sites with high PR value.

Instead of sitting and waiting for the search crawler to knock on the door, spider pool actively traps search crawlers. In other words, it keeps the crawlers visiting sites (sites of both SEOer and customers) within the border of attacker’s network.

How to trap a crawler. One intuitive approach to trap crawler is through link loop, but search engines have already adopted some algorithms to detect loops that are constructed intentionally. To evade detection, spider pool applies techniques including *creation of massive subdomains* and *generation of dynamic contents*. By adding a *wildcard DNS record* (as shown in Figure 1) to the authoritative DNS server, an adversary can configure the web server to feed the crawler whatever subdomain she wants to be visited (*e.g.*, `a.example.com`). The web page fed into the crawler is stuffed with spam links, which instruct the crawler to visit other subdomains (*e.g.*, `b.example.com`). In case the crawler skips the pages with the same content, the site could render page dynamically and provide distinctive content for each visit. Since

Host Name	Type	TTL	Data
*.example.com	Host (A)	Default	172.128.10.101

Figure 1: An example of wildcard DNS record.

the crawler always gets a “valid” page from a “valid” website, it will follow the spam links and keep visiting sites under adversaries’ control.

Effects. The major benefit through using spider pool is the boost of visiting frequency from search crawler, given that there are always new pages fed into them. It can also improve the importance score of the customers’ sites, as the incoming links from spider pool are massive. In addition, the number of indexed pages under customers’ sites can be increased as well.

Comparison with other SEO infrastructures. The price of buying new or expiring domain is much cheaper nowadays. As shown in `domcomp.com`, a web site listing domain prices, one can purchase a domain for only \$0.99 at some registrars [13]. This is a big advantage over PBN asking for expensive expired domains with high PR value, and over link exchange service for expensive links. In the meantime, attackers can easily change the underlying link structure, which outperforms forum spam in flexibility. Moreover, since the sites in spider pool are not compromised, they are less likely to be detected and alarmed compared to sites recruited by SEO botnet, as shown in Section 5.2.

Terms. For simplicity, throughout this paper, we use *domain* to refer to the domain name purchased by the adversary, which is different from *hostname* or *FQDN* that can be created randomly at her will through wildcard DNS. We call domains controlled by the spider pool owner *SEO domains* and pages with spam links *SEO pages*. The parties who use spider pool to promote their sites or messages (explained at the end of this section) are called *customers*.

3.2 Infiltration of a Spider Pool

To better understand the business model, features and operational details of a spider pool, we infiltrated one popular spider pool service provider called *super spider pool*². In this paper we use *SSP* to refer to this service. Different from *dedicated* spider pool which is built for a single customer, this is a *shared* spider pool which sells SEO service to customers publicly. It adds the URL provided by customers to its SEO pages after payment.

Purchasing spider pool service. We bought a domain³ and set up a web site with fake contents generated from template downloaded from `tttuangou.net`⁴. The web

²<http://www.zhizhuche.com>

³`his-and-hers.xyz`, bought on Oct 30th, 2015 from Godaddy.

⁴<http://tttuangou.net/download.html>

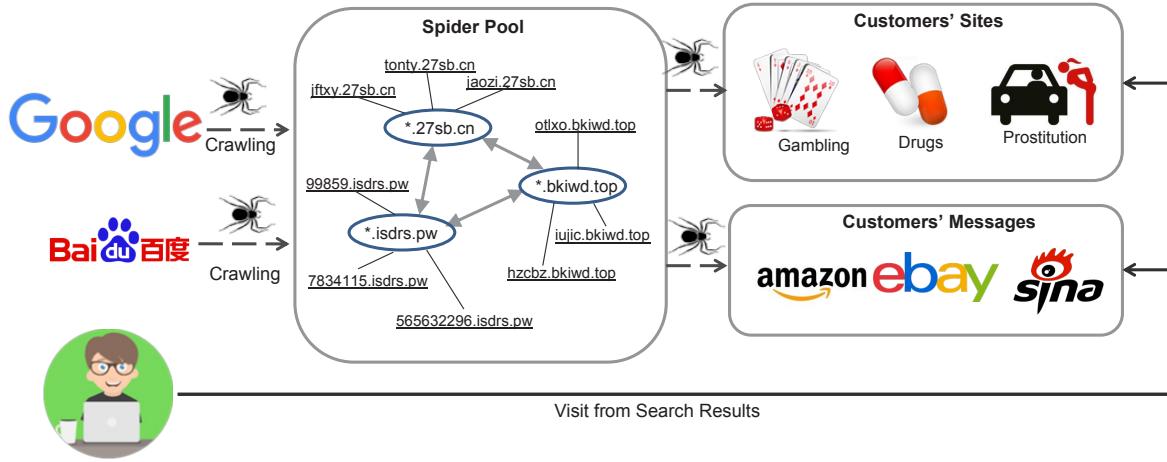

Figure 2: The infrastructure of a spider pool. The spider pool consists of new or expiring domains (*e.g.*, 27sb.cn) which leverage wildcard DNS to breed unlimited numbers of subdomains (*e.g.*, jftxy.27sb.cn). Subdomains under different domains are interconnected and the links are dynamically generated. When a search crawler approaches one subdomain, it will be trapped in the spider pool until being released to customers' sites or URLs bearing customers' messages.

Figure 3: The returned search results from Google (top 5 only) when querying using the homepage URL of our site. Except the No.1 result, all others are linked to SEO pages of SSP.

pages were modified to ensure there is no input box that accepts user's sensitive information (*e.g.*, credit card number) when a real user accidentally visits our site. Server logging functions were turned on to record information of incoming requests like time, user agent, IP address, and etc. We filtered out logs that do not belong to search crawlers using user agent patterns. Then, we registered an account in SSP, uploaded the homepage link, and started an advertising campaign of 14 days (from Nov 1st, 2015 to Nov 14th, 2015) for our testing web site.

Exploring spider pool infrastructure. Several days after starting our campaign, we searched the URL of our site in Google. The results are shown in Figure 3. Our URL was listed in the results, together with URLs of SEO pages set up by the spider pool. This finding motivates us to explore the whole spider pool infrastructure by iteratively sending queries to Google, which nevertheless turns out to be very time-consuming, as described in Appendix A. Therefore, we start to explore the infrastructure through other means. As discussed in Section 2.1, well-structured web site (*e.g.*, a site providing sitemap file) can be visited by crawlers frequently and indexed timely. We sampled several SEO domains and found this was also followed by SSP: a sitemap.html file was put under the root directory of every SEO domain to instruct the crawler to find other SEO or customer domains. An example of the sitemap file is shown in Figure 4. This feature motivates us to build a dedicated crawler which follows sitemap file to excavate sites belonging to SSP.

First, we feed a previously discovered SEO domain as a seed into Q (the queue of domains to be searched). Our crawler starts from requesting the sitemap.html under root folder and extracts all the links inside `<a href>` tags. The domains of the links which have not been visited will be appended to Q . The sitemap file is refreshed twice, to include domains added dynamically by the SEO toolkit. The crawler then visits the next domain in Q , checking if the domain is a SEO domain and extracting all other domain names, until there is no more domain left. With this approach, we are able to harvest a large number of domains in SSP under moderate time.

Figure 4: An example of sitemap file.

3.3 Features of Spider Pool

The preliminary exploration offers us a partial view of *SSP*, and we manually examined the domains included by *SSP* (we demonstrate how to automatically classify the domains in Section 3.4). In particular, we select the domains used for SEO and present the interesting findings below:

Wildcard DNS usage. As expected, wildcard DNS plays an important role in spider pool and greatly improves its scalability: the total number of SEO FQDNs is up to 44,054 but the number of SEO domains is only 514⁵. In other words, the size of the spider pool is inflated 86 times through this technique. We also find that DGA (Domain generation algorithm) is incorporated in domain generation: most of the fabricated subdomain names are 5-10 characters filled with random letters and digits (see domain names in Figure 2).

Content generation. The effects of wildcard DNS on SEO have been discussed by SEO community. In fact, replicating same pages under different subdomains will delay the indexing of legitimate content as Google considers the crawl budget is wasted on these site [14, 33]. However, if pages on subdomains are all distinctive, the site would not be penalized [3]. Therefore, spider pool site dynamically renders page content for each visit.

To understand how the content is generated, we inspected a copy of spider pool toolkit shared for free on a public cloud drive⁶. The SEO pages generated by this toolkit resembles the SEO pages of *SSP*. In fact, the toolkit includes a dictionary of long-tail keywords and text scraped from trending fictions, and randomly assembles keywords and sentences to construct the SEO pages. To make the page look more legitimate, the toolkit em-

Figure 5: An example of SEO pages within *SSP*.

beds images from the local storage. Another interesting discovery is that cloaking technique is not used, so the same contents are presented to both search crawlers and normal browsers. We verified that by manipulating the user-agent string of our crawler. Figure 5 shows an example of the SEO page.

Link structure. Each spider pool site provides a sitemap page (*sitemap.html*) to direct search crawler to visit other sites according to its intention. By connecting the discovered spider pool domains under linking relations, we find that a strongly connected graph can be constructed in which there exists a route from any domain to another. In addition, most of the links on a SEO page are swapped per visit. To a search crawler, such link structure looks like an *ever-changing labyrinth*: every step the crawler makes refreshes the whole link topology, so the crawler is always trapped till arriving at customer’s site. Leveraging this design, the customer’s site connected to the spider pool can be indexed much faster and updates on the site can be timely reflected in search results. For a site running illegal business, such feature is quite ben-

⁵We fold the FQDN to domain name using Public Suffix List [36]. For instance, www.abcd.example.com is folded to example.com.

⁶<http://pan.baidu.com>

Figure 6: An example of site free-ride.

eficial as it allows the site to appear quickly in search results before being taken down.

Domains controlled by adversary are limited and a search crawler can realize when it is trapped by checking if it keeps visiting the same set of domains. However, due to wildcard-DNS techniques, loop detection is much more difficult as a random FQDN can be easily generated and inserted into the path at any time.

Site free-ride. We also discovered a new type of promotion method developed to show customer’s message in search result. This is achieved through crafting a search URL under a popular site with message filled in query string and injecting it into the spider pool. Since some popular sites targeted by adversary display the query string in their search result no matter whether meaningful content is returned or not, the message embedded in query string will be fed into search crawler. Also due to the site’s high PR value, the indexing process is much faster and message is more likely to appear in top of search results. As an example, we found one Amazon search URL⁷ in a SEO page which contains a message for an illegal business (selling counterfeit certificate) with contact information (QQ number, one of the most popular instant messenger in China). Querying with the relevant keywords (“certificate for CET-4/6 qq” translated from Chinese) in Google returns the customer’s message at the top spot of search results (see Figure 6).

We call this SEO trick “site free-ride”, as the reputation of a popular site is abused by blackhat SEO while that site is neither compromised nor spammed at all, which makes detection rather difficult. In Section 5.3, we show many top sites are misused in this way.

3.4 Classifying Spider Pool Domains

Following the trail of sitemap, different types of domains are encountered, including SEO domains, customer site domains, domains abused for message promotion and other innocent domains. Though they can be distinguished through manual investigation, such approach is not scalable. Therefore, we developed a classifier to differentiate these cases automatically.

We started from identifying SEO domains. We found

⁷<http://www.amazon.com/s?ie=utf8&page=1&rh=%22%22> [MESSAGE]

that SEO domains are all powered by wildcard DNS. In addition, the page content is changed per visit while the content from other types of sites is much more stable. Therefore, we limited the scope to wildcard DNS domain and compare the sitemap files for two consecutive visits to determine if the domain was a SEO domain.

A problem we need to address here is how to measure the difference between two visits. We first attempted to measure the text difference between the two HTML pages, but we encountered a large number of false positives caused by dynamic content, *e.g.*, online advertisements. We improve this method by considering the difference of only hyperlinks between two pages. To discard small changes on URLs of hyperlinks customized to visitors, we normalize the URLs by removing the query parameters and values. Taking two pages P_A and P_B as an example, assuming the set of unique hyperlink URLs in P_A and P_B are H_A and H_B , we compute $\frac{|H_A - H_B|}{|H_A|}$ and $\frac{|H_A - H_B|}{|H_B|}$ respectively and then compare the maximum value to a threshold Min_H . If the maximum value is larger than Min_H , the domain is labeled as a SEO domain. We set Min_H to 20% based on the empirical tests and it renders good accuracy.

The above method worked well for exploring *SSP*. In Section 5.2, we tested 20 other spider pools using the same detector with small changes. We found the homepage is also used to guide search crawlers by some spider pools. Therefore, the homepage was also inspected by the detector.

After picking out SEO domains, our tool classifies the remaining domains to the following three types:

- The sites abused for message promotion are identified first by using the URL patterns related to search queries. By inspecting a large corpus of message URLs, we identify 45 URL patterns, like `/search/`, and use them to match all remaining URLs.
- Then, the innocent sites are identified by matching their domain names with Alexa top 1M site list. Though some of them may use spider pool, we believe the chance is small if they want to keep good reputation.
- The sites remained are classified as customer sites.

Our detection mechanism only relies on the feature on link structure and is robust against different templates and languages used by SEO pages. To evade our detector, the adversary could suppress the change rate of the SEO page for each visit, which however will make the link structure less dynamic and more likely to be detected by search engines. Another evasion is to disable wildcard DNS support on SEO domains. Although we

have found some spider pools are beginning to apply this change, the majority of the SEO domains are wildcard DNS powered, suggesting the adversaries are not planning to give up the benefits brought by wildcard DNS.

4 Detecting SEO Domains through DNS Scanning

Motivated by the findings from infiltrating *SSP*, we implemented a scanner aiming to discover and measure SEO domains of spider pool from an internet-wide view. Though the detector described in Section 3 is effective in enumerating SEO domains of spider pool, it highly depends on the seeded domains and the discovery is still limited. Instead, we launched large-scale DNS scanning to identify wildcard DNS domains and crawled their sitemaps and homepages. Then, we applied differential analysis to detect SEO domains, using the heuristics described in Section 3.4. The process is elaborated as follows.

4.1 Data Source

We cluster the SEO domains employed by *SSP* according to their TLDs and SLDs and examine their popularity. Unsurprisingly, a large number of domains are under old generic TLD (gTLD) like .com and country-code TLD (ccTLD) like .cn. Interestingly, we also found a noticeable number of domains under *new gTLDs* [45] like .xyz and *generic SLDs* like .com.cn [9]. In the end, we decide to scan domains under all these categories described above.

For each TLD or SLD under study, we attempt to gain access to its DNS zone file first. If zone file is not available, we resorted to the domain collection offered by third party and passive DNS data source. For .com, we downloaded zone file from Verisign in Dec 2015 through its TLD Zone File Access Program [47]. The unique count of domains is over 125 million and we sample 2 million (1.6%) for study. We also apply for the access to zone files of new gTLDs and several old TLDs through Centralized Zone Data Service (CZDS) managed by ICANN [23]. We obtained zone files from 10 registries for most popular new gTLDs in Dec 2015. The .cn zone file was retrieved from viewdns.info [48] in Dec 2015 (the zone file has over 5.5M domains, accounting for around 64% of all 8.6M .cn domains [12]). For the remaining TLDs, we searched passive DNS database provided by Farsight Security [41] and extracted domains from all A records within 2015. The list of TLDs and the statistics are shown in Table 1⁸.

⁸We did not find SEO domains under .gov, .edu, .edu.cn and .gov.cn in *SSP*. They are only scanned for comparison.

4.2 Detection System

To detect wildcard domains, we implement a DNS scanner to probe all domains (13.5 million) in our list. For any name (*e.g.*, a.com) in the list, our scanner issues a wildcard A record query (*.a.com) to its authoritative server directly, bypassing resolvers provided by local ISP. If we get a valid IP (same as the one used by a.com), we consider that the domain supports wildcard. To prevent ISP’s DNS wildcard injection with its web portal’s IP, we detect such behavior before our large scale probing, and filter out such IP address used by local ISP.

It is challenging to handle such large volume of domains we collected. To optimize the performance, we choose to issue DNS queries and process responses asynchronously. In particular, the scanner runs one thread unremittingly issuing DNS requests in UDP and another thread picking up matched DNS responses from incoming traffic. Our task was able to finish within 120 hours and we report the result in Table 1.

We obtained 2.4 million wildcard domains (17.8% of all scanned domains) after the scanning process and the next step is to determine which domains are used for spider pool. To this end, we use crawler to visit the sitemap (or homepage when sitemap is not available) of the root folder of each wildcard domain twice, then compare the hyperlinks using the same heuristics described in Section 3.4. The domains showing different set of hyperlinks are considered SEO domains. In the end, we captured 458K (19.1% of all wildcard DNS domains) such domains in total. This result suggests an unnegligible proportion of domains have configured wildcard DNS for SEO purposes.

We further classify the detected SEO domains based on how the pages are linked to customer’s content and identify three different types. All of them can be generated from the templates of known spider pool toolkits [22]. We elaborate each type in Appendix B. The number under each type is reported in #iframe, #link and #redir columns in Table 1.

Verification. Our detection system discovered a large amount of SEO domains and we want to know how accurate the outcome is. Counting the true positives among them accurately is nearly impossible because there is no off-the-shelf detection system we can use as the oracle and it will take massive human efforts to examine all of them. As an alternative, we sample 1,000 SEO domains at maximum per TLD/SLD and evaluate them to estimate the accuracy. We manually look into the title, page text and link structure, and compare them with known SEO pages from *SSP*. We consider one as true positive if these features resemble. We find the highest false-positive rate (FPR) per TLD/SLD occurs on .com, which is 1.2%. The main reason for the false positives is that many links

Total	-	-	13,504,022	2,400,938	458,246	92,388	62,576	303,282

on the pages lead to the advertisements which are also changing for each visit. We do not find any false positive under .ren, .link, .party and .click. The FPR for all domains is 0.8%, suggesting that our detector is quite effective.

4.3 Detection Result

As shown in Table 1, the number of wildcard DNS domains and SEO domains distributes unevenly across different TLDs and SLDs. We elaborate our findings for old TLDs, new gTLDs and generic SLDs separately below:

Old TLD. Among old TLDs open for general registration, including .cc, .pw, .com and .cn, we observe a large number of wildcard DNS domains taking unnegligible portion (ranging from 9% to 66%). The number of wildcard DNS domains abused for spider pool is also large, consisting of more than 200K .cn, 30K .com, 10K .cc and 40K .pw domains. The ratio of SEO domains under .pw (17.7%) is much higher than other TLDs. It is reported that .pw domains are extensively used for email spam [38] and our result shows they are also favored by SEOers. To the opposite, due to more restricted controls, only a small ratio of .gov and .edu domains⁹ supports wildcard DNS and we have not found any SEO domain among them.

New gTLD. Since ICANN launched the new gTLD program in 2011, the TLD space has been expanded unprecedentedly. There are more than 1,000 gTLDs rolled out already, comparing to dozens of gTLDs before 2011. The delegated registrars under these TLDs frequently

⁹The number of .edu and .gov domains we have collected is much less than other TLDs, but our result is still meaningful, as it represents 49% and 22% domains known to the public [12].

promote their domain registration business through discounts, which have attracted a large volume of registration [21]. For example, around 1.7 million domains have been registered under .xyz. However, it was also reported that some new gTLDs were ill-managed, leading to a large number of spam/malware domains registered [19]. Our research supports this finding to some extent. We have identified 137K SEO domains already and 8 out of 10 new gTLDs have seen more than 1K SEO domains.

Generic SLD. Similar to TLDs, a generic SLD usually represents domains used for the same general purpose or is managed by a central institute. We have picked 3 out of 7 generic SLDs under .cn for study [9]. Similar to .gov and .edu, domain registration and resell under .edu.cn and .gov.cn are tightly controlled. We did not identify any spider pool domains under .edu.cn, but were able to capture a small amount of SEO domains under .gov.cn. It is nevertheless surprising to capture more than 20K SEO domains (28.1%) under .ac.cn, which represents the research institutes in China. The domain registration is managed by Chinese Academy of Sciences (CAS) and Xinnet and the applicant must prove that she represents a valid research institute. We speculate that the registration policies are not fully enforced and urge authorities to harden the registration process.

5 Measurement

As revealed from the large-scale DNS probing, the number of domains used for spider pool SEO is massive. In this section, we first measure the infrastructure characteristics (*i.e.*, IP and location distribution, domain registrars and registrant distribution) to study how attackers’

Table 2: Top 10 ASNs for hosting SEO domains (sorted by domain count).

NO.	ASN	#IP	#Domain
1	AS6939	35	94,372
2	AS18779	534	57,286
3	AS38197	1,354	47,790
4	AS8100	546	45,808
5	AS15003	6,398	34,583
6	AS18978	3,719	27,325
7	AS40676	5,132	25,384
8	AS32097	431	18,152
9	AS209	3	17,668
10	AS32787	6	12,673
Total	-	18,158	381,061

resources are aligned. Then, to extend our understanding on spider pool business model, we sample SEO domains detected from DNS scanning and use 20 of them as seeds to identify new spider pool campaigns. We show detailed results regarding their customers and impact on search engines. We elaborate our findings as follows.

5.1 SEO Domains

We first evaluate how SEO domains are distributed among spider pools’ hosting infrastructure and how they are registered. Then we selected one spider pool *SSP* and monitored the changes of its SEO domains for one month to measure the dynamics.

IP distribution. Our first question is whether distributed hosting is a popular design choice, since such a structure seems to be more resilient against administrative take-down actions. We issued DNS queries to all 458,246 SEO domains described in Section 4.1 after they were detected. Except the domains that were unresolvable to these queries, we obtained 28,443 IP addresses associated with 434,731 domains in total. Then, we use the API provided by ip-api.com¹⁰ to retrieve their ASN (AS number) and country information. The answer turns out to be positive, as over 28K IPs have been identified and each IP hosted less than 16 domains on average. But on the other hand, the adversaries prefer to assign a large number of SEO domains to certain ASs (autonomous systems), probably for the purpose of reducing the management cost. We obtained ASNs for all 28K IPs and listed the top 10 ASNs sorted by the number of hosted domains in Table 2. It shows that more than 87.6% of all domains (381,041 out of all 434,731) were hosted on these top 10 ASNs and the topmost ASN, AS6939, hosted nearly 95K domains (21.7%).

Next, we look into geo-locations of the hosts, trying to identify if adversaries prefer certain countries to run the operations. It turns out that most of the domains (80.5% over all 434,731 domains) and IP addresses (80.7% of 28,443 IPs) were hosted in United States, as shown in Table 3. In contrast, only 4.5% domains are hosted within

Table 3: Top 5 countries for hosting SEO domains.

Country	#IP	#Domain
United States	22,958	349,879
HongKong	2,319	19,483
China	1,958	13,295
Australia	135	6,387
Japan	285	3,459
Total	27,655	392,503

China, though most of the spider pool campaigns we have encountered were targeting markets in China. The reason for this arrangement, we speculate, is to avoid interventions from local governments including server take-downs and seizures.

Domain registration. Furthermore, we inspect the information regarding how the SEO domains are registered. We queried the TLD Whois servers for registrar, registrant and registration dates about the 458,246 SEO domains. In total, we were able to get valid Whois information for 425,345 domains. We describe our findings below.

Similar to the distribution on ASNs, most of the SEO domains are offered by a small amount of registrars. Table 4 lists the top 10 registrars that account for 81.8% SEO domains (out of 425,345 domains). Among them, 21.0% domains were registered under Chengdu West Dimension Digital Technology CO.. We also found that a lot of SEO domains were owned by a small number of registrants. As shown in Table 5, the top 10 registrants controlled 51.9% SEO domains (220,854 out of 425,345). Perhaps even more interesting is that a lot of registrants in deed provide email addresses instead of leaving them blank or using private registration to hide their identities. It is recommended by spider pool community to acquire new and expiring domains, which has been confirmed by our data. Figure 7 illustrates the number of all SEO domains registered per month. The oldest domain we observed was registered in Jan 2014 and the domain age is about 2 years. Peaks of registration activities were observed during Oct 2015 and Feb 2016, and it turns out the spider pool owners tend to register them in bulk and use them for the same campaigns. Since the domains are disposable, most of them are only registered for only 1 or 2 years.

Structure dynamics. The previous results indicate that spider pool owners usually recruit many new and expiring domains to build up their infrastructures. However, it is not yet clear about their strategies in maintaining the infrastructure, especially on how the infrastructure is evolved. To answer this question, we monitored the structural changes of *SSP* for 25 days within Jan 2016. We use the same spider pool explorer described in Section 3 to crawl *SSP* every day and store the discovered SEO domains separately. Figure 8 illustrates the daily

numbers of all SEO domains and the newly recruited domains that were not seen before. The structure was relatively stable for the first two weeks, but it started to change drastically in the third week: the amount of SEO domains climbed up quickly to 1,800 and then dropped back to 600. By inspecting the registration information, it turns out a large number of domains would expire during that week. So in order to compensate the loss, a bulk of new domains was purchased to replenish the spider pool. As the result, the size of the spider pool bounced back to 1,600 on the 25th day.

5.2 Statistics of Spider Pool Campaigns

The above measurement study shows an overall view of SEO domains recruited for spider pool usage. In this subsection, we studied the structure of individual spider pools, including SEO domains and customer domains/URLs. Among all confirmed SEO domains, we sample one domain per TLD/SLD as seed and run the same crawling method described in Section 3.2 to discover the infrastructure of the whole spider pool. For certain TLD/SLD containing much more SEO domains, like .cn and .ac.cn, we sample several other domains. Each newly discovered spider pool is compared with previous ones. If the overlap of SEO domains is over 50%, the spider pool is likely to have been explored and is discarded therefore. Through this process, we harvested 20 independent spider pools and the statistics are shown in Table 6 (labeled as S_1 to S_{20}). The result of *SSP* is also included. In total, we have discovered 15,816 SEO do-

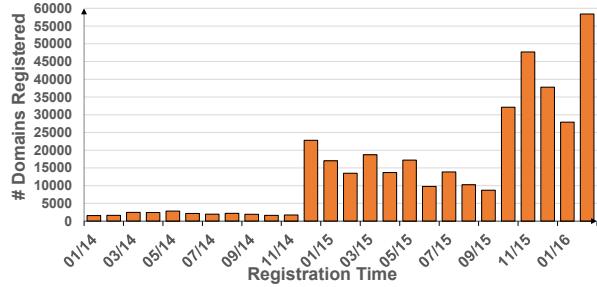

Figure 7: The number of all SEO domains registered per month.

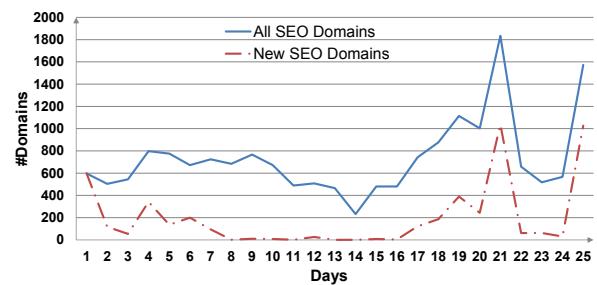

Figure 8: The number of all SEO domains and newly recruited domains observed each day for *SSP*.

mains, 1,453 customer site domains, and 7,236,315 customer search URLs from the crawling results of the total 21 spider pools.

In terms of the number of used SEO domains, we find it largely differs between spider pools, which varies from 100 to 1,933 and is averaged at 753. Regarding served customers, some spider pools include a large amount of search URLs: the maximum number for one spider pool is 2.6M. Such result should be taken with a grain of salt, since the URLs could be dynamically built for each visit from our crawler. On the other hand, the maximum of customer sites promoted by spider pool is only 710. We find that different spider pools tend to have big overlap of customer sites. By looking into the popular spider pool toolkit, we found that a lot of customer sites are included by default. This can explain the big overlap to some extent. Still, we find several different types of business (mostly illegal) leveraging spider pools for promotion and we elaborate our study in Section 5.3.

We are also interested in how good the security companies are at capturing the spider pool domains. To answer this question, we scanned all 15,816 SEO domains using VirusTotal in Feb 2016. Surprisingly, only 474 domains (2.9%) were flagged by at least one blacklist recruited by VirusTotal. The reason could be that most of SEO domains do not contain malicious content, like drive-by-download code and phishing page, since their

main goal is only SEO.

5.3 Customers

We now extend our study to the customers who employ spider pools to promote their business. We first extract customers’ sites referred by SEO pages and classify them into different categories according to the business they served. Also from the infiltration study on *SSP*, we discover that the adversary invent a new promotion technique which abuses the reputation of popular sites to advertise her messages, and such message promotion is also observed in other 20 spider pools as well. We are interested in which sites are abused and how the messages are composed, and we present our measurement results below.

Customer sites characterization. We examine all the crawled web pages from the 1,453 identified customer sites, and cluster them through content analysis. Previous works studying spam/scam campaigns [28, 50] looked into the HTML DOM structure and grouped the pages under the similar structure, on the premise that most pages are built with a small set of templates. However, the pages we have analyzed here do not follow such premise as the page structures are quite diverse. We address this problem through a different way: we used the well-established nature language processing (NLP) techniques to parse the page’s abstract (including title, meta keywords and meta description) into terms and identify the topic model [4] based on the term frequency. We leveraged an online document analysis service [5] to automate this process, which classifies a document into one

Table 7: Classification of customers’ sites.

Topic	#Domains	Ratio
Sales and Services	202	21.72%
Gambling	190	20.43%
Surrogacy	156	16.77%
News	156	16.77%
Sex	114	12.26%
Games	84	9.03%
Hospitals and Drugs	28	3.02%
Total	930	100%

of the topics pre-determined. Then, we manually examined the results and adjusted the topic when it is incorrect. The names of some topics were refined to better characterize the business as well. Through this procedure, we were able to cluster 930 sites ¹¹ into 7 topics. Table 7 lists these topics and the number of corresponding sites. We elaborate each topic in Appendix C.

Different from the results revealed by previous studies on search poisoning [31], we do not find any customer site delivering malware or phishing content. Moreover, we identified new types of business, other than stores selling fake goods or pharmacies [28, 34]. It turns out the goals of the customers are mainly to promote their illegal business without unveiling traces to local legal authorities. As an example, surrogacy is banned in China [7] and the agents behind cannot advertise their business through well regulated channels like TV commercials. Therefore, they spammed the search results using spider pool as an alternative.

Customer message characterization. Starting from the 15K spider pool domains, we identified over 7.2M message URLs free-riding reputable sites. The adversaries tend to keep a pool of candidate sites and attach the message to their search URLs randomly. In Table 8, the top 20 sites being abused are listed and the topmost site serves 114K message URLs. All of these sites are listed in Alexa top 1M, including highly reputable ones, like `amazon.com` and `ebay.com`. For a search engine, these message URLs should be removed, which however is not a trivial task because valid search results about popular goods on sites like `amazon.com` are also included in Google and should not be pruned.

We then look into the promoted messages. Most of them are composed of a long-tail keyword (*e.g.*, “where to buy hallucinogen”) and contact (*e.g.*, “the QQ of customer service is: 90909090”). While the long-tail keyword is readable, the contact number is usually obfuscated. In particular, we saw “0” is replaced with “o” (“9o9o9o9o”) and special symbol was inserted into the number (“909-909-909”). We suspect such obfuscation

¹¹The remaining 523 sites were not processed because their abstracts were invalid, the sites were down when we crawled their homepages or the clusters they belong to were small.

Table 8: Top 20 sites abused for message promotion ordered by the number of associated URLs.

Abused Site	URL Pattern	#URL	Alexa Rank

is used to evade detection of automated tools. Through some manual efforts, we created rules which map the obfuscated number to original one and were able to parse about half of the 7.2M messages (3M). In the end, we identified 23 QQ numbers accounting for 2.4M messages which are all related to illegal services. The details of these numbers are shown in Table 9 of Appendix D. We think extracting the contact information is meaningful for search engines or other departments. By tracing from the contact information, the identities of the criminals could be revealed, which can greatly facilitate criminal investigation.

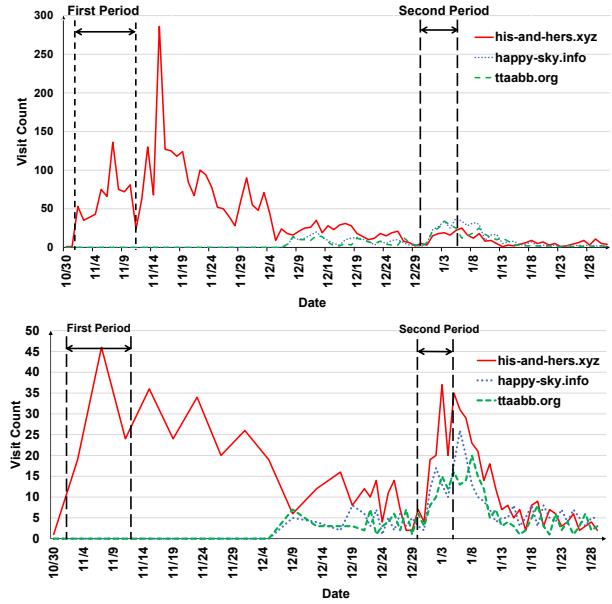

5.4 Impact on Search Engines

Spider pool is mainly used to increase the visiting frequency from search crawlers and we evaluate its effectiveness by examining the logs collected on our servers used for infiltration study of *SSP*. In addition, we look into how search results under long-tail keywords are manipulated.

Visit frequency from search engines. After 14 days, the targeted search engines (Google, Baidu) began to index the homepage and other pages under our test site (*his-and-hers.xyz*). To determine if the effects from spider pool are consistent, we relaunched our testing SEO campaign and added 2 additional sites¹² into *SSP* after a pausing period. Statistics are plotted in Figure 9 for Google and Baidu respectively. As shown in both figures, the effects are obvious: the average number of visits per day jumped from 28 to 66 for Google and from 4.5 to 37.5 for Baidu during the campaign. Once the cam-

¹²*happysky.info* and *ttaabb.org* were purchased on Dec 6th, 2015 from Godaddy and we set up websites on them using templates downloaded from <http://www.dedecms.com/> and <http://www.emlog.net/>.

Figure 9: Google (upper) & Baidu (lower) visit count.

paign was stopped, the visit count dropped significantly, but restored quickly after the campaign was resumed. Data from the other two sites show similar trends, which proves the effectiveness of spider pool services.

Search results manipulation. To assess how search results are manipulated under keywords, especially long-tail keywords, we sample 43 long-tail keywords under 4 categories discovered from customers’ messages and query them on Google and Baidu. Then, we examine the returned results from the first page and look for wildcard DNS domains in particular. If the search result associated with the wildcard DNS domain is filled with spam texts, we consider it is manipulated by spider pool. In

the end, we find spider pool compromised 27 keywords in Google and 30 keywords in Baidu (see Table 10 of Appendix E), indicating spider pool is quite effective and widely used for poisoning long-tail keywords. Interestingly, the poisoned keywords show clear distinction between Google and Baidu under different categories: we see keywords related to sex and medicine are more likely to be poisoned in Baidu while for Google they are under categories of firearms sales and fake certificate. Another interesting finding is that adversary is able to manipulate all search results (100%) under some keywords in Baidu, especially under sex categories.

6 Discussion

Responsible disclosure and feedback. We have contacted the security lab of Baidu and reported our findings and spider pool domains we discovered. Baidu acknowledged our findings and is verifying our results. In fact, Baidu is aware of the existence of spider pool, but is surprised by the scale and the impact on search results. To help Baidu clean the search results and mitigate the threat, we applied the detection system to the indexed URLs offered by Baidu and provide a report of spider pool domains on a weekly basis.

Ethical issues. To understand the internal mechanisms of spider pool, we paid the owner of SSP advertising fee to include our sites into the SEO pages. This could raise ethical concern as the criminal group was funded by us, however, we argue that the influence was rather limited as we ran the campaign for a small period and chose the cheapest service category, costing only 8 dollars in total. Another concern is that our infiltration experiment could contribute to the pollution of search engine results. Yet, we argue that the impact is still limited, as we intentionally chose hot keywords. Our sites were shown in search results only when the user searched our URL directly. In addition, we have closed the 3 test websites and informed Google and Baidu via email to eliminate our URLs from the search results after the study.

Limitations. We have designed and implemented a system to detect SEO domains through DNS probing and another system to explore the spider pool territory from seed domains. However, if adversaries know these detection algorithms, they can upgrade their infrastructures for evasion. We discuss several evasion strategies in Section 3.4. These strategies would increase the running cost or reduce the effectiveness of spider pool without exception. Besides, as an initial step, our goal in this work is to explore the landscape of this rising threat and measure its impacts. A large volume of sites have been discovered with the help of our systems and fulfilled the need for measurement study. For the future work, we will investigate the feasible ways to improve the systems.

Recommendations to search engines. The search engine can refrain from crawling and indexing pages under SEO domains when the FQDNs are random and abundant outbound links are embedded. However, extra efforts should be taken to reduce the false positives. As a matter of fact, it is also common that legitimate web sites delegate subdomains to others, and they may exhibit similar characteristics to SEO domains. We also suggest search engines to keep a close watch on keywords, especially long-tail keywords, under certain topics. As described in Section 5.4, spider pools tend to target limited topics so their campaigns could be discovered by monitoring the associated long-tail keywords.

7 Related Works

Understanding blackhat SEO. The damage caused by blackhat SEO has been known for a long time and there have been a corpus of works studying this issue. One line of such works focused on the infrastructure of blackhat SEO campaigns and how they are managed. Wang *et al.* [51] infiltrated an SEO botnet and showed it is quite effective in poisoning the trending search terms, given its small size though. John *et al.* [24] dissected an SEO campaign which hosted SEO pages on compromised servers. Also an interesting topic is about how the adversary makes use of blackhat SEO. McCoy *et al.* [34] and Levchenko *et al.* [28] revealed that blackhat SEO have been employed extensively for online store selling fake products and pharmaceutical affiliate networks. Leontiadis *et al.* [26] measured the search-redirection attacks used for drug trade and the result suggests such attacks could overwhelm legitimate sites in search results and provide more traffic than email spam to the storefront sites. To fight against these threats, search engines have been taken active actions and the studies show the countermeasures were effective to some extend but there is still long way ahead to win the battle [27, 35, 49].

Detecting blackhat SEO. Inspired by the studies of blackhat SEO campaigns, several detection approaches have been proposed based on different features revealed from known SEO attacks. John *et al.* [24] leveraged URL signatures to identify SEO pages from a dataset of URLs provided by search engines. Lu et al. [31] detected search poisoning by inspecting the redirection chains unfolded when visiting a search result. Zhang *et al.* [56] presented an approach which is capable of detecting compromised sites abused for search poisoning from seed sites. The features related to cloaking behaviors of SEO sites [50] and content spinning on SEO pages [57] were exploited for detection as well.

Wildcard DNS. Wildcard DNS is a widely used to map different hostnames to the same IP and save the administrators from maintaining many different records. The security implications, however, are not thoroughly eval-

uated yet. The only relevant research we knew so far measured the prevalence of wildcard DNS configuration and showed that it is broadly used by malicious sites [25].

Long-tail SEO Spam. Due to the intensive competition on hot keywords, many blackhat SEOers now start to target long-tail keywords. Still, the understanding is limited. So far, we only found one recent work studying this topic and showed the cloud web hosting service is abused for long-tail SEO spam [30]. Our study complements the existing works by revealing a new strategy from blackhat SEOers.

8 Conclusion

In this paper, we conducted the first comprehensive investigation on a new type blackhat SEO technique called “spider pool” which abuses wildcard DNS to tamper long-tail keywords of search engines. Based on the understanding through infiltrating a shared spider pool service, we developed a DNS prober which can identify the SEO domains with high accuracy and efficiency, together with a spider pool explorer which is able to excavate the domains used by individual spider pool through seed expansion. Our results show that spider pool has become a big threat to registrars, search engines and their users, as more than 458K SEO domains have been discovered, popular sites like `amazon.com` are abused to promote illegal messages, and long-tail keywords can be easily polluted. We think this new threat should be mitigated and call for the attention from the security community.

9 Acknowledgements

This work was supported by the Natural Science Foundation of China (grant 61472215). We thank anonymous reviewers for their insightful comments. We also owe a special debt of gratitude to Prof. Thorsen Holz, for his instructive advice on our paper. We deeply indebted to Professor Vern Paxson, his suggestion to our research direction is valuable to us. Finally, Special thanks should go to Baidu company which provide a platform and data for testing our idea.

Appendix

A Seed Expansion through Google Search

We can start from our testing site, identify the first layer of parent sites S_1 leading to it, and recursively identify sites at upper layers $S_n(n > 1)$, till there are no more new sites discovered. We seek the help from Google Search for this task and develop a C++ program which directs Firefox to automatically search on Google. In essence, it keeps a queue of domains to be searched, pops out the first URL and queries Google, extracts all search result URLs in top 10 pages, and saves the domains unvisited into the queue. The process ends when the queue is empty.

Though the spider pool sites could be detected, the performance is poor and the process is hard to converge. We find there are two main reasons. First of all, it takes quite some time for Google to respond to our web request, and CAPTCHA has to be solved occasionally. Second, the returned search results usually include sites not in spider pool, *e.g.*, sites providing domain registration information and fake search engines which copy search results from other search engines¹³. Such irrelevant sites have to be excluded, otherwise the iterations will be inaccurate and may not even converge, but using straightforward filtering metrics like domain ranking and URL patterns are not effective through our testing.

B Classifications of SEO domains

We identified three types of methods of linking customer's content to SEO pages. They are listed below:

1. **Through iframe.** Instead of pointing to customer's site, the SEO page directly encloses the customer's page in an HTML iframe. It leverages JavaScript API `document.write` to inject the iframe, which occupies the whole screen when the user lands on the site. It could accumulate more traffic towards customer's site when visitors happen to land on SEO page.
2. **Through hyperlink.** The hyperlink pointing to customer's site or containing customer's message is displayed in the SEO page. This type is also used in SSP we infiltrated.
3. **Through redirection.** For this type, a visit to SEO page using certain user-agent string (*e.g.*, Opera browser) is immediately redirected to customer's site through HTTP 302 redirect. In fact, it uses JavaScript code to assign customer's URL to `window.top.location.href` and HTML meta refresh tag to redirect visitor's browser. Likewise,

¹³The purpose of setting up such fake search engines is not yet clear. We suspect they are used for click fraud [29].

customer's content can be directly pushed to visitor's browser.

Table 9: QQ Number (anonymized) identified for message promotion.

NO.	QQ Number	Topic	#URL
1	53*95*1	Sex	156,306
2	34*06*58*	Drugs	261,135

C Topics of Customer Sites

The 930 customer sites are classified under 7 categories below:

1. **Sales and Services.** We find industrial equipments and products, like elevator and seamless pipe, are sold on the customers' sites. Services of gray areas are also provided, like private detective and empty invoices.
2. **Gambling.** It includes sites for online casino and sports betting.
3. **Surrogacy.** The sites provide channels for infertile parents to find women willing to carry pregnancy.
4. **News.** The sites serve as news portals about local events.
5. **Sex.** Some of the sites host adult content like porn video and photos, while others list contacts of affiliated prostitutes or their agents.
6. **Games.** Online games developed by less known companies are provided. In addition, some sites provide information about the unauthorized servers for big-brand games, like The Legend of Mir [1], which can be connected to play the same game for free or less fees.
7. **Hospitals and Drugs.** We find the sites in this category introduce hospitals which do not have valid licenses. Besides, illegal drugs, like hallucinogen, are sold in some sites.

D Classifications on Customer Messages

We analyze customer messages, extract QQ numbers from customer messages, and sort them by the number of associated URLs. The result is shown in Table 9.

E Impact on Search Engines

We sampled 43 long-tail keywords extracted from the SEO pages crawled from the 21 spider pools and search them in Google and Baidu. The result is shown in Table 10. We count the percentage of search results showing spider pool domains. If no search results are returned, we write “no search result”. If no spider domains are presented in search results, we write “no keyword”.

A Comprehensive Measurement Study of Domain Generating Malware

Abstract

Recent years have seen extensive adoption of domain generation algorithms (DGA) by modern botnets. The main goal is to generate a large number of domain names and then use a small subset for actual C&C communication. This makes DGAs very compelling for botmasters to harden the infrastructure of their botnets and make it resilient to blacklisting and attacks such as takedown efforts. While early DGAs were used as a backup communication mechanism, several new botnets use them as their primary communication method, making it extremely important to study DGAs in detail.

In this paper, we perform a comprehensive measurement study of the DGA landscape by analyzing 43 DGA-based malware families and variants. We also present a taxonomy for DGAs and use it to characterize and compare the properties of the studied families. By reimplementing the algorithms, we pre-compute all possible domains they generate, covering the majority of known and active DGAs. Then, we study the registration status of over 18 million DGA domains and show that corresponding malware families and related campaigns can be reliably identified by pre-computing future DGA domains. We also give insights into botmasters' strategies regarding domain registration and identify several pitfalls in previous takedown efforts of DGA-based botnets. We will share the dataset for future research and will also provide a web service to check domains for potential DGA identity.

1 Introduction

Botnets are networks of malware-affected machines (*bots*) that are remotely controlled by an adversary (*botmaster*) through a command and control (C&C) communication channel. Botnets have become the primary means for cyber-criminals to carry out their malicious activities, such as launching denial-of-service attacks,

sending spam, and stealing personal data. Recent studies have shown that some botnets consist of more than a million bots [40], illustrating the magnitude of their threat.

Law enforcement and security researchers often try to disrupt active botnets by performing takedown attempts. The main target of these attacks is the C&C communication infrastructure of the botnet. A prominent example of these attacks is *sinkholing*, where all bots are redirected to an attacker-controlled machine called a *sinkhole*. In consequence, the bots will be prevented from communicating with the original C&C servers. As a response to these efforts, botmasters have started inventing new techniques to protect the infrastructure of their botnets. An important approach that has gained wide popularity in recent years is the use of domain generation algorithms.

A domain generation algorithm (DGA) is used to dynamically generate a large number of seemingly random domain names and then selecting a small subset of these domains for C&C communication. The generated domains are computed based on a given *seed*, which can consist of numeric constants, the current date/time, or even Twitter trends. The seed serves as a shared secret between botmasters and the bots to compute shared rendezvous points. By constantly changing the used domains, detection approaches that rely on static domain blacklists are rendered ineffective. Moreover, by dynamically generating domain names, botmasters do not have to include hard-coded domain names in their malware binaries, complicating the extraction of this information. Also, making the generated domains dependent on time lessens the value of domains extracted from dynamic malware analysis systems since different domains will be observed at different time points. Another advantage of using short-lived domains that are registered shortly before they become valid is evading domain reputation services.

The use of DGAs creates a highly asymmetric situation between attackers (botmasters) and defenders (security researchers and law enforcement). Botmasters need

access to a single domain to control or migrate their bots while defenders need to control all of the domains to ensure a successful takedown. With more than 1000 top-level domains (TLDs) [9] to choose from, it is easy for an attacker to create a global spread of responsibility for domains, forcing the defenders into additional coordination and cooperation efforts. For example, the DGA of the infamous Conficker botnet (version C) generated 50,000 domain names per day, which spread out over 113 TLDs. This required global cooperative efforts of 30 different organizations including ICANN [2] to contain the threat.

In this work we perform a comprehensive measurement study of the DGA landscape by analyzing 43 DGA-based malware families and variants. Our analysis is based on reverse-engineering the DGAs of these families. We propose a taxonomy to characterize the main aspects of DGAs and use it to describe and compare the studied DGAs. We furthermore reimplemented all of these DGAs and computed all their possible outputs based on a set of 253 seeds used in previous and ongoing malicious campaigns. We then used this set to identify DGA-generated domains in a set of 9 billion WHOIS records collected over the last 14 years. We analyze the registration status of these domains and their ownership changes, which often indicates transitioning from a malicious into a sinkholed domain. This enables us to profile the registration behaviour of both botmasters and sinkhole operators and investigate in detail the lifetime of DGA domains.

To the best of our knowledge, our work reflects the first systematic study of the DGA landscape as employed by modern botnets. Security researchers have previously examined DGAs and proposed approaches to detect and cluster DGA-based malware [13, 18, 43, 54]. Our study is instead based on an in-depth analysis of the DGAs in a bottom-up manner, by reimplementing the algorithms and enumerating the complete set of domains they generate, enabling us to have a ground truth about DGA-generated domains with no false positives.

In summary, we make the following contributions:

- We propose a taxonomy for DGAs to characterize and compare their properties.
- We analyze the DGAs of 43 malware family and variants. Using 253 identified seeds, we enumerate all possible domains generated by those algorithms, covering the majority of known and active DGAs.
- We study the registration status of 18 million DGA-generated domains covering a period of 8 years and show that corresponding malware families and related campaigns can be reliably identified by pre-computing future DGA domains.
- We analyze the strategies of both botmasters and sinkholders with regard to domain registration and

identify several pitfalls in previous takedown efforts of DGA-based botnets.

- We share the dataset for future research and provide a web service called DGArchive [38] to check whether a queried domain originates from a DGA.

2 A DGA Taxonomy

In this section, we propose a taxonomy for DGAs to characterize their properties and enable a comparison. To model the entire spectrum of different properties, we propose two features designed to capture the different aspects of a domain generation algorithm. Both features are then combined in a single taxonomy that classifies DGAs into classes.

2.1 Seed Source

The seed serves as a shared secret required for the calculation of generated domains, also referred to by the term Algorithmically-Generated Domains (AGD) [54]. It is the aggregated set of parameters required for the execution of a domain generation algorithm. Typical parameters include numerical constants (e.g., length of domains or seeds for pseudo random number generators) or strings (e.g., the alphabet or the set of possible TLDs).

Two properties of seeding have superior significance to characterize a DGA (cp. Barabosch et al.[16]):

Time dependence means that the DGA incorporates a time source (e.g. the system time of the compromised host or the date field in a HTTP response) for calculation of AGDs. In consequence, generated domains will have a validity period only during which these domains are queried by the compromised system.

Determinism addresses the observability and availability of parameters. For the majority of known DGAs, all parameters required for DGA execution are known to a degree that all possible domains can be calculated. Two DGAs use temporal non-determinism to disallow arbitrary prediction of future AGDs by using unpredictable but publicly accessible data for seeding. The malware family Bedep [44] makes use of foreign exchange reference rates published daily by the European Central Bank while a later variant of Torpig [50] used Twitter trends for seeding. In both cases, this only leads to attackers and defenders having to compete for the registration of domains in each active time window once the unpredictable data used for seeding becomes available. However, it does not prevent historic analysis, as the seeding data and thus generated domains can still be collected over time. Another kind of non-determinism has been observed by Symantec [45]. Their analysis of Jiripbot revealed that the malware exfiltrates a set of system properties including MAC address and hard drive volume ID

to make it available to the attacker to be used in a DGA seed. In this case, the system information is considered non-deterministic to the attacker prior to compromise and also never publicly observable.

Time-dependence and determinism allow the following four combinations: time-independent and deterministic (TID), time-dependent and deterministic (TDD), time-dependent and non-deterministic (TDN), time-independent and non-deterministic (TIN). In our dataset, we have only observed DGAs using the first three classes of seeding properties.

2.2 Generation Schemes

Apart from the characteristics of seeding, 4 different generation schemes emerged during our analysis.

Arithmetic-based DGAs calculate a sequence of values that either have a direct ASCII representation usable for a domain name or designate an offset in one or more hardcoded arrays, constituting the alphabet of the DGA. They are the most common type of DGA.

Hash-based DGAs use the hexdigest representation of a hash to produce an AGD. We identified DGAs using MD5 and SHA256 to generate domains.

Wordlist-based DGAs will concatenate a sequence of words from one or more wordlists, resulting in less randomly appealing and thus more camouflaging domains. These wordlists are either directly embedded in the malware binary or obtained from a publicly accessible source.

Permutation-based DGAs derive all possible AGDs through permutation of an initial domain name.

We abbreviate the generation scheme with the respective starting letter: A, H, W, or P. As part of any of the above-mentioned generation schemes, some DGAs leverage pseudo-random number generators (PRNGs) to generate domains. These range from implementing own PRNGs to the use of well-known techniques such as linear congruential generators (LCGs) [36].

2.3 DGA Types

As DGA type, we consider the combination of seeding properties and generation scheme, denominated by the combined abbreviations, e.g. “TID-A” for a time-independent, deterministic DGA using a arithmetic-based domain generation scheme. Of 16 possible combinations, we have only observed 6 types being used by the 43 DGAs in our dataset: TDD-A (20), TID-A (16), TDD-W (3), TDD-H (2), TDN-A (1), TID-P (1).

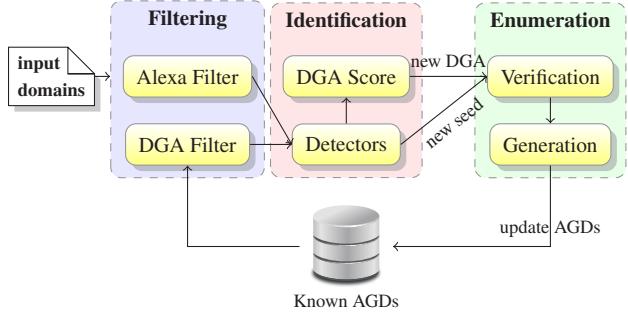

Figure 1: DGA collection approach.

3 DGA-Malware Dataset

In this section, we describe how we identified and collected malware samples that employ a DGA. Then, we describe our efforts to reverse-engineer the algorithms, reimplementing and evaluating their implementation.

3.1 Identifying DGA-based Malware

The first step of our study was to collect a representative set of DGA-based malware families. To this end, we developed a system to automatically identify potentially new DGAs by analyzing a set of domain names generated by a given malware sample. This helps us to minimize the set of malware samples we need to manually reverse-engineer, and thus focus our efforts on samples that are likely to implement new DGAs. A high-level overview of the system is presented in Figure 1. First, we filter out known AGDs and benign domains. Second, we identify domains that are generated by a previously known DGA but with a new seed, and domains potentially generated by new DGAs. Third, if a new DGA or a new seed is identified, we manually reverse-engineer the corresponding sample, extract the seed and the algorithm, and compute the set of domains it generates. In the following, we discuss these steps in detail.

Filtering. We first filter out known benign and popular domains by comparing them against the first 10,000 entries of the Alexa list of top-ranked domain names [10]. Second, we filter out known AGDs by comparing the input domains against our current collection of enumerated AGDs. A good starting point for collecting DGA-based malware samples are malware analysis reports and blogs. Using these as sources and based on our experience, we identified an initial set of 22 families using DGAs. In 9 of these cases, we already found a reimplementation of the DGA that we only had to verify. This enables us to compute an initial set of domains to use in the DGA filter.

Identification. In this step we identify samples that implement a previously known DGA but use new seeds, and potentially new DGAs. To that end, we use a set of *detectors* implemented as regular expressions to quickly decide for a given domain if it matches the expected output of one of these known DGAs. The regular expressions catch major characteristics such as minimum and maximum length of the generated part (L_{min} and L_{max}), DGA alphabet Σ , and the set of known TLDs. If a majority of input domains is matched by the same pattern, we mark the sample as using a known DGA with new seed.

If the detectors produce an inconsistent or insufficient result, we compute a *collective DGA score* for the input domains to measure the likelihood of these domains being generated by a DGA. This score is based on features such as n-gram frequency, entropy, and length analysis. If available, we further increase the score in case of an *NX domain* result. This approach relies on previous work on DGAs [13, 18, 34, 43, 54]. If the score exceeds a threshold derived through prior experiments and manual verification, we mark the sample as a candidate for using a new unknown DGA.

DGA enumeration. Whenever the system identifies a potentially new DGA, we manually verified this by reverse-engineering the corresponding sample. If present, we then extracted the domain generation logic from the binary, reimplemented it, identified the used seed, and finally computed all domains generated by the algorithm. Moreover, by analyzing the algorithm we updated the set of detectors to identify future samples that use the same algorithm with different seeds.

As input to our system, we used a special sandbox feed that was kindly provided by the Shadowserver Foundation, consisting of timestamp, malware sample hash, DNS query, and DNS response. This feed contains a mix of both newly observed malware samples and older samples undergoing re-processing, dating back to at least 2009. This re-processing increases the likelihood to encounter unknown seeds and families that may no longer be active. Taking data of 3 months starting in May 2015 from this feed, we examined a total of 1,235,443 sandbox runs, performing a total of 15,660,256 DNS queries towards 959,607 unique domain names. Based on the data of the Shadowserver feed, our system enabled us to identify, analyze, and re-implement another 21 DGAs and the majority of seeds listed in Table 3.

3.2 Reimplementing DGAs

To ensure our reimplementation is correct, we compared its output against the domain queries issued by the respective malware sample when executed in a sandbox. For each family, the reverse-engineering and reimplementation of the corresponding DGA took around one

day. After analyzing the algorithm, we extracted the DGA seed from the binary. In many cases, we fully automated the process of seed extraction, which enabled us to easily extract seeds from new binaries of the same family. After unpacking the malware binaries, we rarely encountered further protection layers of the original unpacked code, which allowed considerable analysis speed. Nymaim and Suppobox samples are heavily obfuscated and employ family-specific code obfuscations. To handle these cases, we analyzed the obfuscation techniques and implemented custom deobfuscators to automatically deobfuscate these samples. Pykspa 2 was an exceptionally difficult case. Instead of reverse-engineering the seed derivation function, it was much easier to instrument it in order to generate all possible seed values that we later used in the reimplementation of the DGA.

The manual analysis of samples previously identified by the system helped us to eliminate several samples that would otherwise be false positives. For example, during the evaluations of the sandbox DNS feed, we came across many samples whose DNS queries appeared like typical AGDs but were in fact hardcoded domains as verified through our reverse-engineering. Furthermore, we only consider DGAs in which the AGDs are actually used as valid, potential C&C endpoints and not as distractions like in the following cases. For instance, we found an early variant of Sality [1] prepending dynamically generated third-level parts to hardcoded domains, which is the earliest hint to DGA-like behavior we were able to identify. Another example is the Zeus-derivate Citadel, which produces unused decoy AGDs when having detected a virtualized environment [21].

We are aware that more malware families than listed in this paper are potentially using DGAs. However, we believe that the given data set provides a sufficient basis to draw meaningful conclusions on a majority of effects caused by domain generation algorithms.

4 Insights into the DGA Landscape

In this section, we present a comprehensive overview of the 43 DGA implementations and their 253 seeds that we collected. We use our taxonomy to characterize and compare the studied DGAs. More specifically, we compare domain structure, validity periods, and generation schemes. We also study how random the generated domains are and the priority of the DGA as C&C communication mechanism. Table 1 presents an overview of the different DGA features. The table includes different variants of some families with different DGAs. This is the case for Gameover Zeus, Murofet, Pushdo, and Pykspa.

Table 1: Overview of studied DGA implementation characteristics. *Type* according to our taxonomy. $C2_{prio}$ lists the priority of DGA among all C&C rendezvous mechanisms found (with * indicating hardcoded domains being redundant or used as part of seed). *Valid* describes the duration and D_{cycle} the number of domains generated per period. $L_{min,max}$ denotes extrema of domain length, *TLDs* is a combined value over all seeds of this DGA. Σ is the alphabet used in AGDs, H_{rel} normalized entropy.

4.1 Domain Structure

Alphabet. We first study the alphabet, denoted by Σ , used by the DGAs to generate domains. The alphabets contain between 9 and 36 characters. While some DGAs use intentionally short alphabets, the majority of DGAs with small alphabets seems to result from flawed implementations. An example of the first case is VolatileCedar, which generates domains by permuting the second-level part of a hard-coded domain (`dotnetexplorer.net`). Ramdo’s DGA is an example of a buggy implementation. Only letters with odd indexes are chosen when building the domain name (i.e., a, c, e, . . .), resulting in an alphabet with only 13 letters. Hash-based DGAs have alphabets of 16 characters consisting of digits and letters from a to f.

Many DGAs use a hard-coded array of characters from which is chosen by an index computed iteratively. A

common bug in these DGAs are *off-by-one* errors, where one or more characters are never chosen. For example, Geodo omits the last character of its alphabet, thus generated domains never contain a z. Other DGAs with this bug include CryptoLocker, Necurs, Ramnit, Ranbyus, Shifu, TinyBanker, and Torpig. They all miss the last character in their alphabet. This type of error is worse for DGAs that use multiple separate arrays to choose characters from. For example, Mewsei uses two arrays, one for vowels and one for consonants (intentionally or not, missing the letter j). An off-by-one bug results in one character in each array to be missed, reducing the effective alphabet size by two. Rovnix and Corebot use two separate arrays of letters and digits and suffer from the same malfunction, causing their AGDs to never contain a z or 9. We found this bug in 11 of the studied DGAs.

We also observed *truncation* errors, where the alphabet is truncated into a smaller array that is used for computing the domains. For example, Szribi truncates its 26 intended hard-coded letters to only 15. The same error occurs in Urlzone, reducing the possible 35 characters to only 32. Torpig suffers from both bugs: Torpig’s randomness is flawed in a way that only 30 out of 34 possible (36 minus 2 resulting from the off-by-one error) are reachable. The largest alphabet of 36 symbols is used Dyre, Gameover DGA, and Murofet 2.

AGD length. The length of generated domains ranges from 4 to 47 with median minimum length 9 and median maximum length 16. 14 DGAs produce AGDs that all have identical length. In three cases (Banjori, Simda, and Torpig), we found multiple length values across seeds but all AGDs of one seed have the same length.

Domains levels. Only three families (Corebot, Kraken, and Mewsei) generate third-level domains, using one or more Dynamic DNS providers. All remaining DGAs only generate a second-level domain that is then concatenated with a top-level part. Note that we consider constructs as `co.uk` or `com.tw` as top-level part since they are managed by a single registry. Conficker and Necurs make extensive use of TLDs with 123 and 43 TLDs respectively. These cases strikingly illustrate the need of global cooperation to successfully sinkhole some botnets. This also holds for botnets with DGAs that use a smaller set of TLDs. Table 2 shows the most popular TLDs used by the studied DGAs and identified seeds. The 7 most common TLDs are the same in both listings and they only differ in their order. `com` and `net` are the two top TLDs. We observe a trend to use popular TLDs with no regional reference, as `com` and `net` together make up about 45% of all registered domains [8]. We assume that attackers want their generated domains to blend in well with benign traffic.

TLD	per DGAs		per Seeds	
	Occurrences	TLD	Occurrences	TLD
com	28	com	178	
net	21	net	82	
org	16	ru	56

eu	4	cc	18	

Table 2: Popularity of TLDs, both on for DGAs and seeds.

4.2 Domain Validity Periods

More than half of the studied DGAs (24/43) are time-dependent, meaning that the generated domains are only

valid for a certain period of time. Most of these DGAs (21/24) generate domains with disjunct validity periods. That is, only a single set of domains is valid at each point in time. The three exceptions are 1) Matsnu, which generates 3 domains which are each valid for 3 consecutive days, meaning that there are 9 potential C&C domains at a time; 2) Pushdo, which will generate domains relative to a given date, starting 45 days in the past and up to 15 days in the future. With 30 domains per day, this gives 900 domains valid at a time; and 3) Suppobox, producing one AGD per 512 seconds, which is then valid for the next 85 periods, totalling to 12 hours, 5 minutes, 20 seconds per AGD.

11 time-dependent DGAs generate domains that are valid for one day. Other families increase their domain validity by performing certain calculations on the date. For example, both Gameover P2P and Murofet 2 round the day of month down to the next lowest value of 1, 7, 14, 21, or 28, resulting in validity periods of variable length (1-7 days). Qakbot employs a similar scheme but uses different values for rounding (1, 11, and 21). The domains generated by Szribi’s DGA [52] are valid for 1-3 days. This variable period length appears to be a bug since the DGA tries to round the day to the nearest third day (i.e., Julian days).

Both versions of Pykspa have unique characteristics with regard to the validity of generated domains. Pykspa 1 generates a list of 5000 domains every two days, and the validity of each domain depends on its position in this list. The first 20 domains are generated at random while the remaining 4,980 are chosen from two static sets of domains, alternating between these sets every two days. This is caused by the DGA raising the initial 32-bit seed to power of 2 for each new computed domain, thus drastically reducing the randomness of computed domains. In order to increase resilience to detection, Pykspa 2 generates *fake* domains with shorter validity periods than the real ones. While 200 real domains are generated that are valid for 20 days, the DGA generates 800 fake domains, each of which is only valid for one day.

Geodo has a unique generation strategy with regard to validity periods among all time-dependant DGAs. It queries the current date from the response of an HTTP request to a Microsoft website. Then, it will consequently generate one AGD every 900 seconds starting from a hard-coded start date until this current date is reached.

4.3 Generation Schemes

Arithmetic-based DGAs are by far the most common generation scheme (37/43). Among these, 26 DGAs directly compute the ASCII codes of the characters to be used in the domain, while 11 DGAs compute an in-

dex that is used to select characters from hard-coded arrays representing the used alphabet. Three DGAs are wordlist-based: Matsnu, Suppobox, and Gozi. Matsnu and Suppobox embed the list of words in their corresponding malware binary. On the other hand, Gozi extracts its wordlist from a publicly available text file, which is very unlikely to be changed in the future. For example, it uses the United States Declaration of Independence to generate domains such as `amongpeaceknownlife.com`. Matsnu and Gozi randomly combine words until a certain length is reached, while Suppobox only combines 2 of its 384 included words and adds `.net` as TLD.

The two families Bamital and Dyre are hash-based and use the hexdigest output of hashing functions MD5 and SHA256 over date and domain index as input parameters. VolatileCedar is the only permutation-based family, which can produce 170 possible permutations of the initial domain. It is worth mentioning that Banjori, TinyBanker, Urlzone and VolatileCedar use a domain mutation scheme where either a seed or a previously generated domain is used as input for the calculation of the subsequent domain.

4.4 Domain Randomness

Given that various DGAs make use of PRNGs in their domain generation schemes, we analyzed the randomness of generated domains. To this end, for each DGA, we compute the global string by concatenating all generated parts of the domains. Then we calculate the Shannon entropy of this string. This gives a global indicator for the randomness of the algorithm. Finally, we compute the relative entropy, denoted by H_{rel} , by dividing the calculated value with the maximum entropy. This enables us to compare the relative entropy of different DGAs. For simplicity, we use the term entropy to refer to H_{rel} .

We make the following observations. All wordlist-DGAs have a significantly lower entropy ($H_{rel} < 0.9$), which is expected since they combine complete words whose characters are not uniformly distributed. However, the lowest entropy is observed in Dyre, a hash-based DGA. While the SHA256 algorithm produces uniformly distributed characters, Dyre prepends an extra character in the range `[a-z]` to the calculated hexdigest, thus destroying the uniform distribution since the hexdigest does not contain any letters in the range `[g-z]`.

The low entropy ($H_{rel} < 0.99$) observed in other DGAs is a result of specific implementation choices. We discuss this in the following.

1) **Multiple sub-alphabets.** By splitting the alphabet into multiple distinct lists and randomly drawing characters from these lists for different positions in the com-

puted domain name, some DGAs cause an imbalance on the overall distribution of characters. This is the case for Bedep, Gameover DGA, Mewsei, Pushdo, Simda, Torpig, and Virut. Redyms uses a hyphen in every AGD.

2) **Imperfect PRNG.** We observed several causes of imperfect PRNGs: first, some DGAs (Pykspa 1 and Szribi) use their own self-designed PRNGs, which have imperfect randomness. Second, other DGAs (Murofet 1 and TinyBanker) impose certain conditions on the output of the used PRNGs, and thus cause an imbalance in the distribution of derived characters.

3) **Partial modifications.** Some DGAs compute the next domain based on an initial domain name. This transformation may impact the DGA entropy if it does not introduce enough modifications in the initial domain seed. An example of this category is Banjori, which only modifies the first four positions of a given hard-coded seed domain.

It is worth mentioning that several DGAs use well-known PRNG algorithms. Notably, almost a third of the studied DGAs (14/43) use a linear congruential generator (LCG) [36] defined by the recurrence relation $X_{n+1} = (aX_n + c) \bmod m$. By matching the used parameters a , c , and m against those of common LCGs, we found that 10 DGAs use known LCG constants: 4 DGAs use the implementation described in the Numerical Recipes book [39] (NR LCG), 3 DGAs use the *minimal standard* implementation proposed by Park and Miller [36] (PM LCG), 2 DGAs use the Microsoft Visual C library (MS LCG), and one DGA uses the Delphi LCG. The remaining 4 LCGs use self-chosen constants. Other uses of well-known PRNGs we identified are Mersenne Twister [33] and Xorshift [31]. Five DGAs use MD5 for initializing their own PRNG and one uses the checksum CRC32.

4.5 Command & Control Priority

More than half of the studied botnets (23/43) use their DGA as the only C&C rendezvous mechanism. Moreover, although 5 other families (identified by a star in Table 1) first try hard-coded domains before turning to their DGAs, the DGAs can also be considered as the primary communication mechanism. Banjori, TinyBanker, and UrlZone first try a single hard-coded domain that is later used in computing the initial seed of the corresponding DGA. Matsnu contains multiple prioritized hard-coded domains. However, the same domains are also generated by its DGA at some point in time. Nymaim contains a *legacy* primary hard-coded domain that is long mitigated and probably disregarded by the botmasters, meaning that it mainly relies on its DGA instead.

Other families use their DGAs as a backup mechanism when their primary communication method (usu-

ally hard-coded domains) fails. For example, Rovnix tries to connect to one of its hard-coded domains. If this fails, it resorts to its DGA before finally trying a connection via Invisible Internet Project (I2P). The remaining families use their DGAs as a last resort to reach the C&C server.

This clearly shows the prevalence of DGAs in modern botnets. For this reason, we believe that DGAs should be no longer perceived mainly as a backup mechanism but instead as a primary C&C concept.

5 DGA Domain Usage

In this section, we present the results of our analysis on how DGAs are actually used in practice. We base our analysis on WHOIS data for the last 14 years, and give insights into the family activity periods, registration status of DGA domains, and botmaster registration strategies. We also analyze the mitigation response time.

5.1 WHOIS Dataset

We based our analysis on the DomainTools WHOIS dataset, which contains over 9 billion WHOIS records collected over the last 14 years [19]. Based on our reimplementations and the available seeds, we computed all possible domains generated by the studied 43 DGAs. We provided the computed domains to DomainTools, and they kindly provided us with WHOIS records for DGA domains they found in their dataset. The data provided by DomainTools for this study was compiled on the 22nd September of 2015. This enabled us to identify 303,165 DGA-related WHOIS records for 115,387 domains.

A special care had to be given to time-dependant DGAs, which use the date information for computing their domains. To ensure a good coverage and minimize the set of DGA domains we miss, we computed all domains that cover a time period of one year before any publicly known starting date until 31st December 2015 (three months after the last WHOIS record in the DomainTools dataset). This end date provides around 3 months of *lookahead*, detecting domains that are registered for some time before being actually used.

These WHOIS records contain the following fields

- Date of the WHOIS record
- Date of updates to the WHOIS record
- Dates for domain creation and expiration
- Registrar name
- Registrant name and e-mail address
- Nameservers registered in WHOIS

This enabled us to infer the following information:

- 1) *Domain first registration*. This is based on the date of the WHOIS record and date of domain creation.

2) *Start of botnet activity*. The first record for any domain implicitly indicates that the domain is registered and helps to estimate when the corresponding malware family started its operation.

3) *Changes in domain ownership*. The date of updates to a WHOIS record often corresponds to a change in responsibility for a domain. This can be verified by accompanying changes to the registrar, registrant, and registered nameserver fields. This allows us to derive when a potential C&C domain has been mitigated (e.g., sinkholed), by observing changes of the WHOIS record from a non-sinkhole operator to a sinkhole operator. We identify 29 different organizations running sinkholes, but we will not disclose further details about the features used to detect sinkhole organizations to protect their operations.

4) *Parked domains*. The registrar, registrant, and registered nameserver fields convey information that we use to identify parked domains in order to investigate how common AGDs are held for the purpose of picking up accidental traffic or reselling. In total, we identify 36 services offering domain parking or domain reselling.

Our dataset covers all but five of the studied families: Conficker and Virut generate an exceedingly large number of domains, and were therefore not included in the dataset provided to us. Corebot, Kraken, and Mewsei use DDNS-based DGAs, and are thus not available in the original DomainTools WHOIS dataset, which only contains primary domain names but no subdomains. It is noteworthy that non-deterministic seeding as used by Bedep does not prevent retroactive analysis, as we are still able to generate all domains by collecting the used exchange rates over time.

5.2 Family Activity Periods

In this section, we analyze the period of time in which the studied botnets were active and domains were registered for malicious purposes. To this end, we first identify the date of the first related record in our dataset, denoted by T_{first} . In many cases, this is the first observed registration overall. In cases where the data indicates collisions with benign domains (cp. Section 5.4), we analyze records from the first sinkhole event backwards. Then, we identify the time when the domains were either taken down or they were registered last, denoted by T_{last} . The detailed activity periods for the studied botnets are shown in Table 3. For families we did not have data for, their respective T_{first} is estimated from public sources as mentioned before.

In case of Bamital, CryptoLocker, and Gameover P2P, T_{last} is the date of their takedown, marked by a †. For Conficker, T_{last} identifies the date on which the last known Conficker variant deleted itself from compromised systems [26]. A special case is Rovnix, for which

Name	T_{first}	T_{last}	$ S $	$ D_{gen} $	$ D_{uniq} $	$ R_{all} $	$\frac{ R_{all} }{ D_{uniq} }$	$ R_P $	$ R_M $	$ R_S $

Table 3: Overview of DGA usage characteristics. $|S|$: seeds known for this DGA. D : domains generated until 31.12.2015, R : registered domains ($|R_P|$: prior to T_{first} ; $|R_M|$: turned into a sinkhole; $|R_S|$: directly registered as sinkhole; in brackets: related to botnet takedowns). Registration percentage based on D_{uniq^*} , thus considering only AGDs where registration data was available.

we only identified a single registration by a sinkhole operator, and thus decided to leave T_{last} open.

After identifying the starting date for each family (T_{first}), we removed the AGDs we computed for earlier points in time. This reduces the computed set to 165,161,439 AGDs in total, 159,712,234 of them being unique across all DGAs. Additionally, we remove the computed domains for the families not available in the DomainTools dataset, leaving us with a set of 18,446,125 unique AGDs. We denote this set by D_{uniq^*} and use it for all following examinations.

Having a closer look at T_{first} shows that although the concept has been first used in 2007, more than half of the analyzed DGAs (25/43) were introduced 2013 and later. It seems like malware authors waited for early adopters to gather experience with running DGA-based botnets before trying it out themselves. Cases with short activ-

ity times indicate that some authors seemingly also only experimented with DGAs. For example, while early versions of Geodo used hard-coded IP addresses for C&C communication, one version with a DGA was used for only about 6 weeks. After that, the botmasters returned back to the old communication method.

Murofet 2 remained active for three months only, before its widespread successor Gameover P2P, which used a very similar DGA, appeared. Gameover DGA, another successor that appeared shortly after the takedown of Gameover P2P, was active for only about 5 months. Although binary diffing implies that it relies on the same source code as Gameover P2P, it is uncertain whether it was operated by same original author Slavik [42] or if it was only used as a distracting maneuver.

We use T_{last} to identify active families as of this writing. We consider a family to be active if its DGA gener-

ated a domain that was used within the last month of the time period covered by the WHOIS dataset. Based on that, we identify 10 families: Gozi, Nymaim, Suppobox, UrIZone, QakBot, Matsnu, Dyre, TinyBunker, Bedep, and Shifu. This serves as a lower bound for estimating active families since some do not use DGA as their primary C&C rendezvous mechanism.

5.3 Domain Registration Status

Out of the 18,446,125 unique generated AGDs, 115,079 were actually registered (0.62%). 72.37% of these registered AGDs correspond to sinkhole operators, while the remaining 27.63% are non-takedown domains. We divide the set of registered AGDs into four categories:

- 1) **Pre-registered domains (30.25%).** Domains that have been registered before T_{first} . These domains were usually registered long before the corresponding botnet appeared, and are very likely benign.
- 2) **Mitigated domains (3.76%).** Domains that were originally held by a non-sinkhole registrant but then changed to a sinkhole operator, usually indicating that the domain has been mitigated (Section 5.6).
- 3) **Pure sinkhole domains (16.24%).** Domains registered by a sinkhole operator from the start.
- 4) **Remaining domains (49.75%).** This set contains domains that were registered between T_{first} and T_{last} but we were not able to reliably identify them as sinkholes, or otherwise tell whether they are benign or malicious (mostly due to the use of a WHOIS privacy service). However, the number of benign domains (at least for non-wordlist DGAs) is highly likely to be a minority, given that few DGAs have pre-registered domains and the common randomness and domain length produced by most DGAs.

5.4 Domain Collisions

In order to evaluate if AGDs are a good feature to reliably identify the corresponding botnet, we analyze collisions between domains generated by different DGAs. Out of the 43 DGAs, the two aggressive DGAs Virut and Conficker have collisions among each other and with Necurs, Nymaim, and Pykspa 2. More specifically, Virut has 1791 collisions with Pykspa 2, 1316 with Conficker, and 179 with Nymaim. Conficker has 11 collisions with Pykspa 2, 4 with Necurs, and 1 with Nymaim. All of the colliding domains are 5 to 6 characters long. Apart from that, only Nymaim and Pykspa 2 have a single collision since they both generate the AGD `wttttf.net`.

Next, we analyze collisions between DGA-generated domains and benign domains. To this end, we use the Alexa list [10] and compare it to the set of domains generated by each DGA. Again here, only a small num-

ber of collisions were found. Virut has 2507 collisions with Alexa top million domains, which corresponds to 0.016% of its unique AGDs. For all other DGAs, we only found 27 collisions with the Alexa list: 24 collisions with wordlist-based DGAs (Suppobox: 21, Matsnu: 2, Gozi: 1), and three collisions with Pykspa 2 domains that are 6 character long.

We then investigated the collisions between DGA-generated domains and domains that were already registered before the corresponding botnet appeared (before T_{first}). As one would expect, the highest number of collisions were observed with wordlist-based DGAs: 74.39% of Suppobox AGDs and 40.0% of Matsnu AGDs collide with already existing domains. In spite of being a wordlist DGA, Gozi has a low number of collisions with already registered domains. This is because the DGA truncates, with a probability of 33%, a chosen word before appending it to the computed AGD. This creates many domains that contain a *broken* word, making accidental registration far less likely. For the remaining families, 856 of 928 (92.24%) pre-registered AGDs have length 5 to 6, and everything longer is accidentally a word (e.g. `veterans.kz`) or otherwise very pronounceable (e.g. `kankanana.com`, `kandilmed.com`).

These results clearly show that DGAs not based on wordlists and generating domain names longer than 6 characters (which is the case for 34/43 DGAs) serve as a reliable source to detect the corresponding botnet family.

5.5 Domain Registration Lookahead

A special property of AGDs from time-dependent DGAs is, that they are only valid during certain periods of time. In this section, we give insights into the domain registration *lookahead* for time-dependant DGAs, i.e., the amount of time from registering the domain until the point in time where it becomes valid (produced by the DGA at that time). Here, we distinguish between sinkhole and non-sinkhole registrations (potentially by botmasters).

Figure 2 provides an overview of our results for the 22 time-dependant DGAs in our dataset. For each family, the results are summarized using a boxplot showing the registration times of DGA domains relative to the start of the corresponding validity periods (day zero). That is, a registration event at $x = -1$ means that the corresponding domain was registered one day before it became valid. For better visualization, we choose a symmetric mixed linear (for the first 10 days) and logarithmic (everything beyond) scale. This allows best to display data with a finer resolution around the majority of validity periods but also allows to include events up to a thousand days away. For better orientation, the red bars indicate the whole validity period of AGDs per family. In this Fig-

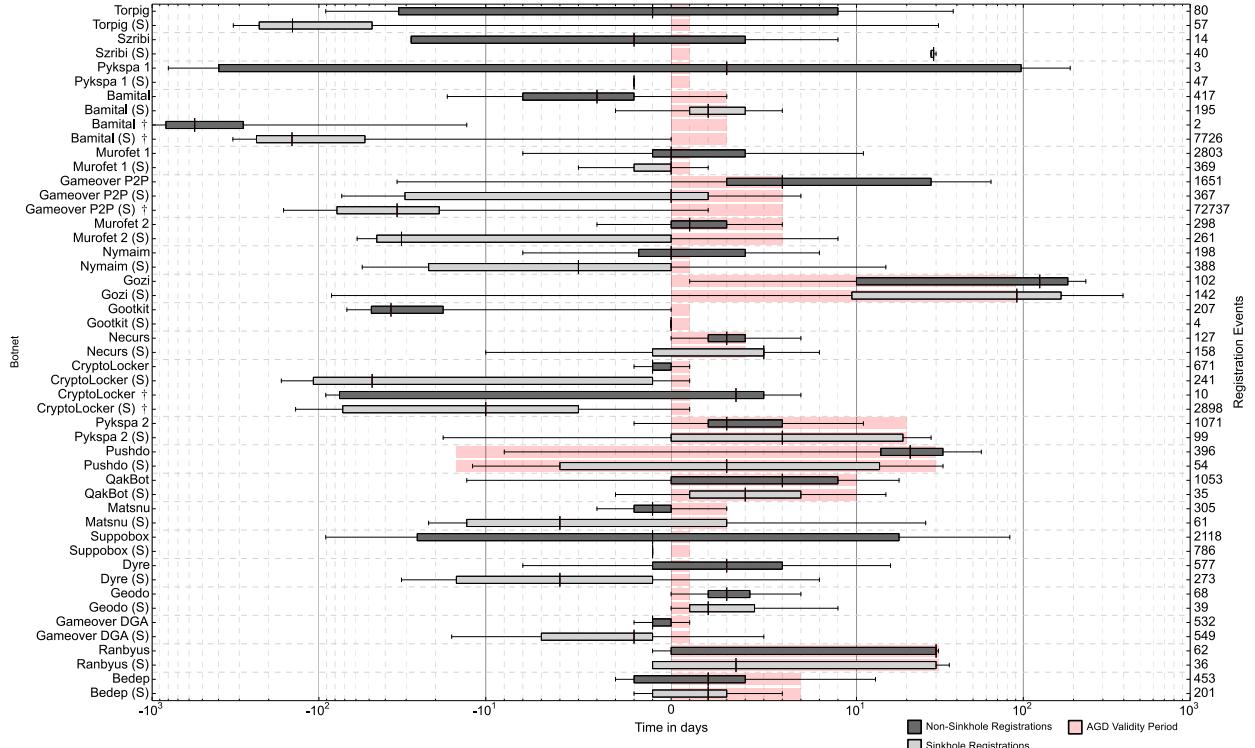

Figure 2: Lookahead of domain registrations in time-dependent DGAs, divided into identifiable sinkholes and remaining domains. The data in this boxplot is applied relative to the start the respective AGD’s validity period (shown in light red for better orientation). Bamital, GameoverP2P, CryptoLocker data is further divided into pre and post takedown (indicated by †).

ure, we distinguish between four possible categories for each family: 1) none sinkhole registrations; 2) sinkhole (marked by S) registrations; 3) pre-takedown registrations; and 4) post-takedown registrations (marked by †). Note that the registration numbers may vary from those in Table 3. This is a result of plotting data after T_{first} with respect to validity start instead of the registration dates.

The main observation is that for 14 of 22 DGAs, sinkhole operators registered the domains earlier than non-sinkholders. Comparing the medians of these cases reveals that in 7 cases sinkhole registrations happen between 1 and 10 days earlier, while in the remaining 7 cases they happen between 18 and 143 days earlier. The 143 days are for Torpig, where the majority of sinkhole domains were registered 5 months in advance with close validity periods, which seems to be a takedown attempt. The second highest difference (48 days) was for CryptoLocker. For 3/22 DGAs, sinkhole and non-sinkhole registrations happened at the same time. In the remaining 5/22 DGAs, non-sinkhole registrations occurred between 2 and 37 days before sinkhole registrations.

In the case of Gootkit, a single sinkhole operator registered DGA domains on the same day when they became valid, indicating a reactive response to these domains be-

ing used by the malware but not being taken yet, potentially blocking the botmaster from registering them.

Sinkhole operators usually do not fear that their domains will be taken away by other entities, which explains the general trend of sinkholders registering domains before botmasters. Moreover, this enables them to evaluate incoming traffic for these domains even before they become valid. On the other hand, botmasters have to assume that their domains will eventually be mitigated. As a result, they register their domains shortly before or inside the validity period in order to ensure the availability of these domains when the bots are expected to try to contact them. This means that constant monitoring of AGDs with validity periods around the takedown date is a necessary condition for success.

For the three families with takedowns, sinkhole registrations happened at least weeks and often months prior to validity of the AGDs. This ensures that botmasters cannot quickly regain control of their botnet by registering further AGDs. While the takedown of Gameover P2P’s AGDs was seemingly complete, AGDs for both Bamital and CryptoLocker were registered by non-sinkholders after the takedown. In case of CryptoLocker, these domains were registered shortly before

their validity started, indicating that not all domains remain blocked through the same central authority.

We observed an interesting pattern in the case of Bamital. On January 1st, 2011, AGDs for January 4th, 2012, January 3rd, 2013, and January 4th, 2014 domains were registered by the same registrant. We believe that this was done by the operators of Bamital in an attempt to timely secure *insurance domains* to be used as backup in case of a later takedown, speculating that these domains do not get discovered. We identified similar strategies by the botmasters of Nymaim and Murofet. In case of Nymaim, on December 6th, 2012 and December 9th, 2012, two domains becoming valid in 1 and 2 years respectively were registered. For Murofet, on March 12th, 2011 and the 3 following days, 4 domains becoming valid in 1 year, 5 valid in 2 years, 3 valid in 3 years, and 3 valid in 4 years have been registered. All of them use different, apparently fake identities but the same registrar. This shows that potential registrations of AGDs should be checked considerably far ahead during the preparation of a takedown campaign.

The number for sinkhole registrations of Pykspa 1 and Suppobox is impressively small. For these families, most AGDs are registered with the same lookahead by single sinkhole operators over longer periods of time. Registering only a small fraction of available domains indicates botnet monitoring operations by sinkholders. On the other hand, we observed many different entities involved on non-sinkhole registrations of Suppobox domains. Given the comparatively high collision rate with benign domains (Section 5.4), we believe that many of these domains belong to benign registrants. This shows that the Suppobox DGA blends in very well with legitimate domain owners, allowing the botmasters to hide their C&Cs among benign domains.

We observed a few peculiarities with regard to domain registrations. Registrations for Gozi tend to be late for both sinkholders and others. We found no coherent explanation for this. Another oddity are the sinkhole registrations for Szribi. While 8 registrations happened in 2008 when the botnet was active, another 32 registrations happened in 2015, more than 4 years after the botnet disappeared. Moreover, all of these 32 domains were registered one month after they became invalid. We believe that the respective sinkholing organization used a wrong DGA reimplementation to calculate the AGDs.

5.6 Mitigation Response Time

By mitigation we mean a change of domain ownership from a non-sinkhole to a sinkhole operator. In this section, we analyze the time offset for these events in order to measure the effectiveness of these operations. Here, we only consider DGAs where 10 or more mitigations

were identified that are not related to takedowns. Table 4 summarizes the results of this examination. In most cases, the first mitigations against new DGAs or seeds are carried out within a week.

One would expect that after initial identification of a DGA or a new seed for a DGA, all further mitigations would have a much lower response time as the potentially generated domains should be known. We observe relatively short median reaction times \tilde{m} for Murofet 1, Suppobox, Gameover DGA, and TinyBanker. These are also the DGAs where most AGDs were mitigated within their respective validity periods. On the other hand, the countermeasures for Bamital and CryptoLocker have been very ineffective as they mostly targeted AGDs that were no longer valid.

Response times for all other DGAs increase after the first mitigation. Interestingly, multiple follow-up mitigations for these DGAs were carried out on the same day. This pattern corresponds to a common practice by defenders. After identifying initial malicious domains, they look at other domains that point to the same C&C server by performing a reverse IP lookup. This identifies additional AGDs which may have been registered even before the initially identified AGD. This was observed for Nymaim, Ramnit, and UrlZone.

5.7 DGAs and Domain Parking

Next, we examine how many AGDs are registered towards domain parking services. For identification of such domains, we used a procedure similar to Vissers et al. [51]. In total, we found 6,458 AGDs that contained a registration pointing to a parking service at some point in time. This corresponds to the common practice that after the registration period of an original owner ends, the expired domain is transferred to domain parking or picked up by a domain reseller.

To our surprise, for 3,852 of these AGDs, the parking registration was also the first and in many cases only registration entry. In particular, first parking registration events constitute a significant portion of registrations for the following DGAs: Banjori 620 (90.78%), QakBot 595 (54.69%), Pykspa 2 883 (45.82%), Necurs 122 (41.36%), Pushdo TID 91 (37.14%), Ramnit 286 (30.46%), Murofet 1 736 (23.20%). Except for Pykspa 2, none of these DGAs has a significant number of pre-registrations $|R_P|$, which makes unintended or accidental registration extremely unlikely. It is also noteworthy, that for these DGAs, 2,917 (87.52%) domains are registered with the same domain parking service. With regard to validity periods, 464 out of 2336 (19.86%) time-dependent AGDs are registered before the end of the respective validity periods. In this special case, together with the time-independent AGDs, at least 1461 AGDs were potentially

Name	Seeds	Mitigations	Validity Period		First Response (in days)				Further Responses (in days)			
			within	after	m_{min}	\bar{m}	\tilde{m}	m_{max}	m_{min}	\bar{m}	\tilde{m}	m_{max}
Murofet 1	1	50	37	13	25	25	25.00	25	0	0	1.77	25
Bamital	1	148	16	132	6	6	6.00	6	3	49	47.37	92
Nymaim	2	16	4	12	1	16	16.00	31	0	5	31.46	212
Ramnit	16	126	-	-	2	19	34.60	153	0	35	54.28	363
CryptoLocker	1	216	25	191	9	9	9.00	9	0	8	14.69	130
Suppobox	2	19	13	6	3	117	117.50	232	0	0	25.12	194
DirCrypt	7	13	-	-	0	3	7.00	26	0	5	10.50	41
UrlZone	4	24	-	-	0	4	6.75	19	0	114	112.40	251
QakBot	1	33	15	18	0	0	0.00	0	0	21	28.41	66
Matsnu	2	33	11	22	2	2	2.50	3	2	7	9.16	72
Gameover DGA	2	14	9	5	0	1	1.50	3	0	1	54.17	161
TinyBanker	51	272	-	-	0	3	6.39	61	0	2	5.66	60
Bedep	2	10	4	6	2	5	5.00	8	1	12	13.12	28

Table 4: Mitigation Response Timings for selected DGAs. For time-dependent DGAs, *Validity Period* describes the identified mitigations for active and outdated AGDs. *First Response* is the time until the first mitigation occurred, with values for minimum, median, average, and maximum, aggregated over seeds. *Further Responses* describes the same measures for all following events.

abused to drive automatically generated traffic from compromised hosts towards a domain parking system.

5.8 Discussion: Countering DGAs

In this section, we summarize the observations made in previous sections and discuss how they influence countermeasures against DGAs.

Looking at the distribution of domain generation schemes (Section 4.3), only 3 of 43 DGAs are based on wordlists and therefore produce somewhat meaningful domain names. On the other hand, methods for the detection of domains that appear randomly generated are well-studied [13, 34, 54] and our data suggests that they remain relevant and applicable in the future.

As the study of activity periods has shown (Section 5.2), DGAs have become very relevant to malware authors, especially over the last 2 years, as 25 out of the 43 considered DGAs surfaced 2013 and later.

One of the core concepts of DGAs is the implied economic asymmetry: A single valid domain grants an attacker control while the defender needs to deny access to all potential domains. The overall low number of actually registered AGDs (Section 5.3) underlines the fact that attackers only need to make sparse use of all potential domains when operating their botnets. Additionally, since most attackers seem to register domains very shortly before their validity or use (Section 5.5), there is a high chance that they can be hit by surprise and the perceived backup utility of DGAs can be cancelled. However, having identified registration events up to 4 years upfront means future domains should be carefully checked to ensure successful takedowns.

Our data indicates that in past takedowns, domains were acquired on a large scale, imposing significant financial efforts connected to the takedown. Having do-

mains registered as consequence of a takedown allows them to be used as sinkholes in order to gather telemetry on compromised systems calling in. However, single AGDs per validity period would be enough to achieve the same monitoring effect, similar to how an attacker only needs a single domain, as long as the remaining domains are not available. Therefore, we propose to raise awareness of the relevance and innerworkings of DGAs to ICANN and make extensive use of blocking AGDs on the level of registry operators. The expected impact of blocking would actually be negligible for the majority AGDs: 34/43 of the DGAs analyzed have AGDs with minimum length 7 or more, for which we observed basically no collisions with existing domains for their entire set of AGDs (Section 5.4), meaning that these domains seem unlikely to be registered for benign purposes anyway. In case of time-dependent DGAs, this blocking could even be lifted once the validity period of the respective AGDs has passed, which could be a compromise to address wordlist-based DGAs.

Furthermore, we identified only 3,302 collisions between 5 DGAs within 159,712,234 unique DGA domains (Section 5.4). This means that a lookup database of AGDs like our data set serves as a very reliable resource to aid the identification of malware families based on contacted domains with basically no false positives. As a service to the community, we continue to collect information on DGAs and provide this data for free through DGArchive [38].

6 Related Work

Among others, the following works have addressed Domain Generation Algorithms in detail. Stone-Gross et al. [50] have performed a botnet takeover for Torpig in early 2009. Based on reverse-engineering, they took ad-

vantage of the fact that this family was using a Domain Generation Algorithm without further protection mechanisms in the C&C protocol. Their publication was one of the first descriptions detailing the concept of DGAs in academic literature. Barabosch et al.[16] have defined a taxonomy of DGA types based on the 2 features time-dependency and causality. They also explained a method for the automated localization of DGA-related code using dynamic analysis for unpacking and API tracing in combination with data flow analysis for code extraction. Mowbray et al. [34] have used collected DNS data to identify potential DGA domains examining the query source IP address and length distribution of queried domain names. With this approach they identified 19 different schemes of AGDs and list a subset of characteristics of those given in Table 1.

Several works target the detection of DGAs and other maliciously used domains based on collected network traffic. In 2010, Yadav et al. [54] have evaluated several statistical measures over character distributions and n-grams in domain names in order to detect generated domain names through anomalies. Antonakakis et al. [13] have presented Pleiades, a DNS-based system that detects clusters of potential DGA domains by monitoring unsuccessful DNS requests. As confirmed by our work, they built their system on the assumption that only a fraction of AGDs is actually registered. They were able to find 6 new DGAs that were unknown at the time by evaluating traffic from a large ISP. Another approach using DNS data named Phoenix is proposed by Schiavoni et al. [43]. They have defined a model for pronounceable domains and afterwards detect those domains deviating from this model. Their system also groups identified domains and allows tracking the activity of DGA-based botnets. Bilge et al. [18] have introduced their system Exposure. It is used to detect malicious domain names based on a selection of 15 features observable for DNS traffic, including time-based, DNS answer-based, TTL, and domain name features.

There are also works that explore capabilities of dynamic and proactive blacklisting. In 2009, Ma et al. [28] have compared the usefulness of different information sources for blacklisting. They found out that WHOIS data, especially temporal information of registrations, are very valuable in this regard. Antonakakis et al. [12] have proposed Notos, a system to automatically assign scores to domain names that can be used to automatically generate blacklists. They focus on features of domain strings and TLDs. Xu et al. [53] have mentioned the idea to pre-generate AGDs in order to enable predictive blocking. However, they did not evaluate the effectiveness of this idea, as shown by us in this paper.

Recently, Vissers et al. [51] have investigated the relationship of domain parking services and malicious do-

mains, using DNS and WHOIS data sets. Nadji et al. [35] have developed a concept for effective botnet takedowns in which they identify covering potential DGA presence as important step for effectiveness. With regard to the analysis of further innovations in C&C rendezvous mechanisms, Holz et al. [23] have investigated Fast-Flux Service Networks, while Rossow et al. [40] have performed a survey of botnets using P2P mechanisms.

7 Conclusion

In this work, we presented the first comprehensive measurement study of domain generation algorithms as used by modern botnets. Our study is based on reverse-engineering the DGAs of 43 malware families and variants. Using reimplementations of the algorithms, we generated a collection of 159,712,234 unique DGA domains. We then performed an analysis on domain registrations, utilizing historic WHOIS data provided by DomainTools. Our main findings are that our domain dataset can be used for both predictive blocking of attempted C&C accesses as well as the accurate determination of malware families and campaigns with basically no false positives. Additionally, we characterized the registration behavior of botmasters and sinkholders and examined the effectiveness of domain mitigations.

As a further contribution, we continuously collect further information on DGAs. The full domain data set which results from our work is published for free here: <https://dgarchive.caad.fkie.fraunhofer.de>. This web service called *DGArchive* offers reverse domain lookups to support malware analysis, as well as forward generation of domain lists, which can be particularly used as blocklists for network protection.

Acknowledgments

The authors would like to express eternal gratitude to the Shadowserver Foundation for continuously supporting malware research. We would also like to thank the anonymous reviewers of USENIX Security as well as Daniela Bennewitz, Arnold Sykosch, and Matthias Wübbeling for their valuable feedback.

EPFL

Abstract

While showing great promise, Bitcoin requires users to wait tens of minutes for transactions to commit, and even then, offering only probabilistic guarantees. This paper introduces ByzCoin, a novel Byzantine consensus protocol that leverages scalable collective signing to commit Bitcoin transactions irreversibly within seconds. ByzCoin achieves Byzantine consensus while preserving Bitcoin’s open membership by dynamically forming hash power-proportionate consensus groups that represent recently-successful block miners. ByzCoin employs communication trees to optimize transaction commitment and verification under normal operation while guaranteeing safety and liveness under Byzantine faults, up to a near-optimal tolerance of f faulty group members among $3f + 2$ total. ByzCoin mitigates double spending and selfish mining attacks by producing collectively signed transaction blocks within one minute of transaction submission. Tree-structured communication further reduces this latency to less than 30 seconds. Due to these optimizations, ByzCoin achieves a throughput higher than Paypal currently handles, with a confirmation latency of 15-20 seconds.

1 Introduction

Bitcoin [47] is a decentralized cryptocurrency providing an open, self-regulating alternative to classic currencies managed by central authorities such as banks. Bitcoin builds on a peer-to-peer network where users can submit transactions without intermediaries. Special nodes, called *miners*, collect transactions, solve computational puzzles (*proof-of-work*) to reach consensus, and add the transactions in form of blocks to a distributed public ledger known as the *blockchain*.

The original Bitcoin paper argues that transaction processing is secure and irreversible, as long as the largest colluding group of miners represents less than 50% of

total computing capacity and at least about one hour has elapsed. This high transaction-confirmation latency limits Bitcoin’s suitability for real-time transactions. Later work revealed additional vulnerabilities to transaction reversibility, double-spending, and strategic mining attacks [25, 31, 34, 35, 48, 3].

The key problem is that Bitcoin’s consensus algorithm provides only probabilistic consistency guarantees. Strong consistency could offer cryptocurrencies three important benefits. First, all miners instantly agree on the validity of blocks, without wasting computational power resolving inconsistencies (*forks*). Second, clients need not wait for extended periods to be certain that a submitted transaction is committed; as soon as it appears in the blockchain, the transaction can be considered confirmed. Third, strong consistency provides *forward security*: as soon as a block has been appended to the blockchain, it stays there forever. Although increasing the consistency of cryptocurrencies has been suggested before [17, 19, 43, 52, 56], existing proposals give up Bitcoin’s decentralization, and/or introduce new and non-intuitive security assumptions, and/or lack experimental evidence of performance and scalability.

This work introduces ByzCoin, a Bitcoin-like cryptocurrency enhanced with strong consistency, based on the principles of the well-studied Practical Byzantine Fault Tolerance (PBFT) [14] algorithm. ByzCoin addresses four key challenges in bringing PBFT’s strong consistency to cryptocurrencies: (1) open membership, (2) scalability to hundreds of replicas, (3) proof-of-work block conflicts, and (4) transaction commitment rate.

PBFT was not designed for scalability to large consensus groups: deployments and experiments often employ the minimum of four replicas [38], and generally have not explored scalability levels beyond 7 [14] or 16 replicas [16, 32, 1]. ByzCoin builds PBFT atop CoSi [54], a collective signing protocol that efficiently aggregates hundreds or thousands of signatures. Collective signing reduces both the costs of PBFT rounds and the costs

for “light” clients to verify transaction commitment. Although CoSi is not a consensus protocol, ByzCoin implements Byzantine consensus using CoSi signing rounds to make PBFT’s *prepare* and *commit* phases scalable.

PBFT normally assumes a well-defined, closed group of replicas, conflicting with Bitcoin’s open membership and use of proof-of-work to resist Sybil attacks [23]. ByzCoin addresses this conflict by forming consensus groups dynamically from *windows* of recently mined blocks, giving recent miners *shares* or voting power proportional to their recent commitment of hash power. Lastly, to reduce transaction processing latency we adopt the idea from Bitcoin-NG [24] to decouple transaction verification from block mining.

Experiments with a prototype implementation of ByzCoin show that a consensus group formed from approximately the past 24 hours of successful miners (144 miners) can reach consensus in less than 20 seconds, on blocks of Bitcoin’s current maximum size (1MB). A larger consensus group formed from one week of successful miners (1008) reached consensus on an 8MB block in 90 seconds, showing that the system scales both with the number of participants and with the block size. For the 144-participant consensus group, with a block size of 32MB, the system handles 974 transactions per second (TPS) with a 68-second confirmation latency. These experiments suggest that ByzCoin can handle loads higher than PayPal and comparable with Visa.

ByzCoin is still a proof-of-concept with several limitations. First, ByzCoin does not improve on Bitcoin’s proof-of-work mechanism; finding a suitable replacement [4, 28, 37, 58] is an important but orthogonal area for future work. Like many BFT protocols in practice [15, 32], ByzCoin is vulnerable to slowdown or temporary DoS attacks that Byzantine nodes can trigger. Although a malicious leader cannot violate or permanently block consensus, he might temporarily exclude minority sets ($< \frac{1}{3}$) of victims from the consensus process, depriving them of rewards, and/or attempt to censor transactions. ByzCoin guarantees security only against attackers who consistently control less than a third (not 50%) of consensus group shares – though Bitcoin has analogous weaknesses accounting for selfish mining [25].

In this paper we make the following key contributions:

- We use collective signing [54] to scale BFT protocols to large consensus groups and enable clients to verify operation commitments efficiently.
- We present (§3) the first demonstrably practical Byzantine consensus protocol supporting not only static consensus groups but also dynamic membership proportional to proof-of-work as in Bitcoin.
- We demonstrate experimentally (§4) that a strongly-consistent cryptocurrency can increase Bitcoin’s throughput by two orders of magnitude, with a trans-

action confirmation latency under one minute.

- We find through security analysis (§5) that ByzCoin can mitigate several known attacks on Bitcoin provided no attacker controls more than $\frac{1}{4}$ of hash power.

2 Background and Motivation

This section first outlines the three most relevant areas of prior work that ByzCoin builds on: cryptocurrencies such as Bitcoin and Bitcoin-NG, Byzantine fault tolerance (BFT) principles, and collective signing techniques.

2.1 Bitcoin and Variations

Bitcoin. At the core of Bitcoin [47] rests the so-called *blockchain*, a public, append-only database maintained by *miners* and serving as a global ledger of all transactions ever issued. Transactions are bundled into *blocks* and validated by a *proof-of-work*. A block is valid if its cryptographic hash has d leading zero bits, where the difficulty parameter d is adjusted periodically such that new blocks are mined about every ten minutes on average. Each block includes a Merkle tree [44] of new transactions to be committed, and a cryptographic hash chaining to the last valid block, thereby forming the blockchain. Upon successfully forming a new block with a valid proof-of-work, a miner broadcasts the new block to the rest of the miners, who (when behaving properly) accept the new block, if it extends a valid chain strictly longer than any they have already seen.

Bitcoin’s decentralized consensus and security derive from an assumption that a majority of the miners, measured in terms of *hash power* or ability to solve hash-based proof-of-work puzzles, follows these rules and always attempts to extend the longest existing chain. As soon as a quorum of miners with the majority of the network’s hash power approves a given block by mining on top of it, the block remains embedded in any future chain [29]. Bitcoin’s security is guaranteed by the fact that this majority will be extending the legitimate chain faster than any corrupt minority that might try to rewrite history or double-spend currency. However, Bitcoin’s consistency guarantee is only probabilistic, which leads to two fundamental problems.

First, multiple miners might find distinct blocks with the same parent before the network has reached consensus. Such a conflict is called a *fork*, an inconsistency that is temporarily allowed until one of the chains is extended yet again. Subsequently, all well-behaved miners on the shorter chain(s) switch to the new longest one. All transactions appearing only in the rejected block(s) are invalid and must be resubmitted for inclusion into the winning blockchain. This means that Bitcoin clients who want high certainty that a transaction is complete (e.g., that

they have irrevocably received a payment) must wait not only for the next block but for several blocks thereafter, thus increasing the time interval until a transaction can be considered complete. As a rule of thumb [47], a block is considered as permanently added to the blockchain after about 6 new blocks have been mined on top of it, for a confirmation latency of 60 minutes on average.

Second, the Bitcoin block size is currently limited to 1 MB. This limitation in turn results in an upper bound on the number of transactions per second (TPS) the Bitcoin network can handle, estimated to be an average of 7 TPS. For comparison, Paypal handles 500 TPS and VISA even 4000 TPS. An obvious solution to enlarge Bitcoin’s throughput is to increase the size of its blocks. Unfortunately, this solution also increases the probability of forks due to higher propagation delays and the risk of double-spending attacks [53, 30, 36]. Bitcoin’s liveness and security properties depend on forks being relatively rare. Otherwise, the miners would spend much of their effort trying to resolve multiple forks [31, 17], or in the extreme case, completely centralize Bitcoin [24].

Bitcoin-NG. Bitcoin-NG [24] makes the important observation that Bitcoin blocks serve two different purposes: (1) election of a leader who decides how to resolve potential inconsistencies, and (2) verification of transactions. Due to this observation, Bitcoin-NG proposes two different block types: *Keyblocks* are generated through mining with proof-of-work and are used to securely elect leaders, at a moderate frequency, such as every 10 minutes as in Bitcoin. *Microblocks* contain transactions, require no proof-of-work, and are generated and signed by the elected leader. This separation enables Bitcoin-NG to process many microblocks between the mining of two keyblocks, enabling transaction throughput to increase.

Bitcoin-NG, however, retains many drawbacks of Bitcoin’s consistency model. Temporary forks due to near-simultaneous keyblock mining, or deliberately introduced by selfish or malicious miners, can still throw the system into an inconsistent state for 10 minutes or more. Further, within any 10-minute window the current leader could still intentionally fork or rewrite history and invalidate transactions. If a client does not wait several tens of minutes (as in Bitcoin) for transaction confirmation, he is vulnerable to double-spend attacks by the current leader or by another miner who forks the blockchain. Although Bitcoin-NG includes disincentives for such behavior, these disincentives amount at most to the “mining value” of the keyblock (coinbase rewards and transaction fees): Thus, leaders are both able and have incentives to double-spend on higher-value transactions.

Consequently, although Bitcoin-NG permits higher transaction throughput, it does not solve Bitcoin’s con-

sistency weaknesses. Nevertheless, Bitcoin-NG’s decoupling of keyblocks from microblocks is an important idea that we build on in Section 3.6 to support high-throughput and low-latency transactions in ByzCoin.

2.2 Byzantine Fault Tolerance

The *Byzantine Generals’ Problem* [39, 49] refers to the situation where the malfunctioning of one or several components of a distributed system prevents the latter from reaching an agreement. Pease et al. [49] show that $3f + 1$ participants are necessary to be able to tolerate f faults and still reach consensus. The *Practical Byzantine Fault Tolerance (PBFT)* algorithm [14] was the first efficient solution to the Byzantine Generals’ Problem that works in weakly synchronous environments such as the Internet. PBFT offers both *safety* and *liveness* provided that the above bound applies, *i.e.*, that at most f faults among $3f + 1$ participants occur. PBFT triggered a surge of research on Byzantine replication algorithms with various optimizations and trade-offs [1, 16, 38, 32].

Every round of PBFT has three distinct phases. In the first, *pre-prepare* phase, the current primary node or *leader* announces the next record that the system should agree upon. On receiving this pre-prepare, every node validates the correctness of the proposal and multicasts a *prepare* message to the group. The nodes wait until they collect a quorum of $(2f + 1)$ prepare messages and publish this observation with a *commit* message. Finally, they wait for a quorum of $(2f + 1)$ commit messages to make sure that enough nodes have recorded the decision.

PBFT relies upon a correct leader to begin each round and proceeds if a two-thirds quorum exists; consequently, the leader is an attack target. For this reason PBFT has a view-change protocol that ensures liveness in the face of a faulty leader. All nodes monitor the leader’s actions and if they detect either malicious behavior or a lack of progress, initiate a view-change. Each node independently announces its desire to change leaders and stops validating the leader’s actions. If a quorum of $(2f + 1)$ nodes decides that the leader is faulty, then the next leader in a well-known schedule takes over.

PBFT has its limitations. First, it assumes a fixed, well-defined group of replicas, thus contradicting Bitcoin’s basic principle of being decentralized and open for anyone to participate. Second, each PBFT replica normally communicates directly with every other replica during each consensus round, resulting in $O(n^2)$ communication complexity: This is acceptable when n is typically 4 or not much more, but becomes impractical if n represents hundreds or thousands of Bitcoin nodes. Third, after submitting a transaction to a PBFT service, a client must communicate with a super-majority of the replicas in order to confirm the transaction has been com-

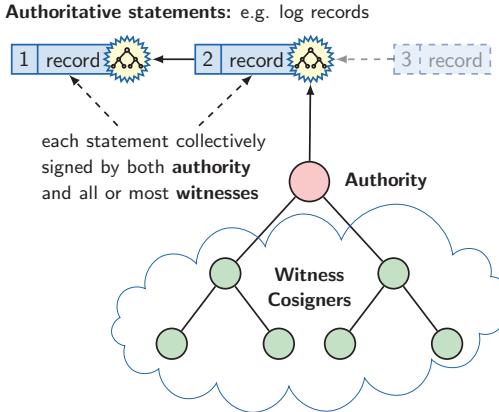

Figure 1: CoSi protocol architecture

mitted and to learn its outcome, making secure transaction verification unscalable.

2.3 Scalable Collective Signing

CoSi [54] is a protocol for scalable collective signing, which enables an authority or *leader* to request that statements be publicly validated and (*co-*)signed by a decentralized group of *witnesses*. Each protocol run yields a *collective signature* having size and verification cost comparable to an individual signature, but which compactly attests that both the leader and its (perhaps many) witnesses observed and agreed to sign the statement.

To achieve scalability, CoSi combines Schnorr multi-signatures [51] with communication trees that are long used in multicast protocols [13, 21, 55]. Initially, the protocol assumes that signature verifiers know the public keys of the leader and those of its witnesses, all of which combine to form a well-known aggregate public key. For each message to be collectively signed, the leader then initiates a CoSi four-phase protocol round that require two round-trips over the communication tree between the leader and its witnesses:

1. **Announcement:** The leader broadcasts an announcement of a new round down the communication tree. The announcement can optionally include the message M to be signed, otherwise M is sent in phase three.
2. **Commitment:** Each node picks a random secret and uses it to compute a Schnorr commitment. In a bottom-up process, each node obtains an aggregate Schnorr commitment from its immediate children, combines those with its own commitment, and passes a further-aggregated commitment up the tree.
3. **Challenge:** The leader computes a collective Schnorr challenge using a cryptographic hash function and broadcasts it down the communication tree, along with the message M to sign, if the latter has not already

been sent in phase one.

4. **Response:** Using the collective challenge, all nodes compute an aggregate response in a bottom-up fashion that mirrors the commitment phase.

The result of this four-phase protocol is the production of a standard Schnorr signature that requires about 64 bytes, using the Ed25519 elliptic curve [6], and that anyone can verify against the aggregate public key nearly as efficiently as the verification of an individual signature. Practical caveats apply if some witnesses are offline during the collective signing process: in this case the CoSi protocol can proceed, but the resulting signature grows to include metadata verifiably documenting which witnesses did and did not co-sign. We refer to the CoSi paper for details [54].

3 ByzCoin Design

This section presents ByzCoin with a step-by-step approach, starting from a simple “strawman” combination of PBFT and Bitcoin. From this strawman, we progressively address the challenges of determining consensus group membership, adapting Bitcoin incentives and mining rewards, making the PBFT protocol scale to large groups and handling block conflicts and selfish mining.

3.1 System Model

ByzCoin is designed for untrustworthy networks that can arbitrarily delay, drop, re-order or duplicate messages. To avoid the FLP impossibility [27], we assume the network has a weak synchrony property [14]. The Byz-Coin system is comprised of a set of N block miners that can generate key-pairs, but there is no trusted public-key infrastructure. Each node i has a limited amount of *hash power* that corresponds to the maximum number of block-header hashes the node can perform per second.

At any time t a subset of miners $M(t)$ is controlled by a malicious attacker and are considered faulty. Byzantine miners can behave arbitrarily, diverting from the protocol and colluding to attack the system. The remaining honest miners follow the prescribed protocol. We assume that the total hash power of all Byzantine nodes is less than $\frac{1}{4}$ of the system’s total hash power at any time, since proof-of-work-based cryptocurrencies become vulnerable to selfish mining attacks by stronger adversaries [25].

3.2 Strawman Design: PBFTCoin

For simplicity, we begin with PBFTCoin, an unrealistically simple protocol that naively combines PBFT with Bitcoin, then gradually refine it into ByzCoin.

For now, we simply assume that a group of $n = 3f + 1$ PBFT replicas, which we call *trustees*, has been fixed and

globally agreed upon upfront, and that at most f of these trustees are faulty. As in PBFT, at any given time, one of these trustees is the *leader*, who proposes transactions and drives the consensus process. These trustees collectively maintain a Bitcoin-like blockchain, collecting transactions from clients and appending them via new blocks, while guaranteeing that only one blockchain history ever exists and that it can never be rolled back or rewritten. Prior work has suggested essentially such a design [17, 19], though without addressing the scalability challenges it creates.

Under these simplifying assumptions, PBFTCoin guarantees safety and liveness, as at most f nodes are faulty and thus the usual BFT security bounds apply. However, the assumption of a fixed group of trustees is unrealistic for Bitcoin-like decentralized cryptocurrencies that permit open membership. Moreover, as PBFT trustees authenticate each other via non-transferable symmetric-key MACs, each trustee must communicate directly with most other trustees in every round, thus yielding $O(n^2)$ communication complexity.

Subsequent sections address these restrictions, transforming PBFTCoin into ByzCoin in four main steps:

1. We use Bitcoin’s proof-of-work mechanism to determine consensus groups dynamically while preserving Bitcoin’s defense against Sybil attacks.
2. We replace MAC-authenticated direct communication with digital signatures to make authentication transferable and thereby enabling sparser communication patterns that can reduce the normal case communication latency from $O(n^2)$ to $O(n)$.
3. We employ scalable collective signing to reduce per-round communication complexity further to $O(\log n)$ and reduce typical signature verification complexity from $O(n)$ to $O(1)$.
4. We decouple transaction verification from leader election to achieve a higher transaction throughput.

3.3 Opening the Consensus Group

Removing PBFTCoin’s assumption of a closed consensus group of trustees presents two conflicting challenges. On the one hand, conventional BFT schemes rely on a well-defined consensus group to guarantee safety and liveness. On the other hand, Sybil attacks [23] can trivially break any open-membership protocol involving security thresholds, such as PBFT’s assumption that at most f out of $3f + 1$ members are honest.

Bitcoin and many of its variations employ a mechanism already suited to this problem: proof-of-work mining. Only miners who have dedicated resources are allowed to become a member of the consensus group. In refining PBFTCoin, we adapt Bitcoin’s proof-of-work mining into a *proof-of-membership* mechanism. This

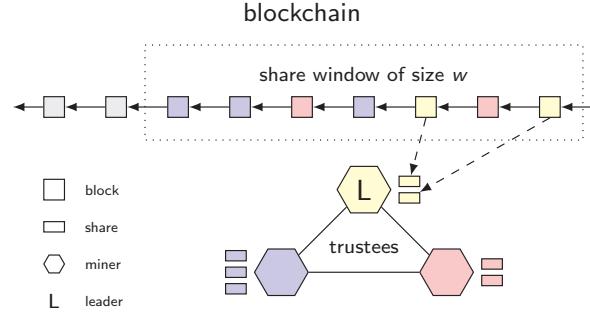

Figure 2: Valid shares for mined blocks in the blockchain are credited to miners

mechanism maintains the “balance of power” within the BFT consensus group over a given fixed-size sliding *share window*. Each time a miner finds a new block, it receives a *consensus group share*, which proves the miner’s membership in the group of trustees and moves the share window one step forward. Old shares beyond the current window expire and become useless for purposes of consensus group membership. Miners holding no more valid shares in the current window lose their membership in the consensus group, hence they are no longer allowed to participate in the decision-making.

At a given moment in time, each miner wields “voting power” of a number of shares equal to the number of blocks the miner has successfully mined within the current window. Assuming collective hash power is relatively stable, this implies that within a window, each active miner wields a number of shares statistically proportionate to the amount of hash power that the miner has contributed during this time period.

The size w of the share window is defined by the average block-mining rate over a given time frame and influences certain properties such as the resilience of the protocol to faults. For example, if we assume an average block-mining rate of 10 minutes and set the duration of the time frame to one day (or one week), then $w = 144$ ($w = 1008$). This mechanism limits the membership of miners to recently active ones, which prevents the system from becoming unavailable due to too many trustees becoming inactive over time, or from miners aggregating many shares over an extended period and threatening the balance in the consensus group. The relationship between blocks, miners and shares is illustrated in Fig. 2.

Mining Rewards and Transaction Fees. As we can no longer assume voluntary participation as in PBFTCoin’s closed group of trustees, we need an incentive for nodes to obtain shares in the consensus group and to remain active. For this purpose, we adopt Bitcoin’s ex-

isting incentives of mining rewards and transaction fees. But instead of these rewards all going to the miner of the most recent block we split a new block’s rewards and fees across all members of the current consensus group, in proportion to the number of shares each miner holds. As a consequence, the more hash power a miner has devoted within the current window, hence the more shares the miner holds, the more revenue the miner receives during payouts in the current window. This division of rewards also creates incentives for consensus group members to remain live and participate, because they receive their share of the rewards for new blocks only if they continually participate, in particular contributing to the prepare and commit phases of each BFT consensus round.

3.4 Replacing MACs by Digital Signatures

In our next refinement step towards ByzCoin, we tackle the scalability challenge resulting from PBFT’s typical communication complexity of $O(n^2)$, where n is the group size. PBFT’s choice of MAC-authenticated all-to-all communication was motivated by the desire to avoid public-key operations on the critical transaction path. However, the cost for public-key operations has decreased due to well-optimized asymmetric cryptosystems [6], making those costs less of an issue.

By adopting digital signatures for authentication, we are able to use sparser and more scalable communication topologies, thus enabling the current leader to collect and distribute third-party verifiable evidence that certain steps in PBFT have succeeded. This removes the necessity for all trustees to communicate directly with each other. With this measure we can either enable the leader to collect and distribute the digital signatures, or let nodes communicate in a chain [32], reducing the normal-case number of messages from $O(n^2)$ to $O(n)$.

3.5 Scalable Collective Signing

Even with signatures providing transferable authentication, the need for the leader to collect and distribute – and for all nodes to verify – many individual signatures per round can still present a scalability bottleneck. Distributing and verifying tens or even a hundred individual signatures per round might be practical. If we want consensus groups with a thousand or more nodes, however (e.g., representing all blocks successfully mined in the past week), it is costly for the leader to distribute 1000 digital signatures and wait for everyone to verify them. To tackle this challenge, we build on the CoSi protocol [54] for collective signing. CoSi does not directly implement consensus or BFT, but it offers a primitive that the leader in a BFT protocol can use to collect and aggregate prepare and commit messages during PBFT rounds.

We implement a single ByzCoin round by using two sequential CoSi rounds initiated by the current leader (*i.e.*, the owner of the current view). The leader’s announcement of the first CoSi round (phase 1 in Section 2.3) implements the *pre-prepare* phase in the standard PBFT protocol (Section 2.2). The collective signature resulting from this first CoSi round implements the PBFT protocol’s *prepare* phase, in which the leader obtains attestations from a two-thirds super-majority quorum of consensus group members that the leader’s proposal is safe and consistent with all previously-committed history.

As in PBFT, this prepare phase ensures that a proposal *can be* committed consistently, but by itself it is insufficient to ensure that the proposal *will be* committed. The leader and/or some number of other members could fail before a super-majority of nodes learn about the successful prepare phase. The ByzCoin leader therefore initiates a second CoSi round to implement the PBFT protocol’s *commit* phase, in which the leader obtains attestations from a two-thirds super-majority that all the signing members witnessed the successful result of the prepare phase and made a positive commitment to remember the decision. This collective signature, resulting from this second CoSi round, effectively attests that a two-thirds super-majority of members not only considers the leader’s proposal “safe” but promises to remember it, indicating that the leader’s proposal is fully committed.

In cryptocurrency terms, the collective signature resulting from the prepare phase provides a proof-of-acceptance of a proposed block of transactions. This block is not yet committed, however, since a Byzantine leader that does not publish the accepted block could double-spend by proposing a conflicting block in the next round. In the second CoSi commit round, the leader announces the proof-of-acceptance to all members, who then validate it and collectively sign the block’s hash to produce a collective commit signature on the block. This way a Byzantine leader cannot rewrite history or double-spend, because by counting arguments at least one honest node would have to sign the commit phase of both histories, which an honest node by definition would not do.

The use of CoSi does not affect the fundamental principles or semantics of PBFT but improves its scalability and efficiency in two main ways. First, during the commit round where each consensus group member must verify that a super-majority of members have signed the prior prepare phase, each participant generally needs to receive only an $O(1)$ -size rather than $O(n)$ -size message, and to expend only $O(1)$ rather than $O(n)$ computation effort by verifying a single collective signature instead of n individual ones. This benefit directly increases the scalability and reduces the bandwidth and computation costs of consensus rounds themselves.

A second benefit is that after the final CoSi commit round has completed, the final resulting collective commitment signature serves as a typically $O(1)$ -size proof, which anyone can verify in $O(1)$ computation time that a given block – hence any transaction within that block – has been irreversibly committed. This secondary scalability-benefit might in practice be more important than the first, because it enables “light clients” who neither mine blocks nor store the entire blockchain history to verify quickly and efficiently that a transaction has committed, without requiring active communication with or having to trust any particular full node.

3.6 Decoupling Transaction Verification from Leader Election

Although ByzCoin so far provides a scalable guarantee of strong consistency, thus ensuring that clients need to wait only for the next block rather than the next several blocks to verify that a transaction has committed, the time they still have to wait *between* blocks can, nevertheless, be significant: *e.g.*, up to 10 minutes using Bitcoin’s difficulty tuning scheme. Whereas ByzCoin’s strong consistency might in principle make it “safe” from a consistency perspective to increase block mining rate, doing so could still exacerbate liveness and other performance issues, as in Bitcoin [47]. To enable lower client-perceived transaction latency, therefore, we build on the idea of Bitcoin-NG [24] to decouple the functions of transaction verification from block mining for leader election and consensus group membership.

As in Bitcoin-NG, we use two different kinds of blocks. The first, *microblocks* or transaction blocks, represent transactions to be stored and committed. The current leader creates a new microblock every few seconds, depending on the size of the block, and uses the CoSi-based PBFT protocol above to commit and collectively sign it. The other type of block, *keyblocks*, are mined via proof-of-work as in Bitcoin and serve to elect leaders and create shares in ByzCoin’s group membership protocol as discussed earlier in Section 3.3. As in Bitcoin-NG, this decoupling allows the current leader to propose and commit many microblocks that contain many smaller batches of transactions, within one ≈ 10 -minute keyblock mining period. Unlike Bitcoin-NG, in which a malicious leader could rewrite history or double-spend within this period until the next keyblock, ByzCoin ensures that each microblock is irreversibly committed regardless of the current leader’s behavior.

In Bitcoin-NG one blockchain includes both types of blocks, which introduces a race condition for miners. As microblocks are created, the miners have to change the header of their keyblocks to mine on top of the latest microblock. In ByzCoin, in contrast, the blockchain

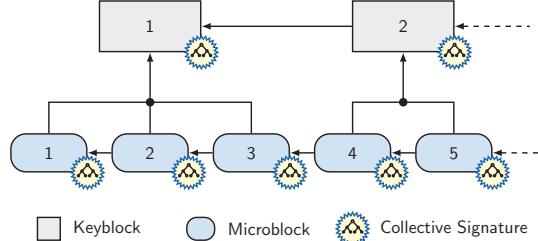

Figure 3: ByzCoin blockchain: Two parallel chains store information about the leaders (keyblocks) and the transactions (microblocks)

becomes two separate parallel blockchains, as shown in Fig. 3. The main blockchain is the keyblock chain, consisting of all mined blocks. The microblock chain is a secondary blockchain that depends on the primary to identify the era in which every microblock belongs to, *i.e.*, which miners are authoritative to sign it and who is the leader of the era.

Microblocks. A microblock is a simple block that the current consensus group produces every few seconds to represent newly-committed transactions. Each microblock includes a set of transactions and a collective signature. Each microblock also includes hashes referring to the previous microblock and keyblock: the former to ensure total ordering, and the latter indicating which consensus group window and leader created the microblock’s signature. The microblock’s hash is collectively signed by the corresponding consensus group.

Keyblocks. Each keyblock contains a proof-of-work, which is used to determine consensus group membership via the sliding-window mechanism discussed earlier, and to pay signers their rewards. Each newly-mined keyblock defines a new consensus group, and hence a new set of public keys with which the next era’s microblocks will be collectively signed. Since each successive consensus group differs from the last in at most one member, PBFT ensures the microblock chain’s consistency and continuity across this group membership change provided at most f out of $3f + 2$ members are faulty.

Bitcoin-NG relies on incentives to discourage the next leader from accidentally or maliciously “forgetting” a prior leader’s microblocks. In contrast, the honest supermajority in a ByzCoin consensus group will refuse to allow a malicious or amnesiac leader to extend any but the most recently-committed microblock, regardless of which (current or previous) consensus group committed it. Thus, although competing keyblock conflicts may still appear, these “forks” cannot yield an inconsistent microblock chain. Instead, a keyblock conflict can at

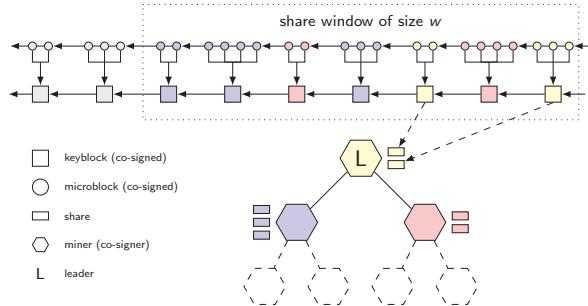

Figure 4: Overview of the full ByzCoin design

worst temporarily interrupt the PBFT protocol’s liveness, until it is resolved as mentioned in Section 3.6.1.

Decoupling transaction verification from leader election and consensus group evolution in this way brings the overall ByzCoin architecture to completion, as illustrated in Fig. 4. Subsequent sections discuss further implications and challenges this architecture presents.

3.6.1 Keyblock Conflicts and Selfish Mining

PBFT’s strong consistency by definition does not permit inconsistencies such as forks in the microblock chain. The way the miners collectively decide how to resolve keyblock conflicts, however, can still allow selfish mining [25] to occur as in Bitcoin. Worse, if the miners decide randomly to follow one of the two blocks, then keyblock forks might frequently lead to PBFT liveness interruptions as discussed above, by splitting miners “too evenly” between competing keyblocks. Another approach to deciding between competing keyblocks is to impose a deterministic priority function on their hash values, such as “smallest hash wins.” Unfortunately, this practice can encourage selfish mining.

One way to break a tie without helping selfish miners, is to increase the entropy of the output of the deterministic prioritization function. We implement this idea using the following algorithm. When a miner detects a keyblock fork, it places all competing blocks’ header hashes into a sorted array, from low to high hash values. The array itself is then hashed, and the final bit(s) of this hash determine which keyblock wins the fork.

This solution, shown in Fig. 5, also uses the idea of a deterministic function applied to the blocks, thus requiring no voting. Its advantage is that the input of the hash function is partially unknown before the fork occurs, thus the entropy of the output is high and difficult for an attacker to be able to optimize. Given that the search space for a possible conflict is as big as the search space for a new block, trying to decide if a block has better than 50% probability of winning the fork is as hard as finding a new block.

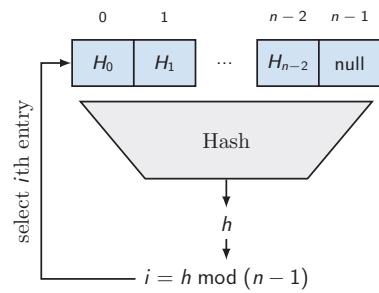

Figure 5: Deterministic fork resolution in ByzCoin

3.6.2 Leader Election and PBFT View Changes

Decoupling transaction verification from the block-mining process comes at a cost. So far we have assumed, as in PBFT, that the leader remains fixed unless he fails. If we keep this assumption, then this leader gains the power of deciding which transactions are verified, hence we forfeit the fairness-enforcing benefit of Bitcoin’s leader election. To resolve this issue, every time a keyblock is signed, ByzCoin forces a mandatory PBFT view-change to the keyblock’s miner. This way the power of verifying transactions in blocks is assigned to the rightful miner, who has an era of microblock creation from the moment his keyblock is signed until the next keyblock is signed.

When a keyblock conflict occurs, more than one such “mandatory” view-change occurs, with the successful miners trying to convince other participants to adopt their keyblock and its associated consensus group. For example, in a keyblock fork, one of the two competing keyblocks wins the resolution algorithm described above. However, if the miner of the “losing” block races to broadcast its keyblock and more than 33% honest miners have already committed to it before learning about the competing keyblock, then the “winning” miner is too late and the system either commits to the first block or (in the worst case) loses liveness temporarily as discussed above. This occurs because already-committed miners will not accept a mandatory view-change except to a keyblock that represents their committed state and whose microblock chain extends all previously-committed microblocks. Further analysis of how linearizability is preserved across view-changes may be found in the original PBFT paper [14].

3.6.3 Tree Creation in ByzCoin

Once a miner successfully creates a new keyblock, he needs to form a CoSi communication tree for collective signing, with himself as the leader. If all miners individually acknowledge this keyblock to transition to

the next view, this coordination normally requires $O(N)$ messages. To avoid this overhead at the beginning of each keyblock round, the miners autonomously create the next round’s tree bottom-up during the previous keyblock round. This can be done in $O(1)$ by using the blockchain as an array that represents a full tree.

This tree-building process has three useful side-effects. First, the previous leader is the first to get the new block, hence he stops creating microblocks and wasting resources by trying to sign them. Second, in the case of a keyblock conflict, potential leaders use the same tree, and the propagation pattern is the same; this means that all nodes will learn and decide on the conflict quickly. Finally, in the case of a view change, the new view will be the last view that worked correctly. So if the leader of the keyblock i fails, the next leader will again be the miner of keyblock $i - 1$.

3.7 Tolerating Churn and Byzantine Faults

In this section we discuss the challenges of fault tolerance in ByzCoin, particularly tree failures and maximum tolerance for Byzantine faults.

3.7.1 Tree Fault Tolerance

In CoSi, there are multiple different mechanisms that allow substantial fault-tolerance. Furthermore the strict membership requirements and the frequent tree changes of ByzCoin increase the difficulty for a malicious attacker with less than around 25% of the total hash power to compromise the system. A security analysis, however, must assume that a Byzantine adversary is able to get the correct nodes of the ByzCoin signing tree so that it can compromise the liveness of the system by a simple DoS.

To mitigate this risk, we focus on recent Byzantine fault tolerance results [32], modifying ByzCoin so that the tree communication pattern is a normal-case performance optimization that can withstand most malicious attacks. But when the liveness of the tree-based ByzCoin is compromised, the leader can return to non-tree-based communication until the end of his era.

The leader detects that the tree has failed with the following mechanism: After sending the block to his children, the leader starts a timer that expires before the view-change timer. Then he broadcasts the hash of the block he proposed and waits. When the nodes receive this message they check if they have seen the block and either send an ACK or wait until they see the block and then send the ACK. The leader collects and counts the ACKs, to detect if his block is rejected simply because it never reaches the witnesses. If the timer expires or a block rejection arrives before he receives two-thirds of the ACKs, the leader knows that the tree has failed and

reverts to a flat ByzCoin structure before the witnesses assume that he is faulty.

As we show in Section 4, the flat ByzCoin structure can still quickly sign keyblocks for the day-long window (144 witnesses) while maintaining a throughput higher than Bitcoin currently supports. Flat ByzCoin is more robust to faults, but increases the communication latency back to $O(n)$. Furthermore, if all faults ($\lfloor \frac{N}{3} \rfloor$) are consecutive leaders, this can lead back to a worst case $O(n^2)$ communication latency.

3.7.2 Membership Churn and BFT

After a new leader is elected, the system needs to ensure that the first microblock of the new leader points to the last microblock of the previous leader. Having $2f + 1$ supporting votes is not enough. This occurs because there is the possibility than an honest node lost its membership when the new era started. Now in the worst case, the system has f Byzantine nodes, f honest nodes that are up to date, f slow nodes that have a stale view of the blockchain, and the new leader that might also have a stale view. This can lead to the leader proposing a new microblock, ignoring some signed microblocks and getting $2f + 1$ support (stale+Byzantine+his own). For this reason, the first microblock of an era needs $2f + 2$ supporting signatures. If the leader is unable to obtain them, this means that he needs to synchronize with the system, *i.e.*, he needs to find the latest signed microblock from the previous roster. He asks all the nodes in his roster, plus the node that lost its membership, to sign a latest-checkpoint message containing the hash of the last microblock. At this point in time, the system has $3f + 2$ ($3f + 1$ of the previous roster plus the leader) members and needs $2f + 1$ honest nodes to verify the checkpoint, plus an honest leader to accept it (a Byzantine leader will be the $f + 1$ fault and compromise liveness). Thus, ByzCoin can tolerate f fails in a total of $3f + 2$ nodes.

4 Performance Evaluation

In this section we discuss the evaluation of the ByzCoin prototype and our experimental setup. The main question we want to evaluate is whether ByzCoin is usable in practice without incurring large overheads. In particular we focus on consensus latency and transaction throughput for different parameter combinations.

4.1 Prototype Implementation

We implemented ByzCoin in Go¹ and made it publicly available on GitHub.² ByzCoin’s consensus mecha-

¹<https://golang.org>

²<https://github.com/DeDiS/Cothority>

nism is based on the CoSi protocol with Ed25519 signatures [6] and implements both flat- and tree-based collective signing layouts as described in Section 3. For comparison, we also implemented a conventional PBFT consensus algorithm with the same communication patterns as above and a consensus algorithm that uses individual signatures and tree-based communication.

To simulate consensus groups of up to 1008 nodes, we oversubscribed the available 36 physical machines (see below) and ran up to 28 separate ByzCoin processes on each server. Realistic wide-area network conditions are mimicked by imposing a round-trip latency of 200 ms between any two machines and a link bandwidth of 35 Mbps per simulated host. Note that this simulates only the connections between miners of the consensus group and not the full Bitcoin network. Full nodes and clients are not part of the consensus process and can retrieve signed blocks only after consensus is reached. Since Bitcoin currently is rather centralized and has only a few dozen mining pools [3], we assume that if/when decentralization happens, all miners will be able to support these rather constrained network requirements.

The experimental data to form microblocks was taken by ByzCoin clients from the actual Bitcoin blockchain. Both micro- and keyblocks are fully transmitted and collectively signed through the tree and are returned to the clients upon request together with the proof. Verification of block headers is implemented but transaction verification is only emulated to avoid further measurement distortion through oversubscribed servers. A similar practice is used in Shadow Bitcoin [45]. We base our emulation both on measurements [31] of the average block-verification delays (around 200 ms for 500 MB blocks) and on the claims of Bitcoin developers [8] that as far as hardware is concerned Bitcoin can easily verify 4000 TPS. We simulate a linear increase of this delay proportional to the number of transactions included in the block. Because of the communication pattern of ByzCoin, the transaction-verification cost delays only the leaf nodes. By the time the leaf nodes finish the block verification and send their vote back to their parents, all other tree nodes should have already finished the verification and can immediately proceed. For this reason the primary delay factor is the transmission of the blocks that needs to be done $\log N$ sequential times.

We ran all our experiments on DeterLab [22] using 36 physical machines, each having four Intel E5-2420 v2 CPUs and 24 GB RAM and being arranged in a star-shaped virtual topology.

4.2 Consensus Latency

The first two experiments focus on how microblock commitment latency scales with consensus group size and

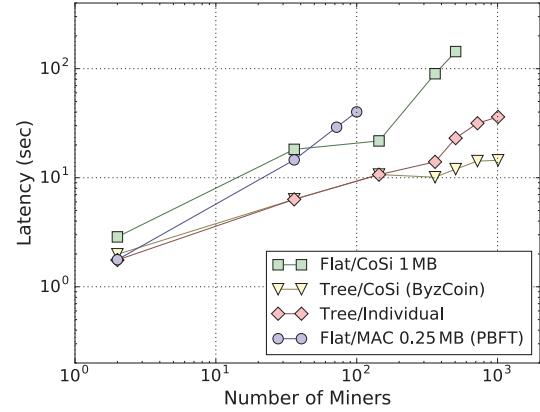

Figure 6: Influence of the consensus group size on the consensus latency

with number of transactions per block.

4.2.1 Consensus Group Size Comparison

This experiment focuses on the scalability of ByzCoin’s BFT protocol in terms of the consensus group size. The number of unique miners participating in a consensus group is limited by the number of membership shares in the window (Section 3.3), but can be smaller if some miners hold multiple shares (*i.e.*, successfully mined several blocks) within the same window.

We ran experiments for Bitcoin’s maximum block size (1 MB) with a variable number of participating hosts. Every time we increased the number of hosts, we also increased the servers’ bandwidth so that the available bandwidth per simulated host remained constant (35 Mbps). For the PBFT simulation, the 1 MB block was too big to handle, thus the PBFT line corresponds to a 250 KB block size.

As Fig. 6 shows, the simple version of ByzCoin achieves acceptable latency, as long as the consensus group size is less than 200. After this point the cost for the leader to broadcast the block to everyone incurs large overheads. On the contrary, the tree-based ByzCoin scales well, since the same 1 MB block for 1008 nodes suffers signing latency less than the flat approach for 36 nodes. Adding 28 times more nodes (from 36 to 1008) causes a latency increase close to a factor 2 (from 6.5 to 14 seconds). The basic PBFT implementation is quite fast for 2 nodes but scales poorly (40 seconds for 100 nodes), whereas the tree-based implementation with individual signatures performs the same as ByzCoin for up to 200 hosts. If we aim for the higher security level of 1008 nodes, however, then ByzCoin is 3 times faster.

Fig. 7 shows the performance cost of keyblock sign-

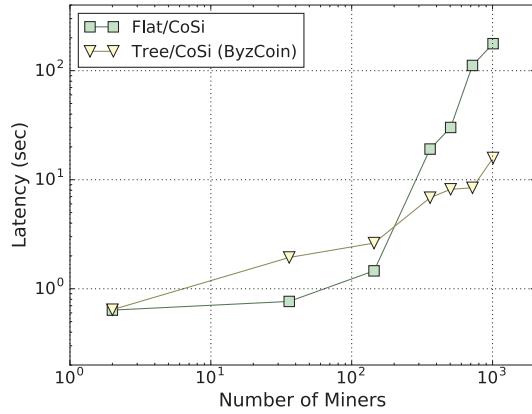

Figure 7: Keyblock signing latency

ing. The flat variant outperforms the tree-based version when the number of hosts is small since the blocks have as many transactions as there are hosts and thus are small themselves. This leads to a fast transmission even in the flat case and the main overhead comes from the block propagation latency, which scales with $O(\log N)$ in the tree-based ByzCoin variant.

4.2.2 Block Size Comparison

The next experiment analyzes how different block sizes affect the scalability of ByzCoin. We used a constant number of 144 hosts for all implementations. Once again, PBFT was unable to achieve acceptable latency with 144 nodes, thus we ran it with 100 nodes only.

Fig. 8 shows the average latency of the consensus mechanism, determined over 10 blocks when their respective sizes increase. As in the previous section we see that the flat implementation is acceptable for a 1 MB block, but when the block increases to 2 MB the latency quadruples. This outcome is expected as the leader's link saturates when he tries to send 2 MB messages to every participating node. In contrast ByzCoin scales well because the leader outsources the transmission of the blocks to other nodes and contacts only his children. The same behavior is observed for the algorithm that uses individual signatures and tree-based communication, which shows that the block size has no negative effect on scalability when a tree is used. Finally, we find that PBFT is fast for small blocks, but the latency rapidly increases to 40 seconds for 250 KB blocks.

ByzCoin's signing latency for a 1 MB block is close to 10 seconds, which should be small enough to make the need for 0-confirmation transactions almost disappear. Even for a 32 MB block (≈ 66000 transactions) the delay is much lower (around 90 seconds) than the ≈ 10 minutes required by Bitcoin.

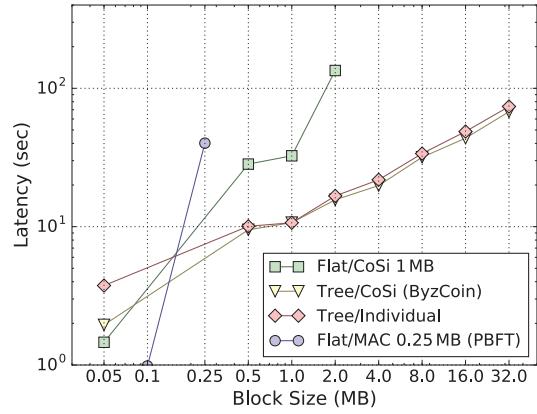

Figure 8: Influence of the block size on the consensus latency

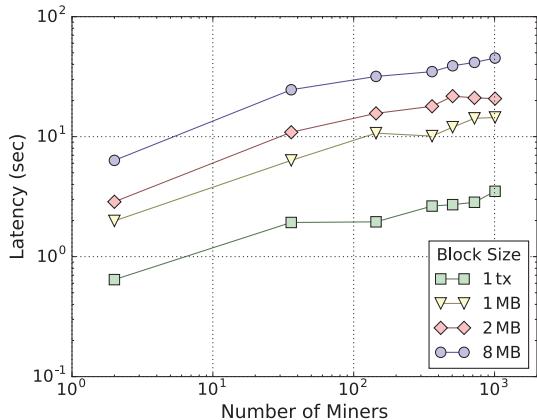

Figure 9: Influence of the consensus group size on the block signing latency

minutes required by Bitcoin.

Fig. 9 demonstrates the signing latency of various blocks sizes on tree-based ByzCoin. Signing one-transaction blocks takes only 3 seconds even when 1008 miners co-sign it. For bigger blocks, we have included Bitcoin's current maximum block size of 1 MB along with the proposed limits of 2 MB in Bitcoin Classic and 8 MB in Bitcoin Unlimited [2]. As the graph shows, 1 MB and 2 MB blocks scale linearly in number of nodes at first but after 200 nodes, the propagation latency is higher than the transmission of the block, hence the latency is close to constant. For 8 MB blocks, even with 1008 the signing latency increases only linearly.

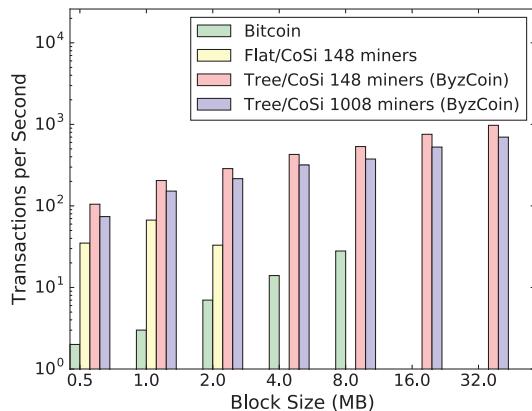

Figure 10: Throughput of ByzCoin

4.3 Transaction Throughput

In this experiment, we investigate the maximum throughput in terms of transactions per second (TPS) that ByzCoin can achieve, and show how Bitcoin could improve its throughput by adopting a ByzCoin-like deployment model. We tested ByzCoin versions with consensus group sizes of 144 and 1008 nodes, respectively. Note that performance-wise this resembles the worst case scenario since the miner-share ratio is usually not 1:1 as miners in the consensus group are allowed to hold multiple shares, as described in Section 3.3.

Analyzing Fig. 10 shows that Bitcoin can increase its overall throughput by more than one order of magnitude through adoption of a flat ByzCoin-like model, which separates transaction verification and block mining and deals with forks via strong consistency. Furthermore, the 144 node configuration can achieve close to 1000 TPS, which is double the throughput of Paypal, and even the 1008-node roster achieves close to 700 TPS. Even when the tree fails, the system can revert back to 1 MB microblocks on the flat and more robust variant of ByzCoin and still have a throughput ten times higher than the current maximum throughput of Bitcoin.

In both Figs. 8 and 10, the usual trade-off between throughput and latency appears. The system can work with 1–2 MB microblocks when the load is normal and then has a latency of 10–20 seconds. If an overload occurs, the system adaptively changes the block size to enable higher throughput. We note that this is not the case in the simple ByzCoin where 1 MB microblocks have optimal throughput and acceptable latency.

5 Security Analysis

In this section, we conduct a preliminary, informal security analysis of ByzCoin, and discuss how its consensus mechanism can mitigate or eliminate some known attacks against Bitcoin.

5.1 Transaction Safety

In the original Bitcoin paper [47], Nakamoto models Bitcoin’s security against transaction double spending attacks as in a Gambler’s Ruin Problem. Furthermore, he models the progress an attacker can make as a Poisson distribution and combines these two models to reach Eq. (1). This equation calculates the probability of a successful double spend after z blocks when the adversary controls q computing power.

$$P = 1 - \sum_{k=0}^z \frac{\lambda^k e^{-\lambda}}{k!} \left(1 - \left(\frac{q}{p}\right)^{(z-k)}\right) \quad (1)$$

In Figs. 11 and 12 we compare the relative safety of a transaction over time in Bitcoin³ versus ByzCoin. Fig. 11 shows that ByzCoin can secure a transaction in less than a minute, because the collective signature guarantees forward security. On the contrary, Bitcoin’s transactions need hours to be considered fully secured from a double-spending attempt. Fig. 12 illustrates the required time from transaction creation to the point where a double spending attack has less than 0.1% chance of success. ByzCoin incurs a latency of below one minute to achieve the above security, which boils down to the time the systems needs to produce a collectively signed microblock. Bitcoin on the other hand needs several hours to reach the same guarantees. Note that this graph does not consider other advanced attacks, such as eclipse attacks [34], where Bitcoin offers no security for the victim’s transactions.

5.2 Proof-of-Membership Security

The security of ByzCoin’s proof-of-membership mechanism can be modeled as a random sampling problem with two possible independent outcomes (honest, Byzantine). The probability of picking a Byzantine node (in the worst case) is $p = 0.25$ and the number of tries corresponds to the share window size w . In this setting, we are interested in the probability that the system picks less than $c = \lfloor \frac{w}{3} \rfloor$ Byzantine nodes as consensus group members and hence guarantees safety. To calculate this probability, we use the cumulative binomial distribution where X is the random variable that represents the number of times we pick a Byzantine node:

³Based on data from <https://blockchain.info>.

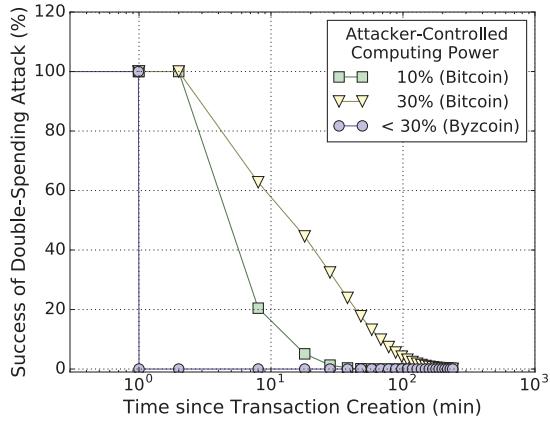

Figure 11: Successful double-spending attack probability

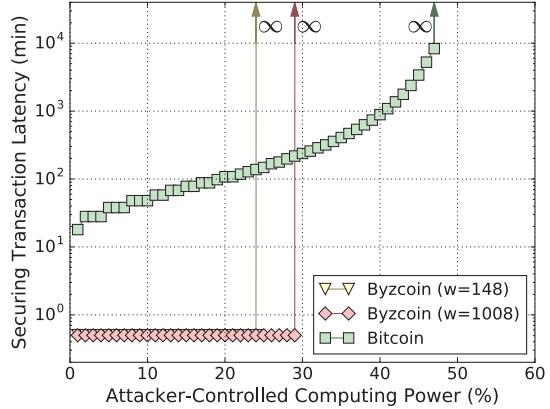

Figure 12: Client-perceived secure transaction latency

$$P[X \leq c] = \sum_{k=0}^c \binom{w}{k} p^k (1-p)^{w-k} \quad (2)$$

Table 1 displays the results for the evaluation of Eq. (2) for various window sizes w both in the common threat model where an adversary controls up to 25% hash power and in the situation where the system faces a stronger adversary with up to 30% computing power. The latter might temporarily occur due to hash power variations and resource churn.

Table 1: Expected proof-of-membership security levels

$p \mid w$	12	100	144	288	1008	2016
0.25	0.842	0.972	0.990	0.999	0.999	1.000
0.30	0.723	0.779	0.832	0.902	0.989	0.999

At this point, recall that w specifies the number of

available shares and not necessarily the number of actual miners as each member of the consensus group is allowed to hold multiple shares. This means that the number of available shares gives an upper bound on the latency of the consensus mechanism with the worst case being that each member holds exactly one share.

In order to choose a value for w appropriately one must take into account not only consensus latency and the desired security level (ideally $\geq 99\%$) but also the increased chance for resource churn when values of w become large. From a security perspective the results of Table 1 suggest that the share window size should not be set to values lower than $w = 144$. Ideally, values of $w = 288$ and above should be chosen to obtain a reasonable security margin and, as demonstrated in Section 4, values up to $w = 1008$ provide excellent performance numbers.

Finally, care should be taken when bootstrapping the protocol, as for small values of w there is a high probability that a malicious adversary is able to take over control. For this reason we suggest that ByzCoin starts with vanilla Nakamoto consensus and only after w keyblocks are mined the ByzCoin consensus is activated.

5.3 Defense Against Bitcoin Attacks

0-confirmation Double-Spend Attacks. Race [35] and Finney [26] attacks belong to the family of 0-confirmation double-spend attacks which might affect traders that provide real-time services to their clients. In such scenarios the time between exchange of currency and goods is usually short because traders often cannot afford to wait an extended period of time (10 or more minutes) until a transaction they received can be considered indeed confirmed.

ByzCoin can mitigate both attacks by putting the merchant’s transaction in a collectively signed microblock whose verification latency is in the order of a few seconds up to a minute. If this latency is also unacceptable, then he can send a single transaction for signing, which will cost more, but is secured in less than 4 seconds.

N-confirmation Double-Spend Attacks. The assumption underlying this family of attacks [7] is that, after receiving a transaction for a trade, a merchant waits $N - 1$ additional blocks until he concludes the interaction with his client. At this point, a malicious client creates a new double-spending transaction and tries to fork the blockchain, which has a non-negligible success-probability if the adversary has enough hash power. For example, if $N = 3$ then an adversary holding 10% of the network’s hash power has a 5% success-chance to mount the above attack [47].

In ByzCoin the merchant would simply check the collective signature of the microblock that includes the

transaction, which allows him to verify that it was accepted by a super-majority of the network. Afterwards the attacker cannot succeed in forking the blockchain as the rest of the signers will not accept his new block. Even if the attacker is the leader, the proposed microblock will be rejected, and a view change will occur.

Eclipse and Delivery-Tampering Attacks. In an eclipse attack [34] it is assumed that an adversary controls a sufficiently large number of connections between the victim and the Bitcoin network. This enables the attacker to mount attacks such as 0- and N-confirmation double-spends with an ever increasing chance of success the longer the adversary manages to keep his control over the network. Delivery-tampering attacks [31] exploit Bitcoin’s scalability measures to delay propagation of blocks without causing a network partition. This allows an adversary to control information that the victim receives and simplifies to mount 0- and 1-confirmation double-spend attacks as well as selfish-mining.

While ByzCoin does not prevent an attacker from eclipsing a victim or delaying messages in the peer-to-peer network, its use of collective signatures in transaction commitment ensure that a victim cannot be tricked into accepting an alternate attacker-controlled transaction history produced in a partitioned network fragment.

Selfish and Stubborn Mining Attacks. Selfish mining [25] allows a miner to increase his profit by adding newly mined blocks to a hidden blockchain instead of instantly broadcasting them. This effect can be further amplified if the malicious miner has good connectivity to the Bitcoin network. The authors of selfish mining propose a countermeasure that thwarts the attack if a miner has less than 25% hash power under normal circumstances or less than 33% in case of an optimal network. Stubborn mining [48] further generalizes the ideas behind selfish mining and combines it with eclipse attacks in order to increase the adversary’s revenue.

In ByzCoin, these strategies are ineffective as forks are instantly resolved in a deterministic manner, hence building a hidden blockchain only wastes resources and minimizes revenue. Another approach to prevent the above attacks would be to include bias-resistant public randomness [40] in every keyblock. This way even if an attacker gains control over the consensus mechanism (*e.g.*, by having > 33% hash power) he would still be unable to mine hidden blocks. We leave exploring this approach for future research.

Transaction Censorship. In Bitcoin-NG, a malicious leader can censor transactions for the duration of his epoch(s). The same applies for ByzCoin. However, as

not every leader is malicious, the censored transactions are only delayed and will be processed eventually by the next honest leader. ByzCoin can improve on this, as the leader’s actions are double-checked by all the other miners in the consensus group. A client can announce his censored transaction just like in classic PBFT; this will indicate a potential leader fault and will either stop censorship efforts or lead to a view-change to remove the malicious leader. Finally, in Bitcoin(-NG) a miner can announce his intention to fork over a block that includes a transaction, giving an incentive to other miners to exclude this transaction. In ByzCoin using fork-based attacks to censor transactions is no longer possible due to ByzCoin’s deterministic fork resolution mechanism. An attacker can therefore only vote down a leader’s proposals by refusing to co-sign. This is also a limitation, however, as an adversary who controls more than 33% of the shares (Section 7) deny service and can censor transactions for as long as he wants.

6 Related Work

ByzCoin and Bitcoin [47] share the same primary objective: implement a state machine replication (SMR) system with open membership [9, 29]. Both therefore differ from more classic approaches to Byzantine fault-tolerant SMRs with static or slowly changing consensus groups such as PBFT [14], Tendermint [10], or Hyperledger [42].

Bitcoin has well-known performance shortcomings; there are several proposals [41, 57] on how to address these. The GHOST protocol [53] changes the chain selection rule when a fork occurs. While Bitcoin declares the fork with the most proof-of-work as the new valid chain, GHOST instead chooses the entire subtree that received the most computational effort. Put differently, the subtree that was considered correct for the longest time will have a high possibility of being selected, making an intentional fork much harder. One limitation of GHOST is that no node will know the full tree, as invalid blocks are not propagated. While all blocks could be propagated, this makes the system vulnerable to DoS attacks since an adversary can simply flood the network with low-difficulty blocks.

Off-chain transactions, an idea that originated from the two-point channel protocol [33], are another alternative to improve latency and throughput of the Bitcoin network. Other similar proposals include the Bitcoin Lightning Network [50] and micro-payment channels [20], which allow transactions without a trusted middleman. They use contracts so that any party can generate proof-of-fraud on the main blockchain and thereby deny revenue to an attacker. Although these systems enable faster cryptocurrencies, they do not address the core problem

of scaling SMR systems, thus sacrificing the open and distributed nature of Bitcoin. Finally, the idea behind sidechains [5] is to connect multiple chains with each other and enable the transfer of Bitcoins from one chain to another. This enables the workload distribution to multiple subsets of nodes that run the same protocol.

There are several proposals that, like ByzCoin, target the consensus mechanism and try to improve different aspects. Ripple [52] implements and runs a variant of PBFT that is low-latency and based on collectively-trusted subnetworks with slow membership changes. The degree of decentralization depends on the concrete configuration of an instance. Tendermint [10] also implements a PBFT-like algorithm, but evaluates it with at most 64 “validators”. Furthermore, Tendermint does not address important challenges such as the link-bandwidth between validators, which we found to be a primary bottleneck. PeerCensus [19] is an interesting alternative that shares similarities with ByzCoin, but is only a preliminary theoretical analysis.

Finally, Stellar [43] proposes a novel consensus protocol named Federated Byzantine Agreement, which introduces Quorum slices that enable a BFT protocol “open for anyone to participate”. Its security, however, depends on a nontrivial and unfamiliar trust model requiring correct configuration of trustees by each client.

7 Limitations and Future Work

This section briefly outlines several of ByzCoin’s important remaining limitations, and areas for future work.

Consensus-Group Exclusion. A malicious ByzCoin leader can potentially exclude nodes from the consensus process. This is easier in the flat variant, where the leader is responsible for contacting every participating miner, but it is also possible in the tree-based version, if the leader “reorganizes” the tree and puts nodes targeted for exclusion in subtrees where the roots are colluding nodes. A malicious leader faces a dilemma, though: excluded nodes lose their share of newly minted coins which increases the overall value per coin and thus the leader’s reward. The victims, however, will quickly broadcast view-change messages in an attempt to remove the Byzantine leader.

As an additional countermeasure to mitigate such an attack, miners could run a peer-to-peer network on top of the tree to communicate protocol details. Thus each node potentially receives information from multiple sources. If the parent of a node fails to deliver the announcement message of a new round, this node could then choose to attach itself (together with its entire subtree) to another participating (honest) miner. This self-adapting

tree could mitigate the leader’s effort to exclude miners. As a last resort, the malicious leader could exclude the commitments of the victims from the aggregate commitment, but as parts of the tree have witnessed these commitments, the risk of triggering a view-change is high.

In summary, the above attack seems irrational as the drawbacks of trying to exclude miners seem to outweigh the benefits. We leave a more thorough analysis of this situation for future work.

Defenses Against 33%+ Attacks. An attacker powerful enough to control more than $\frac{1}{3}$ of the consensus shares can, in the Byzantine threat model, trivially censor transactions by withholding votes, and double-spend by splitting honest nodes in two disjoint groups and collecting enough signatures for two conflicting microblocks. Fig. 12 shows how the safety of ByzCoin fails at 30%, whereas Bitcoin remains safe even for 48%, if a client can wait long enough.

However, the assumption that an attacker completely controls the network is rather unrealistic, especially if messages are authenticated and spoofing is impossible [3]. The existence of the peer-to-peer network on top of the tree, mentioned in the previous paragraph, enables the detection of equivocation attacks such as microblock forks and mitigates the double-spending efforts, as honest nodes will stop following the leader. Thus, double-spending and history rewriting attacks in ByzCoin become trivial only after the attacker has 66% of the shares, effectively increasing the threshold from 51% to 66%. This assumption is realistic, as an attacker controlling the complete network can actually split Bitcoin’s network in two halves and trivially double-spend on the weaker side. This is possible because the weak side creates blocks that will be orphaned once the partition heals. We again leave a more thorough analysis of this situation for future work.

Proof-of-Work Alternatives. Bitcoin’s hash-based proof-of-work has many drawbacks, such as energy waste and the efficiency advantages of custom ASICs that have made mining by “normal users” impractical. Many promising alternatives are available, such as memory-intensive puzzles [4], or proof-of-stake designs [37]. Consensus group membership might in principle also be based on other Sybil attack-resistant methods, such as those based on social trust networks [58]. A more democratic alternative might be to apportion mining power on a “1 person, 1 vote” principle, based on anonymous *proof-of-personhood* tokens distributed at pseudonym parties [28]. Regardless, we treat the ideal choice of Sybil attack-resistance mechanism as an issue for future work, orthogonal to the focus of this paper.

Other Directions. Besides the issues outlined above, there are many more interesting open questions worth considering: Sharding [17] presents a promising approach to scale distributed protocols and was already studied for private blockchains [18]. A sharded variant of ByzCoin might thus achieve even better scalability and performance numbers. A key obstacle that needs to be analyzed in that context before though is the generation of bias-resistant public randomness [40] which would enable to pick members of a shard in a distributed and secure manner. Yet another challenge is to find ways to increase incentives of rational miners to remain honest, like binding coins and destroying them when misbehavior is detected [10]. Finally, asynchronous BFT [12, 11] is another interesting class of protocols, which only recently started to be analyzed in the context of blockchains [46].

8 Conclusion

ByzCoin is a scalable Byzantine fault tolerant consensus algorithm for open decentralized blockchain systems such as Bitcoin. ByzCoin’s strong consistency increases Bitcoin’s core security guarantees—shielding against attacks on the consensus and mining system such as N-confirmation double-spending, intentional blockchain forks, and selfish mining—and also enables high scalability and low transaction latency. ByzCoin’s application to Bitcoin is just one example, though: theoretically, it can be deployed to any blockchain-based system, and the proof-of-work-based leader election mechanism might be changed to another approach such as proof-of-stake. If open membership is not an objective, the consensus group could be static, though still potentially large. We developed a wide-scale prototype implementation of ByzCoin, validated its efficiency with measurements and experiments, and have shown that Bitcoin can increase the capacity of transactions it handles by more than two orders of magnitude.

Acknowledgments

We would like to thank the DeterLab project team for providing the infrastructure for our experimental evaluation, Joseph Bonneau for his input on our preliminary design, and the anonymous reviewers for their helpful feedback.

Faster Malicious 2-party Secure Computation with Online/Offline Dual Execution

Peter Rindal*

Mike Rosulek*

Oregon State University

Abstract

We describe a highly optimized protocol for general-purpose secure two-party computation (2PC) in the presence of malicious adversaries. Our starting point is a protocol of Kolesnikov et al. (TCC 2015). We adapt that protocol to the online/offline setting, where two parties repeatedly evaluate the same function (on possibly different inputs each time) and perform as much of the computation as possible in an offline preprocessing phase before their inputs are known. Along the way we develop several significant simplifications and optimizations to the protocol.

We have implemented a prototype of our protocol and report on its performance. When two parties on Amazon servers in the same region use our implementation to securely evaluate the AES circuit 1024 times, the amortized cost per evaluation is *5.1ms offline + 1.3ms online*. The total offline+online cost of our protocol is in fact less than the *online* cost of any reported protocol with malicious security. For comparison, our protocol’s closest competitor (Lindell & Riva, CCS 2015) uses 74ms offline + 7ms online in an identical setup.

Our protocol can be further tuned to trade performance for leakage. As an example, the performance in the above scenario improves to *2.4ms offline + 1.0ms online* if we allow an adversary to learn a single bit about the honest party’s input with probability 2^{-20} (but not violate any other security property, e.g. correctness).

1 Introduction

Secure two-party computation (2PC) allows mutually distrusting parties to perform a computation on their combined inputs, while revealing only the result. 2PC was conceived in a seminal paper by Yao [34] and shown to be feasible in principle using a construction now known as *garbled circuits*. Later, the Fairplay

project [24] was the first implementation of Yao’s protocol, which inspired interest in the practical performance of 2PC.

1.1 Cut & Choose, Online/Offline Setting

The leading technique to secure Yao’s protocol against malicious adversaries is known as *cut-and-choose*. The idea is to have the sender generate many garbled circuits. The receiver will choose a random subset of these to be checked for correctness. If all checked circuits are found to be correct, then the receiver has some confidence about the unopened circuits, which can be evaluated.

The cost of the cut-and-choose technique is therefore tied to the number of garbled circuits that are generated. To restrict a malicious adversary to a 2^{-s} chance of violating security, initial cut-and-choose mechanisms required approximately 17s circuits [20]. This overhead was later reduced to 3s circuits [21, 31, 32] and then s circuits [19].

Suppose two parties wish to perform N secure computations of the same function f (on possibly different inputs each time), and are willing to do offline preprocessing (which does not depend on the inputs). In this *online/offline setting*, far fewer garbled circuits are needed per execution. The idea, due to [14, 22], is to generate many garbled circuits (enough for all N executions) and perform a single cut-and-choose on them all. Then each execution of f will evaluate a *random* subset (typically called a *bucket*) of the unopened circuits. Because the unopened circuits are randomly assigned to executions, only $O(s/\log N)$ circuits are needed per bucket to achieve security 2^{-s} . Concretely, 4 circuits per bucket suffice for security 2^{-40} and $N = 1024$.

1.2 Dual-execution Paradigm

An alternative to cut-and-choose for malicious-secure 2PC is the dual-execution protocol of Mohassel & Franklin [25], which requires only two garbled circuits.

*Supported by NSF award 1149647. The first author is also supported by an ARCS foundation fellowship.

The idea is that two parties run two instances of Yao’s protocol, with each party acting as sender in one instance and receiver in the other. They then perform a *reconciliation* step in which their garbled outputs are securely compared for equality. Intuitively, one of the garbled outputs is guaranteed to be correct, so the reconciliation step allows the honest party to check whether its garbled output agrees with the correct one held by the adversary.

Unfortunately, the dual execution protocol allows an adversary to learn an arbitrary bit about the honest party’s input. Consider an adversary who instead of garbling the function f , garbles a different function f' . Then the output of the reconciliation step (secure equality test) reveals whether $f(x_1, x_2) = f'(x_1, x_2)$. However, it can be shown that the adversary can learn *only* a single bit, and, importantly, cannot violate output *correctness* for the honest party.

1.3 Reducing Leakage in Dual-execution

Kolesnikov et al. [16] proposed a combination of dual-execution and cut-and-choose that reduces the probability of a leaked bit. The idea is for each party to garble and send s circuits instead of 1, and perform a cut-and-choose to check each circuit with probability $1/2$. Each circuit should have the same garbled encoding for its outputs, so if both parties are honest, both should receive just one candidate output.

However, a malicious party could cause the honest party to obtain several candidate outputs. The approach taken in [16] is to have the parties use *private set intersection (PSI)* to find a common value among their *sets* of reconciliation values. This allows the honest party to identify which of its candidate outputs is the correct one.

In Section 4 we discuss in more detail the security offered by this protocol. Briefly, an adversary cannot violate output correctness for the honest party, and learns only a *single bit* about the honest party’s input with probability at most $1/2^s$ (which happens only when the honest party doesn’t evaluate any correct garbled circuit).

2 Overview of Our Results

We adapt the dual-execution protocol of [16] to the online/offline setting. The result is the fastest protocol to date for 2PC in the presence of malicious adversaries. At a very high level, both parties exchange many garbled circuits in the offline phase and perform a cut-and-choose. In the online phase, each party evaluates a random bucket of its counterpart’s circuits. The parties then use the PSI-based reconciliation to check the outputs.

2.1 Technical Contributions

While the high-level idea is straight-forward, some non-trivial technical changes are necessary to adapt [16] to the online/offline setting while ensuring high performance in practice.

In particular, an important part of any malicious-secure protocol is to ensure that parties use the same inputs in all garbled circuits. The method suggested in [16] is incompatible with offline pre-processing, whereas the method from [23] does not ensure consistency between circuits generated by different parties, which is the case for dual-execution (both parties generate garbled circuits). We develop a new method for input consistency that is tailored specifically to the dual-execution paradigm and that incurs less overhead than any existing technique.

In [16], the parties evaluate garbled circuits and then use *active-secure* private set intersection (PSI) to reconcile their outputs. We improve the analysis of [16] and show that it suffices to use PSI that gives a somewhat weaker level of security. Taking advantage of this, we describe an extremely lightweight PSI protocol (a variant of one in [30]) that satisfies this weak level of security while being round-optimal.

2.2 Implementation, Performance

We implemented a C++ prototype of our protocol using state-of-the-art optimizations, including the garbled-circuit construction of [35]; the OT-extension protocol of [15] instantiated with the base OTs of [7]. The prototype is heavily parallelized within both phases. Work is divided amongst threads that concurrently generate & evaluate circuits, allowing network throughput to be the primary bottleneck. The result is an extremely fast 2PC system. When securely evaluating the AES circuit on co-located Amazon AWS instances, we achieve the lowest amortized cost to date of 5.1ms offline + 1.3ms online per execution.

2.3 Comparison to GC-based Protocols

There have been several implementations of garbled-circuit-based 2PC protocols that achieve malicious security [1, 12, 18, 23, 29, 31, 32]. Except for [23], none of these protocols are in the online/offline settings so their performance is naturally much lower ($100\text{-}1000\times$ slower than online/offline protocols). Among them, the fastest reported secure evaluation of AES is that of [12], which was 0.46s exploiting consumer GPUs. Other protocols have been described (but not implemented) that combine cut-and-choose with the dual-execution paradigm to achieve malicious security [13, 26]. The protocol of [13] leaks more than one bit when the adversary successfully cheats during cut-and-choose.

Our protocol is most closely related to that of [23], which also achieves fast, active-secure 2PC in the online/offline setting. [23] is an implementation of the protocol of [22], and we refer to the protocol and its implementation as “LR” in this section. Both the LR protocol and ours are based on garbled circuits but use fundamentally different approaches to achieving malicious secu-

	Input Labels	Reconciliation
LR [23]	$ x (B+B')\kappa_c$	$ x B'\kappa_c$
Us (Async PSI)	$ x B\kappa_c$	$B^2\kappa_s\kappa_c$
Us (Sync PSI)		$B\kappa_s+B^2\kappa_c$

Figure 1: Asymptotic communication costs of the LR protocol vs. ours (comparing online phases). B is the number of circuits in a bucket; $B' \approx 3B$ is the number of auxiliary cheating-recovery circuits in [23]; $|x|$ is length of sender’s inputs; κ_s is the statistical security parameter; κ_c is the computational security parameter.

riety. For clarity, we now provide a list of major differences between the two protocols.

(1) LR uses a more traditional cut-and-choose mechanism where one party acts as sender and the other as receiver & evaluator. Our protocol on the other hand uses a dual-execution paradigm in which both parties play symmetric roles, so their costs are identical.

Since parties act as both sender and receiver, each party performs more work than in the traditional cut-and-choose paradigm. However, the symmetry of dual-execution means that both parties are performing computational work simultaneously, rather than idle waiting. The increase in combined work does not significantly affect *latency* or *throughput* if the communication channel is full-duplex.

(2) Our protocol can provide more flexible security guarantees; in particular, it may be used with smaller parameter choices. In more detail, let κ_s denote a statistical security parameter, meaning that the protocol allows the adversary to completely break security with probability $1/2^{\kappa_s}$. In the LR protocol, a failure of the cut-and-choose step can violate all security properties, so the number of garbled circuits is proportional to κ_s .

Our protocol has an additional parameter κ_b , where the protocol leaks (only) a single bit to the adversary with probability $1/2^{\kappa_b}$. In our protocol (as in [16]), the number of garbled circuits is proportional to κ_b . When instantiated with $\kappa_b = \kappa_s = 40$, our protocol gives an equivalent guarantee to the LR protocol with $\kappa_s = 40$. From this baseline, our protocol allows either κ_s to be increased (strictly improving the security guarantee without involving more garbled circuits) or κ_b to be decreased (trading performance for a small chance of a single bit leaking).¹

(3) Our online phase has superior asymptotic cost, stemming from the differences in protocol paradigm — see a summary in Figure 1. LR uses a *cheating-recovery phase*, introduced in [19]: after evaluating the main circuits, the parties evaluate auxiliary circuits that allow the receiver to learn the sender’s input if the receiver can

¹For example, two parties might want to securely evaluate AES a million times on the same secret-shared key each time, where the key is not used for anything else. In that case, a $1/2^{20}$ or $1/2^{30}$ chance of leaking a single bit about this key might be permissible.

“prove” that the sender was cheating. Our protocol uses the PSI-based dual-execution reconciliation phase.

The important difference is that in the LR protocol, the sender’s input is provided to both the main circuits and auxiliary circuits. If there are B main garbled circuits in a bucket, then there are $B' \approx 3B$ auxiliary circuits, and garbled inputs must be sent for all of them in the online phase. Each individual garbled input is sent by decommitting to an offline commitment, so it contributes to communication as well as a call to a hash function. Furthermore, the cheating-recovery phase involves decommitments to garbled outputs for the auxiliary circuits, which are again proportional to the sender’s input length.

In contrast, our protocol uses no auxiliary circuits so has less garbled inputs to send (and less associated decommitments to check). Our reconciliation phase scales only with B and is independent of the parties’ input size. The overall effect is that our online phase involves significantly less communication and computation, with the difference growing as the computations involve longer inputs. With typical parameters $B = 4$ and $\kappa_s = 40$, our reconciliation phase is cheaper whenever $|x| \geq 54$ bits. Even for the relatively small AES circuit, our protocol sends roughly $10\times$ less data in the online phase.

(4) LR’s online phase uses 4 rounds of interaction² and delivers output only to one party. If both parties require output, their protocol must be modified to include an additional round. Our online phase also delivers outputs to both parties using either 5 or 6 rounds (depending on the choice of PSI subprotocols). We conjecture that our protocol can be modified to use only 4 rounds, but leave that question to follow-up work.

(5) Our implementation is more efficient than LR. The offline phase more effectively exploits parallelism and LR is implemented using a mix of Java & C++. The architecture of LR has a serial control flow with computationally heavy tasks performed in parallel using low level C++ code. In contrast, our protocol implementation is in C++ and fully parallelized with low level synchronization primitives.

2.4 Comparison to Non-GC Protocols

Another paradigm for malicious security in the online/offline setting is based not on garbled circuits but arithmetic circuits and secret sharing. Notable protocols and implementations falling into this paradigm include [8, 9, 10, 11, 27]. These protocols indeed have

²For our purposes, a *round* refers to both parties sending a message. In other words, messages in the same round are allowed to be sent simultaneously, and our implementation takes advantage of full-duplex communication to reduce latency. We emphasize that synchronicity is *not* required for our security analysis. The protocol is secure against an adversary who waits to obtain the honest party’s message in round i before sending its own round i message.

lightweight online phases, and many instances can be batched in parallel to achieve *throughput* comparable to our protocol. However, all of these protocols have an online phase whose number of rounds depends on the depth of the circuit being evaluated. As a result, they suffer from significantly higher *latency* than the constant-round protocols in the garbled circuit paradigm like ours. The latest implementations of [9] can securely evaluate AES with online latency 20ms [33]. Of special note is the implementation of the [11] protocol reported in [10], which achieves latency of only 6ms to evaluate AES. However, the implementation is heavily optimized for the special case of computing AES, and it is not clear how applicable their techniques are for general-purpose MPC. In any case, no protocol has reported online latency for AES that is less than our protocol’s total offline+online cost.

The above protocols based on secret-sharing also have significantly more expensive offline phases. Not all implementations report the cost of their offline phases, but the latest implementations of the [9] protocol require 156 seconds of offline time for securely computing AES [33]; many orders of magnitude more than ours. We note that the protocols in the secret-sharing paradigm have an offline phase which does *not* depend on the function that will be evaluated, whereas ours does.

3 Preliminaries

Secure computation. We use the standard notion of universally composable (UC) security [6] for 2-party computation. Briefly, the protocol is secure if for every adversary attacking the protocol, there is a straight-line simulator attacking the ideal functionality that achieves the same effect. We assume the reader is familiar with the details.

We define the ideal functionality $\mathcal{F}_{\text{multi-sfe}}$ that we achieve in Figure 2. The functionality allows parties to evaluate the function f , N times. Adversaries have the power to delay (perhaps indefinitely) the honest party’s output, which is typical in the setting of malicious security. In other words, the functionality does not provide output fairness.

Furthermore, the functionality occasionally allows the adversary to learn an arbitrary additional bit about the inputs. This leakage happens according to the distribution \mathcal{L} chosen by the adversary at setup time. The probability of a leaked bit in any *particular* evaluation of f is guaranteed to be at most ϵ . Further, the leakage is “risky” in the sense that the honest party detects cheating when the leaked bit is zero.

Building blocks. In Figures 10 & 11 we define oblivious transfer (OT) and commitment functionalities that are used in the protocol. In the random oracle model, where H is the random oracle, a party can commit to v by choosing random $r \leftarrow \{0, 1\}^{k_c}$ and sending $c = H(r \| v)$.

We use and adapt the Garbled Circuit notation and terminology of [5]; for a formal treatment, consult that paper. In Appendix A we define the syntax and security requirements, highlighting the differences we adopt compared to [5].

4 The Dual Execution Paradigm

We now give a high-level outline of the (non-online/offline) 2PC protocol paradigm of [16], which is the starting point for our protocol. The protocol makes use of a **two-phase PSI subprotocol**. In the first phase, both parties become committed to their PSI inputs; in the second phase, the PSI output is revealed. This component is modeled in terms of the $\mathcal{F}_{\text{psi}}^{n, \ell}$ functionality in Figure 12.

Assume the parties agree on a function f to be evaluated on their inputs. The protocol is symmetric with respect to Alice and Bob, and for simplicity we describe only Alice’s behavior.

- (1) Alice generates κ_b garbled circuits computing f , using a common garbled output encoding for all of them.
- (2) Alice announces a random subset of Bob’s circuits to open. However, the actual checking of the circuits is delayed until later in the protocol.
- (3) Alice uses OT to receive garbled inputs for the circuits generated by Bob, as in Yao’s protocol. Alice sends the garbled circuits she generated, along with her own garbled input for these circuits.
- (4) Alice evaluates the garbled circuits received from Bob. If Bob is honest, then all of his circuits use the same garbled output encoding and Alice will receive the same garbled output from each one. But in the general case, Alice might obtain several inconsistent garbled outputs.
- (5) Assume that Alice can decode the garbled outputs to obtain the logical circuit output. For each candidate circuit output y with garbled encoding Y_y^b (b for a garbled output under Bob’s encoding), let Y_y^a denote the encoding of y under Alice’s garbled output encoding (which Alice can compute). Interpreting Y_y^a and Y_y^b as *sets* of individual wire labels, let R_y be the XOR of all items in $Y_y^a \cup Y_y^b$, which we write as $R_y = \bigoplus [Y_y^a \cup Y_y^b]$ and which we call the *reconciliation value* for y . Alice sends the set of all $\{R_y\}$ values as input to a PSI instance.
- (6) With the PSI inputs committed, the parties open and check the circuits chosen in the cut-and-choose step. They abort if any circuit is not correctly garbled, or the circuits do not have consistent garbled output encodings.
- (7) The parties release the PSI output. Alice aborts if the PSI output is not a singleton set. Otherwise, if

Setup stage: On common input $(\text{SETUP}, f, N, \varepsilon)$ from both parties, where f is a boolean circuit:

- If neither party is corrupt, set $L = 0^N$. Otherwise, wait for input $(\text{CHEAT}, \mathcal{L})$ where \mathcal{L} is a distribution over $\{0, 1\}^N \cup \{\perp\}$ with the property that for every i , $\Pr_{L \leftarrow \mathcal{L}}[L_i = 1] \leq \varepsilon$. Sample $L \leftarrow \mathcal{L}$ using random coins χ and give $(\text{CHEATRESULT}, \chi)$ to the adversary. If $L = \perp$ then give output (CHEATING!) to the honest party and stop responding.
- Send output (READY) to both parties. Initialize counter $ctr = 1$. Proceed to the execution stage.

Execution stage: Upon receiving inputs (INPUT, x_1) from P_1 and (INPUT, x_2) from P_2 :

- Compute $z = f(x_1, x_2)$. If both parties are honest, give (OUTPUT, ctr, z) to both parties.
- If any party is corrupt, give (OUTPUT, ctr, z) to the adversary.
- If $L_{ctr} = 1$, wait for a command (LEAK, P) from the adversary, where P is a boolean predicate. Compute $p = P(x_1, x_2)$ and give $(\text{LEAKRESULT}, p)$ to the adversary.
- If any party is corrupt, then on input (DELIVER) from the adversary, if $p = 0$ above, then give output (CHEATING!) to the honest party, else give output (OUTPUT, ctr, z) to the honest party.
- If $ctr = N$ then stop responding; otherwise set $ctr = ctr + 1$ and repeat the execution stage.

Figure 2: The $(\varepsilon\text{-leaking})$ secure function evaluation functionality $\mathcal{F}_{\text{multi-sfe}}$.

the output is $\{R^*\}$ then Alice outputs the value y such that $R^* = R_y$.

4.1 Security Analysis and Other Details

Suppose Alice is corrupt and Bob is honest. We will argue that Alice learns nothing beyond the function output, except that with probability $2^{-\kappa_b}$ she learns a single bit about Bob’s input.

Suppose Alice uses input x_1 as input to the OTs, and Bob has input x_2 . Since Bob’s circuits are honestly generated and use the same garbled output encoding, every circuit evaluated by Alice leads to the same garbled output $Y_{y^*}^b$ that encodes logical value $y^* = f(x_1, x_2)$. Note that by the *authenticity* property of the garbled circuits, this is the *only* valid garbled output that Alice can predict.

Since Alice may generate malicious garbled circuits, honest Bob may obtain several candidate outputs from these circuits. Bob’s input to the PSI computation will be a collection of reconciliation values, each of the form $R_y = \bigoplus [Y_y^a \cup Y_y^b]$.

At the time of PSI input, none of Bob’s (honestly) garbled circuits have been opened, so they retain their authenticity property. Then Alice cannot predict any *valid* reconciliation value except for this R_{y^*} . This implies that the PSI output will be either $\{R_{y^*}\}$ or \emptyset . In particular, Bob will either abort or output the correct output y^* . Furthermore, the output of the PSI computation can be simulated knowing only whether honest Bob has included R_{y^*} in his PSI input.

The protocol includes a mechanism to ensure that Alice uses the same x_1 input for all of the garbled circuits. Hence, if Bob evaluates *at least one* correctly generated garbled circuit, it will give output y^* and Bob will surely include the R_{y^*} reconciliation value in his PSI input. In that case, the PSI output can be simulated as usual.

The probability the Alice manages to make Bob evaluate *no* correctly generated garbled circuits is $2^{-\kappa_b}$ — she would have to completely predict Bob’s cut-and-choose challenge to make all opened circuits correct and all evaluated circuits incorrect. But even in this event, the simulator only needs to know whether $f'(x_1, x_2) = y^*$ for any of the f' computed by Alice’s malicious garbled circuits. This is only one bit of information about x_2 which the simulator can request from the ideal functionality.

4.2 Outline for Online/Offline Dual-Execution

Our high-level approach is to adapt the [16] protocol to the online/offline setting. The idea is that the two parties plan to securely evaluate the same function f , N times, on possibly different inputs each time. In preparation they perform an offline pre-processing phase that depends only on f and N , but not on the inputs. They generate many garbled circuits and perform a cut-and-choose on all of them. Then the remaining circuits are assigned randomly to *buckets*. Later, once inputs are known in the online phase, one bucket’s worth of garbled circuits are consumed for each evaluation of f .

Our protocol will leak a single bit about the honest party’s input only when a bucket contains no “good” circuit from the adversary (where “good” is the condition that is verified for opened circuits during cut-and-choose). Following the lead of [23], we focus on choosing the number of circuits so that the probability of such an event in *any particular* bucket is $2^{-\kappa_b}$. We note that the analysis of parameters in [14, 22] considers an *overall* cheating condition, i.e., that *there exists* a bucket that has no “good” circuits, which leads to slightly different numbers.

Lemma 1 ([23]). *If the parties plan to perform N exe-*

cutions, using a bucket of B circuits for each execution and a total of $\hat{N} \geq NB$ garbled circuits generated for the overall cut-and-choose, then the probability that a specific bucket contains no good circuit is at most:

$$\max_{t \in \{B, \dots, NB\}} \left\{ \frac{\binom{\hat{N}-t}{NB-t}}{\binom{\hat{N}}{NB}} \cdot \frac{\binom{t}{B}}{\binom{NB}{B}} \right\}.$$

Suppose the parties will perform N executions, using buckets of size B in the online phase, and wish for 2^{-k_b} probability of leakage. We can use the formula to determine the smallest compatible \hat{N} . In the full version we show all reasonable parameter settings for $k_b \in \{20, 40, 80\}$ and $N \in \{8, 16, 32, \dots, 32768\}$.

By adapting [16] to the online/offline setting, we obtain the generic protocol outlined in Figure 3. Even with pre-processing, an online OT requires two rounds, one of which can be combined with the direct sending of garbled inputs. The protocol therefore requires three rounds plus the number of rounds needed for the PSI subprotocol (at least two).

4.3 Technicalities

We highlight which parts of the [16] protocol break down in the online/offline setting and require technical modification:

Same garbled output encoding. In [16] each party is required to generate garbled circuits that have a common output encoding. Their protocol includes a mechanism to enforce this property. In our setting, we require each bucket of circuits to have the same garbled output encoding. But this is problematic because in our setting a garbled circuit is generated before the parties know which bucket it will be assigned to.

Our solution is to have the garbler provide for each bucket a *translation* of the following form. The garbler chooses a bucket-wide garbled output encoding; e.g., for the first output wire, he chooses wire labels W_0^*, W_1^* encoding false and true, respectively. Then if W_0^j, W_1^j are the output wire labels already chosen for the j th circuit in this bucket, the garbler is supposed to provide *translation values* $W_v^j \oplus W_v^*$ for $v \in \{0, 1\}$. After evaluating, the receiver will use these values to translate the garbled input to this bucket-wide encoding that is used for PSI reconciliation.

Of course, a cheating party can provide invalid translation values. So we use step 3 of the online phase (Figure 3) to check them. In more detail, a sender must commit in the offline phase to the output wire labels of every garbled circuit. These will be checked if the circuit is chosen in the cut-and-choose. In step 3 of the online phase, these commitments are opened so that the receiver can check the consistency of the translation values (i.e., whether

Offline phase:

- (1) Parties perform offline preprocessing for the OTs that will be needed, and for the PSI subprotocol, if appropriate.
- (2) Based on N and κ_b , the parties determine appropriate parameters \hat{N}, B according to the discussion in Section 4.2. Each party generates and sends \hat{N} garbled circuits, and chooses a random subset of $N - NB$ of their counterpart's circuits to be opened. The chosen circuits are opened and parties abort if circuits are found to be generated incorrectly.
- (3) Each party randomly assigns their counterpart's circuits to *buckets* of size B . Each online execution will consume one bucket's worth of circuits.

Online phase:

- (1) Parties exchange garbled inputs: For one's own garbled circuits in the bucket, a party directly sends the appropriate garbled inputs; for the counterpart's garbled circuits, a party uses OT as a receiver to obtain garbled inputs as in Yao's protocol.
- (2) Parties evaluate the garbled circuits and compute the corresponding set of reconciliation values. They commit their sets of reconciliation values as inputs to a PSI computation.
- (3) With the PSI inputs committed, the parties open some checking information (see text in Section 4.3) and abort if it is found to be invalid.
- (4) The parties release the PSI output and abort if the output is \emptyset . Otherwise, they output the plaintext value whose reconciliation value is in the PSI output.

Figure 3: High-level outline of the online/offline, dual-execution protocol paradigm.

they map to a hash of the common bucket-wide encoding provided during bucketing.). This step reveals all of the bucket-wide encoding values, making it now easy for an adversary to compute any reconciliation value. This is why we employ a 2-phase PSI protocol, so that PSI inputs are committed before these translation values are checked.

Adaptive garbling. Standard security definitions for garbled circuits require the evaluator to choose the input before the garbled circuit is given. However, the entire purpose of offline pre-processing is to generate & send the garbled circuits before the inputs are known. This requires the garbling scheme to satisfy an appropriate *adaptive security* property, which is common to all works in the online/offline setting [14, 22]. See Appendix A for details.

Input consistency. To achieve security against active adversaries, GC-based protocols must ensure that parties provide the same inputs to all circuits that are evaluated. This is known as the problem of *input consistency*. The protocol of [16] uses the input consistency mechanism of shelat & Shen [32] which is unfortunately not compatible with the online/offline setting. More details follow in the next section.

5 Input Consistency

In this section we describe a new, extremely lightweight input-consistency technique that is tailored for the dual-execution paradigm.

5.1 Consistency Between Alice’s & Bob’s Circuits

We start with the “classical” dual-execution scenario, where Alice and Bob each generate one garbled circuit. We describe how to force Alice to use the same input in both of these garbled circuits (of course, the symmetric steps are performed for Bob). The high-level idea is to bind her behavior as OT receiver (when obtaining garbled inputs for Bob’s circuits) to the commitments of her garbled inputs in her own circuits.

It is well-known [2] that oblivious transfers on random inputs can be performed offline, and later “derandomized” to OTs of chosen inputs. Suppose two parties perform a random string OT offline, where Alice receives c, m_c and Bob receives m_0, m_1 , for random $c \in \{0, 1\}$ and $m_0, m_1 \in \{0, 1\}^k$. Later when the parties wish to perform an OT of chosen inputs c^* and (m_0^*, m_1^*) , Alice can send $d = c \oplus c^*$ and Bob can reply with $m_0^* \oplus m_d$ and $m_1^* \oplus m_{1 \oplus d}$.

In the offline phase of our protocol, the parties perform a random OT for each Alice-input wire of each circuit, where Alice acts as the receiver. These will be later used for Alice to pick up her garbled input for Bob’s circuit. Let c denote the *string* denoting Alice’s random choice bits for this collection of OTs.

Also in the offline phase, we will have Alice commit to all of the possible garbled input labels for the circuits that she generated. Suppose she commits to them in an order determined by the bits of c ; that is, the wire label commitments for the first input wire are in the order (false,true) if the first bit of c is 0 and (true,false) otherwise.

In the online phase with input x , Alice sends the OT “derandomized” message $d = x \oplus c$. She also sends her garbled inputs for the circuits she generated by opening the commitments indexed by d ; that is, she opens the first or second wire label of the i th pair, depending on whether $d_i = 0$ or $d_i = 1$, respectively. Bob will abort if Alice does not open the correct commitments.

Alice’s effective OT input is $x = d \oplus c$, so she picks

up garbled input corresponding to x . If Alice did indeed commit to her garbled inputs arranged according to c , then she opens the commitments whose *truth values* are also $x = d \oplus c$. More formally,

Offline: Alice garbles the labels A_0, A_1 and Bob garbles B_0, B_1 for Alice’s input. Alice receives OT message m_c and Bob holds m_0, m_1 . Alice sends $(\text{COMMIT}, (\text{sid}, i), A_{i \oplus c})$ to \mathcal{F}_{com} for $i \in \{0, 1\}$.

Online: Alice sends $d = c \oplus x$ to Bob and $(\text{OPEN}, (\text{sid}, d))$ to \mathcal{F}_{com} . Bob receives $(\text{OPEN}, (\text{sid}, d), A_x)$ from \mathcal{F}_{com} and sends $(B_0 \oplus m_d, B_1 \oplus m_{1 \oplus d})$ to Alice who computes $B_x = m_c \oplus (B_{c \oplus d} \oplus m_c)$.

Figure 4: Input consistency on a single bit of Alice’s input for “classic” dual-execution.

Looking ahead, we will use cut-and-choose to guarantee that there is at least one circuit for which Alice’s garbled input commitments are correct in this way.

5.2 Aggregating Several OTs

In our protocol, both parties evaluate a bucket of several circuits. Within the bucket, each of Alice’s circuits is paired with one of Bob’s, as above. However, this implies that Alice uses *separate* OTs to pick up her garbled inputs in each of Bob’s circuits. To address this, we *aggregating* several OTs together to form a single OT.

Suppose Alice & Bob have performed *two* random string OTs, with Alice receiving c, c', m_c, m'_c and Bob receiving m_0, m_1, m'_0, m'_1 , for random $c, c' \in \{0, 1\}$. Suppose further that Alice sends $\delta = c \oplus c'$ to Bob in an offline phase. To aggregate these two random OTs into a *single* chosen-input OT with inputs c^*, m_0^*, m_1^* , Alice can send $d = c \oplus c^*$, and Bob can reply with $m_0^* \oplus (m_d \oplus m'_{d \oplus \delta})$ and $m_1^* \oplus (m_{1 \oplus d} \oplus m'_{1 \oplus d \oplus \delta})$.

The idea extends to aggregate any number B of different random OTs into a single one, with Alice sending $B - 1$ different δ difference values. In our protocol, we aggregate in this way the OTs for the same wire across different circuits. Intuitively, Alice either receives wire labels for the same value on each of these wires (by reporting correct δ values), or else she receives nothing for this wire on *any* circuit.

5.3 Combining Everything with Cut-and-Choose

Now consider a bucket of B circuits. In the offline phase Alice acts as receiver in many random OTs, one collection of them for each of Bob’s circuits. Let c_j be her (string of) choice bits for the OTs associated with the j th circuit. Alice is then supposed to commit to the garbled inputs of her j th circuit arranged according to c_j . Bob will check this property for all circuits that are opened during the cut-and-choose phase by Alice showing the

corresponding OT messages.³ Hence with probability at least $1 - 2^{-\kappa_b}$, at least one circuit in any given bucket has this property. Alice also reports aggregation values $\delta_j = c_1 \oplus c_j$ for these OTs.

In the online phase Alice chooses her input x and sends $d_1 = c_1 \oplus x$ as the OT-derandomization message. This is equivalent to Alice sending $d_j = \delta_j \oplus d_1$ as the message to derandomize the j th OTs. To send her garbled input for the j th circuit, Alice is required to open her commitments indexed by d_j .

If Alice lies in any of the aggregation strings, then she will be missing at least one of the B -out-of- B secret shares which mask her possible inputs. Intuitively, Alice's two strategies are either to provide honest aggregation strings or not obtain any garbled inputs in the position that she lied. In the latter case, the simulator can choose an arbitrary input for Alice in that position.

If we then consider the likely case where Bob's j th circuit is “good” and Alice provided honest aggregation strings, then Alice will have decommitted to inputs for the j th circuit that are consistent with her effective OT input x_1^* . From the discussion in Section 4.1, this is enough to guarantee that the reconciliation phase leaks nothing.

Even if there are no “good” circuits in the bucket (which happens with probability $1/2^{\kappa_b}$), it is still the case that Alice learns no more than if she had received consistent garbled input x_1^* for all of Bob's circuits. So the reconciliation phase can be simulated knowing only whether Bob evaluates any circuit resulting in $f(x_1^*, x_2)$. This is a single bit of information about Bob's input x_2 .

6 Selective Failure Attacks

In the garbled circuit paradigm, suppose Alice is acting as evaluator of some garbled circuits. She uses OT to pick up the wire labels corresponding to her input. A corrupt Bob could provide incorrect inputs to these OTs, so that (for instance) Alice picks up an invalid garbled input if and only if the first bit of her input is 0. By observing whether the evaluator aborts (or produces otherwise unexpected behavior), Bob can deduce the first bit of Alice's input. This kind of attack, where the adversary causes the honest party to abort/fail with probability *depending on its private input* is called a **selective failure attack**.

A common way to prevent selective failure is to use what is called a k -probe-resistant input encoding:

Definition 2 ([20, 32]). *Matrix $M \in \{0, 1\}^{\ell \times n}$ is called **k -probe resistant** if for any $L \subseteq \{1, 2, \dots, n\}$, the Hamming distance of $\bigoplus_{i \in L} M_i$ is at least k , where M_i denotes the i th row vector of M .*

³In fact, since the OT messages are long random strings, Alice can prove that she had particular choice bits in *many* OTs by simply reporting the XOR of all of the corresponding OT messages.

The idea is for Alice to choose a random encoding \tilde{x}_1 of her logical input x_1 satisfying $M\tilde{x}_1 = x_1$. Then the parties evaluate the function $f'(\tilde{x}_1, x_2) = f(M\tilde{x}_1, x_2)$. This additional computation of $M\tilde{x}_1$ involves only XOR operations, so it does not increase the garbled circuit size when using the Free-XOR optimization [17] (it does increase the number OTs needed).

Alice will now use \tilde{x}_1 as her choice bits to the OTs. The adversary can *probe* any number of bits of \tilde{x}_1 , by inserting invalid inputs to the OT in those positions, and seeing whether the other party aborts. For each position probed, the adversary incurs a $1/2$ probability of being caught.⁴

The property of k -probe-resistance implies that probing k bits of the *physical* input \tilde{x}_1 leaks no information about the *logical* input $M\tilde{x}_1$. However, probing k bits incurs a $1 - 2^{-k}$ probability of being caught. Hence, our protocol requires a matrix that is κ_s -probe resistant, where κ_s is the statistical security parameter. We refer the reader to [23] for the construction details of k -probe resistant matrices and their parameters.

6.1 Offlining the k -probe computations

Using k -probe-resistant encodings, the encoded input \tilde{x}_1 is significantly longer than the logical input x_1 . While the computation of $M\tilde{x}_1$ within the garbled circuit can involve no *cryptographic* operations (using Free-XOR), it still involves a quadratic number of XOR operations.

Lindell & Riva [22] suggest a technique that moves these computations associated with k -probe-resistant encodings to the offline phase. The parties will compute the related function $f'(\hat{x}_1, c, x_2) = f(\hat{x}_1 \oplus Mc, x_2)$. In the offline phase, Alice will use OT to obtain wire labels for a random string c . She can also begin to partially evaluate the garbled circuit, computing wire labels for the value Mc .

In the online phase, Alice announces $\hat{x}_1 = x_1 \oplus Mc$ where x_1 is her logical input. Then Bob directly sends the garbled inputs corresponding to \hat{x}_1 . This introduces an asymmetry into our input consistency technique. The most obvious solution to maintain compatibility is to always evaluate circuits of the form $f'(\hat{x}_1, c_1, \hat{x}_2, c_2) = f(\hat{x}_1 \oplus Mc_1, \hat{x}_2 \oplus Mc_2)$, so that Alice uses the same *physical* input (c_1, \hat{x}_1) in both hers and Bob's circuits. However, we would prefer to let Alice use logical input x_1 rather than its (significantly longer) k -probe-encoded input, to reduce the concrete overhead. It turns out that we can accommodate this by exploiting the \mathbb{Z}_2 -linearity of the encoding/decoding operation.

Consider a bucket of circuits $\{1, \dots, B\}$. For the j th

⁴Technically, the sender will commit to all garbled inputs, and then the OTs will be used to transfer the decommitment values. That way, the receiver can abort immediately if an incorrect decommitment value is received.

circuit, Alice acts as receiver in a set of random OTs, and receives random choice bits c_j . The number of OTs per circuit is the number of bits in a k -probe-resistant encoding of Alice’s input.

For Alice’s j th circuit, she must commit to her garbled inputs in the order given by the string Mc_j (rather than just c_j as before). This condition will be checked by Bob in the event that this circuit is opened during cut-and-choose. To assemble a bucket, Alice reports aggregation values $\delta_j = c_1 \oplus c_j$ as before. Imagine Alice derandomizing these OTs by sending an all-zeroes derandomization message. This corresponds to her accepting the random c_1 as her choice bits. (Of course, an all-zeroes message need not be actually sent.) Bob responds and uses the aggregated OTs to send Alice the garbled inputs for c_1 for all of his garbled circuits (indeed, even in the j th circuit Alice receives garbled inputs corresponding to c_1).

In the online phase, Alice decides her logical input x_1 , and she sends $\hat{x}_1 = Mc_1 \oplus x_1$. This value derandomizes the offline k -probe-resistant encoding. Then in her own j th circuit, Alice must open the garbled input commitments indexed by the (public) string $\hat{x}_1 \oplus M\delta_j$.

To see why this solution works, suppose that Alice’s j th circuit is “good” (i.e., garbled correctly and input commitments arranged by Mc_j). As before, define her *effective* OT input to the j th OTs as $c^* = c_j \oplus \delta_j$ (which should be c_1 if Alice did not lie about δ_j). Even if Alice lied about the δ values she surely learns no more than she would have learned by being truthful about the δ values and using effective input c^* in all OTs. Hence, we can imagine that she uses logical input $x_1^* = \hat{x}_1 \oplus Mc^*$ in all of Bob’s garbled circuit.

Alice is required to open garbled inputs indexed by $\hat{x}_1 \oplus M\delta_j = \hat{x}_1 \oplus M(c^* \oplus c_j) = x_1^* \oplus Mc_j$. These are exactly the garbled inputs corresponding to logical input x_1^* , since the commitments were arranged according to Mc_j . We see that Bob evaluates at least one correctly garbled circuit with Alice using input x_1^* , which is all that is required for weak input consistency.

7 Optimizing PSI Reconciliation

7.1 Weaker security.

Our main insight is that our PSI reconciliation step does not require a fully (UC) secure PSI protocol. Instead, a weaker security property suffices. Recall that the final steps of the [16] protocol proceed as follows:

- Alice & Bob commit to their PSI inputs.
- The garbled-output translations are opened and checked.
- The parties either abort or release the PSI output.

For simplicity, assume for now that only one party receives the final PSI output. We will address two-sided output later.

Suppose Alice is corrupt and Bob is honest. Following from the discussion of security in Section 4, Bob will use as PSI input a collection of valid reconciliation values. At the time Alice provides her PSI inputs, the *authenticity* property of the garling scheme is in effect. This means that Alice can predict a valid reconciliation value only for the “correct” output y^* . All other valid reconciliation values that might be part of Bob’s PSI input are unpredictable.

Below we formalize a weak notion of security for input distributions of this form:

Definition 3. Let Π be a two-phase protocol for set intersection ($\mathcal{F}_{psi}^{n,\ell}$, Figure 12). We say that Π is **weakly malicious-secure** if it achieves UC-security with respect to environments that behave as follows:

- (1) The adversary sends a value $a^* \in \{0, 1\}^\ell$ to the environment along with the description of a distribution \mathcal{D} whose support is cardinality- $(n - 1)$ subsets of $\{0, 1\}^\ell$. We further require that \mathcal{D} is **unpredictable** in the sense that the procedure “ $A \leftarrow \mathcal{D}$; output a uniformly chosen element of A ” yields the uniform distribution over $\{0, 1\}^\ell$ (the joint distribution of all elements of A need not be uniform).
- (2) The environment (privately) samples $A \leftarrow \mathcal{D}$ and gives input $A \cup \{a^*\}$ to the honest party for the first phase of PSI.
- (3) After the first phase finishes (i.e., both parties’ inputs are committed), the environment gives the coins used to sample A to the adversary.
- (4) The environment then instructs the honest party to perform the second phase of PSI to obtain output.

In this definition, the adversary knows only one value in the honest party’s set, while all other values are essentially uniform. We claim that when ℓ is large, the simulator for this class of environments *does not need to fully extract the adversary’s PSI input!* Rather, the following are enough to ensure weakly-malicious security:

- The adversary is indeed committed to *some* (unknown to the simulator) effective input during the commit phase.
- The simulator can *test* whether the adversary’s effective PSI input contains the special value a^* .

With overwhelming probability, no effective input element other than a^* can contribute to the PSI output. Any other values in the adversary’s effective input can simply be ignored; they do not need to be extracted.

For technical reasons and convenience in the proof, we have the environment give the adversary the coins used to sample A , but only after the PSI input phase.

7.2 PSZ protocol paradigm.

We now describe an inexpensive protocol paradigm for PSI, due to Pinkas et al. [30]. Their protocol is proven

secure only against passive adversaries. We later discuss how to achieve weak malicious security.

The basic building block is a protocol for **private equality test (PEQT)** based on OT. A benefit of using OT-based techniques is that the bulk of the effort in generating OTs can be done in the offline phase, again leading to a lightweight online phase for the resulting PSI protocol.

Suppose a sender has input s and receiver has input r , with $r, s \in \{0, 1\}^n$, where the receiver should learn whether $r = s$ (and nothing more). The PEQT protocol requires n string OTs; in the i th one, the receiver uses choice bit $r[i]$ and the sender chooses random string inputs (m_0^i, m_1^i) . The sender finally sends $S = \bigoplus_i m_{s[i]}^i$, and the receiver checks whether $S = \bigoplus_i m_{r[i]}^i$, which is the XOR of his OT outputs.

The PEQT can be extended to a **private set membership test (PSMT)**, in which the sender has a set $\{s^1, \dots, s^t\}$ of strings, and receiver learns whether $r \in \{s^1, \dots, s^t\}$. We simply have the sender randomly permute the s^j values, compute for each one $S^j = \bigoplus_i F(m_{s^j[i]}, j)$ and send $\{S^1, \dots, S^t\}$, where F is a PRF.⁵ The receiver can check whether $\bigoplus_i F(m_{r[i]}, j)$ matches S^j for any j . Finally, we can achieve a PSI where the receiver has strings $\{r^1, \dots, r^t\}$ by running independent PSMTs of the form $r^j \in \{s^1, \dots, s^t\}$ for each r^j (in random order).

The overhead of this approach is $O(t^2)$, and [30] describe ways to combine hashing with this basic PSI protocol to obtain asymptotically superior PSI protocols for large sets. However, we are dealing with very small values of t (typically at most 5), so the concrete cost of this simple protocol is very low.

To make the PSI protocol two-phase, we run the OTs and *commit* to the S values in the input-committing phase. Then the output phase consists simply of the sender opening the commitments to S .

7.3 Achieving weakly-malicious security and double-sided output.

We use the [30] protocol but instantiate it with malicious-secure OTs. This leads to the standard notion of security against an active receiver since the simulator can extract the receiver's input from its choice bits to the OTs.

However, the protocol does not achieve full security against a malicious sender. In the simple PEQT building block, the simulator cannot extract a malicious sender's input. Doing so would require inspecting $S, \{m_b^i\}$ and determining a value s such that $S = \bigoplus_i m_{s[i]}^i$. Such an s may not exist, and even if it did, the problem seems

⁵Simply XORing the m_b^i values would reveal some linear dependencies; applying a PRF renders all of the S^j values independently random except the ones for which $r = s^j$.

closely related to a subset-sum problem.

However, if the simulator knows a *candidate* s^* , it can certainly check whether the corrupt sender has sent the corresponding S value. This is essentially the only property required for weakly malicious security.

We note that a corrupt sender could use inconsistent sets $\{s^1, \dots, s^t\}$ in the parallel PSMT instances. However, the simulator can still extract whether the candidate s^* was used in each of them. If the sender used s^* in t' of the t subprotocols, then the simulator can send s^* to the ideal PSI functionality with probability t'/t , which is a sound simulation for weakly-malicious security.

Regarding double-sided output, it suffices to simply run two instances of the one-sided-output PSI protocol, one in each direction, in parallel. Again, this way of composing PSI protocols is not sound *in general*, but it is sound for the special case of weakly-malicious security.

7.4 Trading computation for lower round complexity.

Even when random OTs are pre-processed offline, the PSI protocol as currently described requires two rounds to commit to the outputs, and one round to release the output. The two input-committing rounds are (apparently) inherently sequential, stemming from the sequential nature of OT derandomization.

In terms of round complexity, these two PSI rounds are a bottleneck within the overall dual-execution protocol. We now describe a variant of the PSI protocol in which the two input-committing messages are *asynchronous* and can be sent simultaneously. The modified protocol involves (a nontrivial amount of) additional computation but reduces the number of rounds in the overall 2PC online phase by one. This tradeoff does not *always* reduce the overall latency of the 2PC online phase — only sometimes, depending on the number of garbled circuits being evaluated and the network latency. The specific break-even points are discussed in Section 9.

In our PEQT protocol above, the two parties have pre-processed random OTs, with choice bits c and random strings m_0^i, m_1^i . To commit to his PSI input, the receiver's first message is $d = c \oplus r$, to which the sender responds with $S = \bigoplus_i m_{d[i] \oplus s[i]}^i$.

Consider randomizing the terms of this summation as $S = \bigoplus_i [m_{d[i] \oplus s[i]}^i \oplus z_i]$ where z_i are random subject to $\bigoplus_i z_i = 0$. Importantly, (1) each term in this sum depends only on a single bit of d ; (2) revealing *all* terms in the sum reveals no more than S itself. We let the sender commit to all the potential terms of this sum and reveal them individually in response to d . In more detail, the sender commits to the following values (in this order):

$$(*) \quad [m_{s[1]}^1 \oplus z_1] \quad [m_{s[2]}^2 \oplus z_2] \quad \cdots \quad [m_{s[n]}^n \oplus z_n] \\ [m_{s[1] \oplus 1}^1 \oplus z_1] \quad [m_{s[2] \oplus 1}^2 \oplus z_2] \quad \cdots \quad [m_{s[n] \oplus 1}^n \oplus z_n]$$

Importantly, these commitments can be made before d is known. In response to the message d from the receiver, the sender is expected to release the output by opening the commitments indexed by the bits of d . The sender will open the commitments $\{m_{d[i] \oplus s[i]}^i \oplus z_i\}$; the receiver will compute their XOR S and proceed as before.

The simulator for a corrupt sender simulates a random message d and then checks whether the sender has used a candidate input s^* by extracting the commitments indexed by d to see whether their XOR is $\bigoplus_i m_{d[i] \oplus s^*[i]}^i$.⁶

We can further move the commitments to the offline phase, since there are two commitments per bit of s per PEQT. Observe that the commitments in (\star) are arranged according to the bits of s , which are not known until the online phase. Instead, in the offline phase the sender can commit to these values arranged according to a random string π . In the online phase, the sender commits to its input s by sending $s \oplus \pi$. Then in response to receiver message d , the sender must open the commitments indexed by the bits of $d \oplus (s \oplus \pi)$.

When extending the asynchronous PEQT to a PSMT protocol, the sender commits to an array of $F(m_b^j, j) \oplus z_i^j$ values for each j .

7.5 Final Protocols

For completeness, we provide formal descriptions of the final PSI protocols (synchronous 3-round and asynchronous 2-round) in Figures 13 & 14.

We defer the proof of their security to the full version.

Theorem 4. *The protocols $\Pi_{\text{sync-psi}}$ and $\Pi_{\text{async-psi}}$ described in Figures 13 & 14 are weakly-malicious secure (in the sense of Definition 3) when $\ell \geq \kappa_s$, the statistical security parameter.*

8 Protocol Details & Implementation

The full details of our protocol are given in Figure 15 and the c++ implementation may be found at <https://github.com/osu-crypto/batchDualEx>. The protocol uses three security parameters:

κ_b is chosen so that the protocol will leak a bit to the adversary with probability at most $2^{-\kappa_b}$. This parameter controls the number of garbled circuits used per execution.

κ_s is the statistical security parameter, used to determine the length of the reconciliation strings used as PSI input (the PSI protocol scales with the length of the PSI input values). The adversary can guess an unknown reconciliation value with probability at most $2^{-\kappa_s}$.

⁶Note: although we intend for the two parties' messages to be sent simultaneously, we must be able to simulate in the case that a corrupt sender waits for incoming message d before sending its commitments.

κ_c is the computational security parameter, that controls the key sizes for OTs, commitments and garbled circuits.

In our evaluations we consider $\kappa_c = 128$, $\kappa_s \in \{40, 80\}$ and $\kappa_b \in \{20, 40, 80\}$. In the full version we prove the security of our protocol:

Theorem 5. *Our protocol (Figure 15) securely realizes the $\mathcal{F}_{\text{multi-sfe}}$ functionality, in the presence of malicious adversaries.*

8.1 Implementation & Architecture

In the offline phase, the work is divided between p parallel sets of 4 threads. Within each set, two threads generate OTs and two threads garble and receive circuits and related commitments. Parallelizing OT generation and circuit generation is key to our offline performance; we find that these two activities take roughly the same time.

We generate OTs using an optimized implementation of the Keller et al. [15] protocol for OT extension. Starting from 128 base OTs (computed using the protocol of [28]), we first run an OT extension to obtain $128 \cdot p$ OT instances. We then distribute these instances to the p different thread-sets, and each thread-set uses its 128 OT instances as base OTs to perform its own *independent* OT extension.

We further modified the OT extension protocol to process and finalize OT instances in blocks of 128 instances. This has two advantages: First, OT messages can be used by other threads in the offline phase as they are generated. Second, OT extension involves CPU-bound matrix transposition computations along with I/O-bound communication, and this approach interlaces these operations.

The offline phase concludes by checking the circuits in the cut-and-choose, bucketing the circuits, and exchanging garbled inputs for the random k -probe-encoded inputs.

The online phase similarly uses threading to exploit the inherently parallel nature of the protocol. Upon receiving input, a primary thread sends the other party their input correction value as the first protocol message. This value is in turn given to B sub-threads (where B is the bucket size) that transmit the appropriate wire labels. Upon receiving the labels, the B threads (in parallel) each evaluate a circuit. Each of the B threads then executes (in parallel) one of the set-membership PSI sub-protocols. After the other party has committed to their PSI inputs, the translation tables of each circuit is opened and checked in parallel. The threads then obtain the intersection and the corresponding output value.

8.2 Low-level Optimizations

We instantiate the garbled circuits using the state-of-the-art *half-gates* construction of [35]. The implementation

utilizes the hardware accelerated AES-ni instruction set and uses fixed-key AES as the gate-level cipher, as suggested by [3]. Since circuit garbling and evaluation is the major computation bottleneck, we have taken great care to streamline and optimize the execution pipeline.

The protocol requires the bucket’s common output labels to be random. Instead, we can optimize the online phase choose these labels as the output of a hash at a random seed value. The seed can then be sent instead of sending all of the common output labels. From the seed the other party regenerates the output labels and proceed to validate the output commitments.

9 Performance Evaluation

We evaluated the prototype on Amazon AWS instances c4.8xlarge (64GB RAM and 36 virtual 2.9 GHz CPUs). We executed our prototype in two network settings: a LAN configuration with both parties in the same AWS geographic region and 0.2 ms round-trip latency; and a WAN configuration with parties in different regions and 75 ms round-trip latency.

We demonstrate the scalability of our implementation by evaluating a range of circuits:

- The AES circuit takes a 128-bit key from one party and a 128-bit block from another party and outputs a 128-bit block to both. The circuit consists of 6800 AND gates and 26,816 XOR gates.
- The SHA256 circuit takes 512 bits from both parties, XORs them together and returns the 256-bit hash digest of the XOR’ed inputs. The circuit consists of 90,825 AND gates and 145,287 XOR gates.
- The AES-CBC-MAC circuit takes a 16-block (2048-bit) input from one party and a 128-bit key from the other party and returns the 128-bit result of 16-round AES-CBC-MAC. The circuit consists of 156,800 AND gates and 430,976 XOR gates.⁷

In all of our tests, we use system parameters derived from Lemma 1. N denotes the number of executions, and B denotes the bucket size (number of garbled circuits per execution) and we use $\sim B$ online threads.

9.1 PSI protocol comparison

In Section 7 we describe two PSI protocols that can be used in our 2PC protocol — a *synchronous* protocol that uses three rounds total, and an *asynchronous* protocol that uses two rounds total (at higher communication cost). We now discuss the tradeoffs between these two PSI protocols. A summary is given in Figure 5. For small parameters in the LAN setting, the 2-round asynchronous protocol is faster overall, but for larger parameters the 3-round synchronous protocol is faster. This is

⁷The circuit is not optimized; each call to AES recomputes the entire key schedule.

κ_s	B	PSI		Async		Sync	
		Time	Size	Time	Size	Time	Size
40	2	0.31	2,580	0.35	138		
	3	0.34	5,790	0.39	303		
	4	0.42	10,280	0.46	532		
	6	0.65	32,100	0.55	1,182		
	5	0.55	23,100	0.51	850		
	7	0.83	62,860	0.66	1,638		
80	9	1.39	103,860	0.83	2,682		

Figure 5: The running time (ms) and online communication size (bytes) of the two PSI protocols when executed with κ_s -bit strings and input sets of size B .

$\kappa_s = \kappa_b = 40$		[23]		This		
	Circuit	N	Offline	Online	Offline	Online
LAN	AES	32	197	12	45	1.7
		128	114	10	16	1.5
		1024	74	7	5.1	1.3
	SHA256	32	459	50	136	10.0
		128	275	40	78	8.8
		1024	206	33	48	8.4
WAN	AES	32	1,126	163	282	190
		128	919	164	71	191
		1,024	760	160	34	189
	SHA256	32	3,638	290	777	194
		128	3,426	256	399	192
		1,024	2,992	207	443	191

Figure 6: Amortized running times per execution (reported in ms) for [23] and our prototype. We used bucket size $B = 6, 5, 4$ for $N = 32, 128, 1024$.

due to the extra data sent by the 2-round protocol. Specifically, the asynchronous protocol sends $O(B^2 \kappa_s \kappa_c)$ bytes while the synchronous one sends $O(B \kappa_s + B^2 \kappa_c)$. In the remaining comparisons, we always use the PSI protocol with lowest latency, according to Figure 5.

9.2 Comparison to the LR protocol

We compare our prototype to that of [23] with 40-bit security. That is, we use $\kappa_b = \kappa_s = 40$; both protocols have identical security and use the same bucket size. We use identical AWS instances and a similar number of threads to those reported in [23].

Figure 6 shows the results of the comparison in the LAN setting. It can be seen that our online times are 5 to 7 times faster and our offline times are 4 to 15 times faster. Indeed, for $N = 1024$ our total (online plus offline) time is less than the online time of [23].

In the WAN setting with small circuits such as AES where the input size is minimal we see [23] achieve faster online times. Their protocol has one fewer round than ours protocol, which contributes 38ms to the difference in performance. However, for the larger SHA256 circuit our implementation outperforms that of [23] by 16 to 100ms per execution and we achieve a much more ef-

	1,024	109.5	378	15.8	31.0	95	12.3	15.6	71	10.6

Figure 7: Amortized running times per execution (reported in ms) and total offline storage (reported in GB) for our prototype in the LAN configuration. The peak offline storage occurs before the cut and choose, consisting of the circuits, commitments, and OT messages. For $\kappa_b = 80$ we use parameters $(N, B) \in \{(32, 12), (128, 9), (1024, 7)\}$. For $\kappa_b = 40$ we use parameters $(N, B) \in \{(32, 6), (128, 5), (1024, 5)\}$. For $\kappa_b = 20$ we use parameters $(N, B) \in \{(32, 3), (128, 2), (1024, 2)\}$.

ficient offline phase ranging from 4 to 22 times faster for both circuits.

As discussed in [Section 2.3](#), our protocol has asymptotically lower online communication cost, especially for computations with larger inputs. Since both protocols are more-or-less I/O bound in these experiments, the difference in communication cost is significant. Concretely, when evaluating AES with $N = 1024$ and $B = 4$ our protocol sends 16,384 bytes of wire labels and just 564 bytes of PSI data. The online phase of [\[23\]](#) reports to use 170,000 bytes with the same parameters. Even using our asynchronous PSI sub-protocol, the total PSI cost is only 10,280 bytes.

9.3 Effect of security parameters

We show in [Figure 7](#) how our prototype scales for different settings of security parameters in the LAN setting. In particular, the security properties of our protocol allow us to consider smaller settings of parameters than are advised with traditional cut-and-choose protocols such as [\[23\]](#). As a representative example, we consider $\kappa_b = 20$ and $\kappa_s = 40$ which means that our protocol will leak a single bit only with probability $1/2^{20}$ but guarantee all other security properties with probability $1 - 1/2^{40}$.

Our protocol scales very well both in terms of security parameter and circuit size. Each doubling of κ_s only incurs an approximate 25% to 50% increase in running time. This is contrasted by [\[23\]](#) reporting a 200% to 300% increase in running time for larger security parameters. Our improvement is largely due to reducing the number of cryptographic steps and no cheat-recovery circuit which consume significant online bandwidth.

We see a more significant trend in the total storage requirement of the offline phase. For example, when performing $N = 1024$ AES evaluations for security parameter $\kappa_b = 20$ the protocol utilizes a maximum of 0.76 GB of storage while $\kappa_b = 40$ requires 1.6 GB of storage. This further validates $\kappa_b = 20$ as a storage and bandwidth saving mechanism. [\[23\]](#) reports that 3.8 GB of offline com-

		LAN		WAN

	9	2.42	465	3.41	331

Figure 8: Maximum amortized throughput (ms/execution) and resulting bandwidth (Kbps) when performing many parallel evaluations of AES with the given bucket size B and statistical security κ_s .

munication for $N = 1024$ and 40-bit security.

9.4 Throughput & Bandwidth

In addition to considering the setting when executions are performed sequentially, we tested our prototype when performing many executions in parallel to maximize *throughput*. [Figure 8](#) shows the maximum average throughput for AES evaluations that we were able to achieve, under different security parameters and bucket sizes. The time reported is the average number of milliseconds per evaluation.

In the LAN setting, 8 evaluations were performed in parallel and achieved an amortized time of 0.26ms per evaluation for bucket size $B = 2$. A bucket size of 2 can be obtained by performing a modest number (say $N = 256$) of executions with $\kappa_b = 20$, or a very large number of executions with $\kappa_b = 40$. We further tested our prototype in the WAN setting where we obtain a slightly decreased throughput of 0.72ms per AES evaluation with 40-bit security.

A Adaptively Secure Garbling Schemes

A **garbling scheme** is a tuple of algorithms $(\text{Gb}, \text{En}, \text{Ev}, \text{De})$ with the following syntax and semantics. All algorithms accept a security parameter as explicit input, which we leave implicit.

- $\text{Gb}(f, d) \rightarrow (F, e)$; Here f is a boolean circuit with m inputs and n outputs; d is an $n \times 2$ array of (output) **wire labels**; F is a **garbled circuit**; and e is an $m \times 2$ array of input wire labels.

By wire labels, we simply mean strings (i.e., elements of $\{0, 1\}^{\kappa_c}$). We deviate from [5] in requiring the output wire labels d to be chosen by the caller of Gb , rather than chosen by Gb itself. In the notation of [5], we assume that the scheme is **projective** in both its input and output encodings, meaning that e and d consist of two possible wire labels for each wire.

- $\text{En}(e, x) \rightarrow X$ takes an $m \times 2$ array of wire labels e and a plaintext input $x \in \{0, 1\}^m$ and outputs a **garbled encoding** X of x . By assuming that the scheme is projective, we assume that $X = (X_1, \dots, X_m)$ where $X_i = e[i, x_i]$.

- $\text{Ev}(F, X) \rightarrow Y$; takes a garbled circuit F and garbled encoding X of an input, and returns a garbled encoding of the output Y .

- $\widetilde{\text{De}}(Y) \rightarrow y$. We assume a way to decode a garbled output to a plaintext value. It is a deviation from [5] to allow this to be done without the decoding information d . Rather, we may assume that the garbled outputs contain the plaintext value, say, as the last bit of each wire label.

Our correctness condition is that for the variables defined above, we have $\text{Ev}(F, \text{En}(e, x)) = \text{En}(d, f(x))$ and $\widetilde{\text{De}}(\text{Ev}(F, \text{En}(e, x))) = f(x)$ for all inputs x to the circuit f . In other words, evaluating the garbled circuit should result in the garbled output that encodes $f(x)$ under the encoding d .

In our construction, an adversary sees the garbled circuit F first, then it receives some of the garbled inputs (corresponding to the k -probe matrix encoded inputs). Finally in the online phase it is allowed to choose the rest of its input to the circuit and receive the rest of the garbled inputs. Hence, our security game considers an adversary that can obtain the information in this order.

We overload the syntax of the encoding algorithm En . Since En is projective, we write $\text{En}(e, i, b)$ to denote the component $e_{i,b}$ — that is, the garbled input for the i th wire corresponding to truth value b . Recall that we also garble a circuit with output wire labels d specified (rather than chosen by the Gb algorithm). Our security definition lets the adversary choose d .

Definition 6. For a garbling scheme $(\text{Gb}, \text{En}, \text{Ev}, \text{De})$, an interactive oracle program Adv , and algorithms $S = (S_0, S_1, S_2)$, we define the following two games/interactions:

$\mathcal{G}_{\text{ideal}}^{\text{Adv}, S}$:
get f, d from Adv^{S_0}
$F \leftarrow S_1(f)$
give F to Adv^{S_0}
for $i = 1$ to $m - 1$:
get x_i from Adv^{S_0}
$X_i \leftarrow S_2(i)$
give X_i to Adv^{S_0}
get x_m from Adv^{S_0}
$y = f(x_1 \dots x_m)$
$Y \leftarrow \text{En}(d, y)$
$X_m \leftarrow S_2(m, y, Y)$
give X_m to Adv^{S_0}
Adv^{S_0} outputs a bit

In $\mathcal{G}_{\text{ideal}}$, H is a random oracle. In $\mathcal{G}_{\text{ideal}}$, the tuple $S = (S_0, S_1, S_2)$ all share state. All algorithms receive the security parameter as implicit input.

Then the garbling scheme is **adaptively secure** if there exists a simulator S such that for all polynomial-time adversaries Adv , we have that

$$|\Pr[\mathcal{G}_{\text{real}}^{\text{Adv}} \text{ outputs } 1] - \Pr[\mathcal{G}_{\text{ideal}}^{\text{Adv}, S} \text{ outputs } 1]|$$

is negligible in the security parameter.

Note that in the $\mathcal{G}_{\text{ideal}}$ game, the simulator receives no information about the input x as it produces the garbled circuit F and all but one of the garbled input components. Finally when producing the last garbled input component, the simulator learns $f(x)$ and its *garbled output encoding* $\text{En}(d, f(x))$. In particular, the simulator receives no information about x , so its outputs carry no information about x beyond $f(x)$. The game also implies an authenticity property for garbled outputs of values other than $f(x)$ — the simulator’s total output contains no information about the rest of the garbled outputs d .

In [Figure 9](#) we describe a generic, random-oracle transformation from a standard (static-secure) garbling scheme to one with this flavor of adaptive security. The construction is quite similar to the transformations in [\[4\]](#), with some small changes. First, since we know in advance which order the adversary will request its garbled inputs, we include the random oracle nonce R in the last garbled input value (rather than secret-sharing across all garbled inputs). Second, since we garble a circuit with particular garbled output values in mind, we provide “translation values” that will map the garbled outputs of the static scheme to the desired ones. These translation values also involve the random oracle, so they can be equivocated by the simulator.

Theorem 7. If $(\text{Gb}, \text{En}, \text{Ev}, \text{De}, \widetilde{\text{De}})$ is a doubly-projective garbling scheme satisfying the (static) prv and aut properties of [\[5\]](#) then the scheme in [Figure 9](#) satisfies adaptive security notion of [Definition 6](#) in the random oracle model.

The proof is very similar to analogous proofs in [\[4\]](#). The main idea is that the simulator can choose the “masked” \widehat{F} and δ translation values upfront. Then it is only with negligible probability that an adversary will call the random oracle on the secret nonce R , so the relevant parts of the oracle are still free to be programmed by the simulator. When the adversary provides the final bit of input, the simulator gets $f(x)$ and can obtain a simulated garbled circuit \widehat{F} and garbled outputs \widehat{d} from the static-secure scheme. Then it can program the random oracle to return the appropriate masks.⁸

$\widehat{\text{Gb}}(f, \widehat{d}):$ $(F, e, d) \leftarrow \text{Gb}(f)$ $R \leftarrow \{0, 1\}^\kappa$ $\text{for each output wire } i:$ $\delta_i^b \leftarrow H(R \parallel \text{out} \parallel i \parallel b \parallel d_i^b) \oplus \widehat{d}_i^b$ $\widehat{F} \leftarrow (F \oplus H(R \parallel \text{gc}), \{\delta_i^b\})$ $\widehat{e} \leftarrow (e_1^0, e_1^1, e_2^0, e_2^1, \dots, e_m^0 \parallel R, e_m^1 \parallel R)$ $\text{return } (\widehat{F}, \widehat{e})$
$\widehat{\text{Ev}}(\widehat{F}, \widehat{X}):$ $\text{parse } \widehat{X}_m \text{ as } X_m \parallel R \text{ and } \widehat{F} \text{ as } (F', \delta)$ $X \leftarrow (\widehat{X}_1, \widehat{X}_2, \dots, X_m)$ $Y \leftarrow \text{Ev}(F' \oplus H(R \parallel \text{gc}), X)$ $y \leftarrow \widetilde{\text{De}}(Y)$ $\text{for each output wire } i:$ $\widehat{Y}_i = \delta_i^{y_i} \oplus H(R \parallel \text{out} \parallel i \parallel y_i \parallel Y_i)$ $\text{return } \widehat{Y}$

Figure 9: Transformation from a static-secure doubly-projective garbling scheme $(\text{Gb}, \text{En}, \text{Ev}, \text{De}, \widetilde{\text{De}})$ to one satisfying [Definition 6](#).

⁸Technically, the proof assumes that the simulator for the static-secure scheme can set the (simulated) garbled input encoding arbitrarily. This is true for common existing schemes; e.g., [\[35\]](#).

Setup stage: On common input $(\text{sid}, \text{SETUP}, f, N, \epsilon)$, where f is a boolean circuit, N is the number of executions. The parties agree on parameters B, \hat{N} derived from [Lemma 1](#). Let $M \in \{0, 1\}^{\mu \times n}$ be a κ_s -probe resistant matrix for each party's input of size n . Let $a \in \{0, 1\}$ denote the role of the current party and $b = a \oplus 1$. Note: the protocol is symmetric where both parties simultaneously play the roles of P_a and P_b .

- **Cut-and-Choose Commit:** P_a chooses at random the cut and choose set $\sigma_a \subset [\hat{N}]$ of size $\hat{N} - NB$. P_a send $(\text{COMMIT}, (\text{sid}, \text{CUT-AND-CHOOSE}, a), \sigma_a)$ to \mathcal{F}_{com} . For $j \in [\hat{N}]$:
 - **OT Init:** P_a sends $(\text{INIT}, (\text{sid}, \text{OT}, a, j))$ to $\mathcal{F}_{\text{rot}}^\mu$ and receives choice bits c_j^a in response.
 - **Send Circuit:** P_a chooses random output wire labels d_j , computes $(F_j^a, e_j) \leftarrow \widehat{\text{Gb}}(f', d_j)$ and sends the F_j^a to P_b where $f'(x_a, r, \tilde{x}_b) = f(x_a, Mr \oplus \tilde{x}_b)$ and r, \tilde{x}_b are P_b 's inputs. Let e_j^a, e_j^b, e_j^r respectively be the labels encoding x_a, \tilde{x}_b, r , for circuit F_j^a and $e_{j,t,h}^*$ index the label of the t^{th} wire with value h in the set e_j^*
 - **Input Commit:** P_a sends the following to \mathcal{F}_{com} :
 - ▶ $(\text{COMMIT}, (\text{sid}, x_a\text{-INPUT}, a, j, t, h), e_{j,t,Mc[t] \oplus h}^a)_{t \in [n], h \in \{0,1\}}$.
 - ▶ $(\text{COMMIT}, (\text{sid}, x_b\text{-INPUT}, a, j, t, h), e_{j,t,h}^b)_{t \in [n], h \in \{0,1\}}$
 - ▶ $(\text{COMMIT}, (\text{sid}, r\text{-INPUT}, a, j, t, h), e_{j,t,h}^r)_{t \in [\mu], h \in \{0,1\}}$
 - **Output Commit:** P_a sends $(\text{COMMIT}, (\text{sid}, \text{OUTPUT}, a, j), d_j)$ to \mathcal{F}_{com} .
- **Cut-and-Choose:** P_b sends $(\text{OPEN}, (\text{sid}, \text{CUT-AND-CHOOSE}, b))$ to \mathcal{F}_{com} and P_a receives σ_b . For $j \in \sigma_b$:
 - **OT Decommit:** P_a sends $(\text{OPEN}, (\text{sid}, \text{OT}, a, j))$ to $\mathcal{F}_{\text{rot}}^\mu$ and P_b receives choice bits c_j^b .
 - **Check Circuit:** P_a sends P_b the d_j and coins used to garble F_j^a . P_b verifies the correctness of F_j^a .
 - **Input Decommit:** Let e_j^a, e_j^b, e_j^r be the verified labels as above.
 - ▶ P_a sends $(\text{OPEN}, (\text{sid}, x_a\text{-INPUT}, a, j, t, h))_{\forall t, h}$ to \mathcal{F}_{com} and P_b receives labels e^a .
 - ▶ P_a sends $(\text{OPEN}, (\text{sid}, x_b\text{-INPUT}, a, j, t, h))_{\forall t, h}$ to \mathcal{F}_{com} and P_b receives labels e^b .
 - ▶ P_a sends $(\text{OPEN}, (\text{sid}, r\text{-INPUT}, a, j, t, h))_{\forall t, h}$ to \mathcal{F}_{com} and P_b receives labels e^r .
 - ▶ If there exists a $e_{j,t,h}^a \neq e_{j,t,Mc[t] \oplus h}^a$, or $e_{j,t,h}^b \neq e_j^b$, or $e_{j,t,h}^r \neq e_j^r$, P_b returns ABORT .
 - **Output:** P_a sends $(\text{OPEN}, (\text{sid}, \text{OUTPUT}, a, j))$ to \mathcal{F}_{com} . P_b receives d' and return ABORT if $d' \neq d_j$.
- **Bucketing:** P_b randomly maps the indices of $[\hat{N}] - \sigma_b$ into sets $\beta_1^a, \dots, \beta_N^a$ s.t. $|\beta_i^a| = B$. For $i \in [N]$:
 - **Bucket Labels:** P_a generates random output labels O_i^a for bucket β_i^a . For $j \in \beta_i^a$, P_a send the output translation $T_j^a := \{O_{i,t,h}^a \oplus d_{j,t,h}\}_{t,h}$ and $H(O_{i,t,h}^a)$ to P_b , where d_j are the output labels of F_j^a .
 - **Offline Inputs:**
 - ▶ P_a sends $(\text{AGGREGATE}, (\text{sid}, \text{OT-AG}, a, i), \{(\text{sid}, \text{OT}, a, j) | j \in \beta_i^a\})$ to $\mathcal{F}_{\text{rot}}^\mu$ and P_b receives the OT aggregation strings δ_j^a for $j \in \beta_i^a$.
 - ▶ P_b sends $(\text{DELIVER}, (\text{sid}, \text{OT-AG}, a, i), \{e_j^r, w_j | j \in \beta_i^a\})$ to $\mathcal{F}_{\text{rot}}^\mu$ where w_j are the decommitment strings to $\{(\text{sid}, r\text{-INPUT}, b, j, t, h)\}_{t,h}$.
 - ▶ For $j \in \beta_i^a$, P_a receives X_j^r and W_j from $\mathcal{F}_{\text{rot}}^\mu$. P_a send $(\text{OPEN}, (\text{sid}, r\text{-INPUT}, b, j, t, c_j^a[t]), W_{j,t})_{\forall t}$ to \mathcal{F}_{com} and receives $X_j'^r$. P_a returns ABORT if $X_j'^r \neq X_j^r$.

Execution stage: On common bucket index i and P_a 's input x_a .

- **Receiver's Inputs:** Let j' be the first index in β_i^a . P_a sends $\tilde{x}_a := x_a \oplus Mc_{j'}^a$ to P_b where $c_{j'}^a$ are the choice bits of $(\text{sid}, \text{OT}, a, j')$. For all $j \in \beta_i^b$:
 - P_b sends $X_j^a := \{e_{j,t,(\tilde{x}_a \oplus M\delta_j^a)[t]}^a\}_t$ and $W_j^a := \{w_{j,t,(\tilde{x}_a \oplus M\delta_j^a)[t]}^a\}_t$ to P_a where e_j^a encodes \tilde{x}_a for F_j^b and w_j are the decommitments string to $\{(\text{sid}, x_a\text{-INPUT}, b, j, t, h)\}_{t,h}$.
 - P_a receives X_j^a, W_j^a and sends $(\text{OPEN}, (\text{sid}, x_a\text{-INPUT}, b, j, t, (x_a \oplus Mc_j^a)[t]), W_{j,t}^a)_{\forall t}$ to \mathcal{F}_{com} and receives $X_j'^a$. P_a returns ABORT if $X_j'^a \neq X_j^a$.
- **Sender's Inputs:** For $j \in \beta_i^b$, P_b sends $(\text{OPEN}, (\text{sid}, x_b\text{-INPUT}, b, j, t, (x_b \oplus Mc_j^b)[t]))_{\forall t}$ to \mathcal{F}_{com} . P_a receives the labels X_j^b . P_a returns ABORT if $\tilde{x}_b \oplus M\delta_j^b \neq (x_b \oplus Mc_j^b)$.
- **Evaluate:** For $j \in \beta_i^b$, let $Y_j := \widehat{\text{Ev}}(F_j^b, (X_j^b, X_j^r, X_j^a))$ with semantic value y_j .
- **PSI Commit:** For $\forall j, t$, if $(H(Y_{j,t}) \neq H(O_{i,t,y_j[t]}^b))$, then $Y_{j,t} \leftarrow \{0, 1\}^{\kappa_c}$. Let $I := \{\bigoplus_t Y_{j,t} \oplus T_{j,t,y_j[t]}^b \oplus O_{i,t,y_j[t]}^a\}_{j \in \beta_i^b}$. P_a pads I to size B with random values and sends $(\text{INPUT}, (\text{sid}, \text{PSI}, i), I)$ to \mathcal{F}_{psi} and receives (INPUT, P_b) .
- **Output Decommit:** For $j \in \beta_i^b$, P_b sends $(\text{OPEN}, (\text{sid}, \text{OUTPUT}, b, j))$ to \mathcal{F}_{com} and P_a receives d'_j .
If there exists j, j' s.t. $d'_{j,t,h} \oplus T_{j,t,h}^b \neq d'_{j',t,h} \oplus T_{j',t,h}^b$, P_a returns ABORT.
- **PSI Decommit:** P_b sends $(\text{OPEN}, (\text{sid}, \text{PSI}, i))$ to \mathcal{F}_{psi} and P_a receives the intersection R . If $|R| \neq 1$, P_a returns CHEATING!, else P_A returns y_j s.t. $I_j \in R$.

Figure 15: Malicious secure online/offline dual-execution 2PC protocol $\Pi_{\text{multi-sfe}}$.

Parameters: A sender P_1 and receiver P_2 .

Setup: On common input S from both parties, for every $s \in S$ choose random $m_0, m_1 \leftarrow \{0, 1\}^{\kappa_c}$ and random $c \leftarrow \{0, 1\}$. Internally store a tuple (s, m_0, m_1, c) .

P_1 output: On input (GET, s) from P_1 , if there is a tuple (s, m_0, m_1, c) for some m_0, m_1, c then give $(OUTPUT, s, m_0, m_1)$ to P_1 .

P_2 output: On input (GET, s) from P_2 , if there is a tuple (s, m_0, m_1, c) for some m_0, m_1, c then give $(OUTPUT, s, c, m_c)$ to P_2 .

Figure 10: Random OT functionality \mathcal{F}_{ot} .

Parameters: A sender P_1 and receiver P_2 .

Commit: On input $(COMMIT, \text{sid}, v)$ from P_1 : If a tuple of the form $(\text{sid}, \cdot, \cdot)$ is stored, then abort. If P_1 is corrupt, then obtain value r from the adversary; otherwise choose $r \leftarrow \{0, 1\}^{\kappa_c}$ and give r to P_1 . Internally store a tuple (sid, r, v) and give $(COMMITTED, \text{sid})$ to P_2 .

Reveal: On input $(OPEN, \text{sid}, r')$ from P_2 : if a tuple (sid, r', v) is stored for some v , then give $(OPENED, \text{sid}, v)$ to P_2 . Otherwise, give $(ERROR, \text{sid})$ to P_2 .

Figure 11: Non-interactive commitment functionality \mathcal{F}_{com} .

Parameters: Two parties: a sender P_1 and receiver P_2 ; $\ell =$ length of items; $n =$ size of parties' sets.

First phase (input commitment): On input $(INPUT, A_i)$ from party P_i ($i \in \{1, 2\}$), with $A_i \subseteq \{0, 1\}^\ell$ and $|A_i| = n$: If this is the first such command from P_i then internally record A_i and send message $(INPUT, P_i)$ to both parties.

Second phase (output): On input $(OUTPUT)$ from P_i , deliver $(OUTPUT, A_1 \cap A_2)$ to the other party.

Figure 12: Two-phase private set intersection (PSI) functionality $\mathcal{F}_{\text{psi}}^{n, \ell}$.

Parameters: Two parties: a sender P_1 and receiver P_2 ; $\ell =$ bit-length of items in the set; $n =$ size of parties' sets; $F =$ a PRF.

Offline phase: Parties perform random OTs, resulting in P_1 holding strings $m_{\{0,1\}}^{i,t} \leftarrow \{0, 1\}^{\kappa_c}$; and P_2 holding c_i and $m_{c_i[t]}^{i,t}$. Here, $c_i \in \{0, 1\}^\ell$ and $i \in [n], t \in [\ell]$.

Input committing phase:

- On input $(INPUT, \{A_{2,1}, \dots, A_{2,n}\})$ to P_2 , P_2 randomly permutes its input and then sends $d_i := A_{2,i} \oplus c_i$ for each $i \in [n]$.
- On input $(INPUT, \{A_{1,1}, \dots, A_{1,n}\})$ for P_1 , P_1 randomly permutes its input and then computes $S_{i,j} = \bigoplus_t F(m_{d_i[t] \oplus A_{1,j}[t]}^{i,t}, j)$ for $i, j \in [n]$.
- P_1 sends $(COMMIT, \text{sid}, (S_{1,1}, \dots, S_{n,n}))$ to \mathcal{F}_{com} .

Output phase: On input $(OUTPUT)$, P_1 sends $(OPEN, \text{sid})$ to \mathcal{F}_{com} and P_2 receives $(OPENED, \text{sid}, (S_{1,1}, \dots, S_{n,n}))$. P_2 then outputs $\{A_{2,i} \mid \exists j : \bigoplus_t F(m_{c_i[t]}^{i,t}, j) = S_{i,j}\}$.

Figure 13: Weakly-malicious-secure, synchronous (3-round), two-phase PSI protocol $\Pi_{\text{sync-psi}}$.

Parameters: Two parties: a sender P_1 and receiver P_2 ; $\ell =$ bit-length of items in the set; $n =$ size of parties' sets; $F =$ a PRF.

Offline phase: Parties perform random OTs, resulting in P_1 holding strings $m_{\{0,1\}}^{i,t} \leftarrow \{0, 1\}^{\kappa_c}$; and P_2 holding c_i and $m_{c_i[t]}^{i,t}$. Here, $c_i \in \{0, 1\}^\ell$ and $i \in [n], t \in [\ell]$.

For $i \in [n]$, P_1 chooses $\pi_i \leftarrow \{0, 1\}^\ell$. Then for $i, j \in [n]$, party P_1 does the following:

- For $t \in \{0, 1\}^\ell$, choose $z_t^{i,j} \leftarrow \{0, 1\}^\ell$ subject to $\bigoplus_t z_t^{i,j} = 0$
- for $t \in [\ell], b \in \{0, 1\}$; P_1 sends $(COMMIT, (\text{sid}, i, j, t, b), F(m_{\pi_j[t] \oplus b}^{i,t}, j) \oplus z_t^{i,j})$ to \mathcal{F}_{com} .

Input committing phase: On input $(INPUT, \{A_{1,1}, \dots, A_{1,n}\})$ for P_1 and $(INPUT, \{A_{2,1}, \dots, A_{2,n}\})$ for P_2 , the parties randomly permute their inputs and asynchronously do:

- P_1 sends $d_{1,j} := A_{1,j} \oplus \pi_j$ for each $j \in [n]$
- P_2 sends $d_{2,i} := A_{2,i} \oplus c_i$ for each $i \in [n]$

Output phase: On input $(OUTPUT)$: for $i, j \in [n]$, $t \in [\ell]$, party P_1 sends $(OPEN, (\text{sid}, i, j, t, d_{1,j}[t] \oplus d_{2,i}[t]))$ to \mathcal{F}_{com} and P_2 expects to receive $(OPENED, (\text{sid}, i, j, t, d_{1,j}[t] \oplus d_{2,i}[t]), \rho_t^{i,j})$.

P_2 outputs $\{A_{2,i} \mid \exists j : \bigoplus_t F(m_{c_i[t]}^{i,t}, j) = \bigoplus_t \rho_t^{i,j}\}$

Figure 14: Weakly-malicious-secure, asynchronous (2-round), two-phase PSI protocol $\Pi_{\text{async-psi}}$.

Abstract

In this paper we explore several contexts where an adversary has an upper hand over the defender by using special hardware in an attack. These include password processing, hard-drive protection, cryptocurrency mining, resource sharing, code obfuscation, etc.

We suggest memory-hard computing as a generic paradigm, where every task is amalgamated with a certain procedure requiring intensive access to RAM both in terms of size and (very importantly) bandwidth, so that transferring the computation to GPU, FPGA, and even ASIC brings little or no cost reduction. Cryptographic schemes that run in this framework become *egalitarian* in the sense that both users and attackers are equal in the price-performance ratio conditions.

Based on existing schemes like Argon2 and the recent generalized-birthday proof-of-work, we suggest a generic framework and two new schemes:

- MTP, a memory-hard Proof-of-Work based on the memory-hard function with fast verification and short proofs. It can be also used for memory-hard time-lock puzzles.
- MHE, the concept of memory-hard encryption, which utilizes available RAM to strengthen the encryption for the low-entropy keys (allowing to bring back 6 letter passwords).

Keywords: MTP, MHE, Argon2, memory-hard, asymmetric, proof-of-work, botnets, encryption, time-lock puzzles.

1 Introduction

1.1 Motivation

Historically attackers have had more resources than defenders, which is still mostly true. Whether it is secret key recovery or document forgery, the attackers are

ready to spend tremendous amount of computing power to achieve the goal. In some settings it is possible to make most attacks infeasible by simply setting the key length to 128 bits and higher. In other settings the secret is limited and the best the defender can do is to increase the time needed for the attack, but not to render the attack impossible.

Passwords, typically stored in a hashed form, are a classical example. As people tend to choose passwords of very low entropy, the security designers added unique salts and then increased the number of hash iterations. In response the attackers switched to dedicated hardware for password cracking, so that the price of single password recovery dropped dramatically, sometimes by a few orders of magnitude.

A similar situation occurred in other contexts. The Bitcoin cryptocurrency relies on continuous preimage search for the SHA-256 hash function, which is much cheaper on custom ASICs, consuming up to 30,000 times less energy per solution than most efficient x86 laptops [2]. Eventually, the original concept of an egalitarian cryptocurrency [25] vanished with the emergence of huge and centralized mining pools.

Related problems include password-based key derivation for hard-drive encryption, where the data confidentiality directly depends on the password entropy, and where offline attack is exceptionally easy once the drive is stolen. Similar situation arise in the resource sharing and spam countermeasures. In the latter it is proposed that every user presents a certain proof (often called proof-of-work), which should be too expensive for spammers to generate on a large scale. Yet another setting is that of code obfuscation, in which powerful reverse-engineering/de-compilation tools can be used in order to lift the proprietary code or secrets embedded in the software.

1.2 Egalitarian computing

Our idea is to remedy the disparity between ordinary users and adversaries/cheaters, where latter could use botnets, GPU, FPGA, ASICs to get an advantage and run a cheaper attack. We call it *egalitarian computing* as it should establish the same price for a single computation unit on all platforms, so that the defender's hardware is optimal both for attack and defence. Equipped with egalitarian crypto schemes, defenders may hope to become to be on par with the most powerful attackers.

The key element of our approach is large (in size) and intensive (in bandwidth) use of RAM as a widely available and rather cheap unit for most defenders. In turn, RAM is rather expensive on FPGA and ASIC¹, and slow on GPU, at least compared to memoryless computing tasks. All our schemes use a lot of memory and a lot of bandwidth — almost as much as possible.

We suggest a single framework for this concept and concrete schemes with an unique combination of features.

In the future, adoption of our concept could allow a homogenization of computing resources, a simplified security analysis, and relaxed security requirements. When all attackers use the same hardware as defenders, automated large-scale attacks are no longer possible. Shorter keys, shorter passwords, faster and more transparent schemes may come back to use.

Related work The idea of extensive memory use in the context of spam countermeasures dates back at least to 2003 [5, 13] and was later refined in [15]. Fast memory-intensive hash functions were proposed first by Percival in 2009 [27] and later among the submissions of the Password Hashing Competition. Memory-intensive proofs-of-work have been studied both in theory [16] and practice [6, 32].

Paper structure We describe the goals of our concept and give a high level overview in Section 2. Then we describe existing applications where this approach is implicitly used: password hashing and cryptocurrency proofs of work (Section 3). We present our own progress-free Proof-of-Work MTP with fast verification, which can also serve as a memory-hard time-lock puzzle, in Section 4. The last Section 5 is devoted to the

¹The memory effect on ASICs can be illustrated as follows. A compact 50-nm DRAM implementation [17] takes 500 mm² per GB, which is equivalent to about 15000 10 MHz SHA-256 cores in the best Bitcoin 40-nm ASICs [1] and is comparable to a CPU size. Therefore, an algorithm requiring 1 GB for 1 minute would have the same AT cost as an algorithm requiring 2⁴² hash function calls, whereas the latter can not finish on a PC even in 1 day. In other words, the use of memory can increase the AT cost by a factor of 1000 and more at the same time cost for the desktop user.

novel concept of memory-hard encryption, where we present our scheme MHE aimed to increase the security of password-based disk encryption.

2 Egalitarian computing as framework

2.1 Goal

Our goal is to alter a certain function \mathcal{H} in order to maximize its computational cost on the most efficient architecture – ASICs, while keeping the running time on the native architecture (typically x86) the same. We ignore the design costs due to nontransparent prices, but instead estimate the running costs by measuring the time-area product [8, 31]. On ASICs the memory size M translates into certain area A . The ASIC running time T is determined by the length of the longest computational chain and by the ASIC memory latency.

Suppose that an attacker wants to compute \mathcal{H} using only a fraction αM of memory for some $\alpha < 1$. Using some tradeoff specific to \mathcal{H} , he has to spend $C(\alpha)$ times as much computation and his running time increases by the factor $D(\alpha)$ (here $C(\alpha)$ may exceed $D(\alpha)$ as the attacker can parallelize the computation). In order to fit the increased computation into time, the attacker has to place $\frac{C(\alpha)}{D(\alpha)}$ additional cores on chip. Therefore, the time-area product changes from AT_1 to AT_α as

$$AT_\alpha = A \cdot (\alpha + \frac{\beta C(\alpha)}{D(\alpha)}) T \cdot D(\alpha) = \\ = AT_1 (\alpha D(\alpha) + C(\alpha)\beta), \quad (1)$$

where β is the fraction of the original memory occupied by a single computing core. If the tradeoff requires significant communication between the computing cores, the memory bandwidth limit Bw_{max} may also increase the running time. In practice we will have $D(\alpha) \geq C(\alpha) \cdot Bw/Bw_{max}$, where Bw is the bandwidth for $\alpha = 1$.

Definition 1 We call function \mathcal{F} memory-hard (w.r.t. M) if any algorithm \mathcal{A} that computes \mathcal{H} using αM memory has the computation-space tradeoff $C(\alpha)$ where $C()$ is at least a superlinear function of $1/\alpha$.

It is known [19] that any function whose computation is interpreted as a directed acyclic graph with T vertices of constant in-degree, can be computed using $O(\frac{T}{\log T})$ space, where the constant in $O()$ depends on the degree. However, for concrete hash functions very few tradeoff strategies have been published, for example [9].

2.2 Framework

Our idea is to combine a certain computation \mathcal{H} with a memory-hard function \mathcal{F} . This can be done by modifying \mathcal{H} using input from \mathcal{F} (*amalgamation*) or by transforming its code to an equivalent one (*obfuscation*).

The **amalgamation** is used as follows. The execution of \mathcal{H} is typically a sequence of smaller steps $H_i, i < T$, which take the output V_{i-1} from the previous step and produce the next output V_i . For our purpose we need another primitive, a memory-hard function \mathcal{F} , which fills the memory with some blocks $X[i], i < T$. We suggest combining \mathcal{H} with \mathcal{F} , for example like:

$$\mathcal{H}' = H'_T \circ H'_{T-1} \circ \cdots \circ H'_1,$$

where

$$H'_i(V_{i-1}) = H(V_{i-1} \oplus X[i-1]).$$

Depending on the application, we may also modify $X[i]$ as a function of V_{i-1} so that it is impossible to precompute \mathcal{F} . The idea is that any computation of \mathcal{H}' should use T blocks of memory, and if someone wants to use less, the memory-hardness property would impose computational penalties on him. This approach will also work well for any code that uses nonces or randomness produced by PRNG. PRNG could then be replaced by (or intermixed with the output of) F .

The **obfuscation** principle works as follows. Consider a compiler producing an assembly code for some function \mathcal{H} . We make it to run a memory-hard function \mathcal{F} on a user-supplied input I (password) and produce certain number of memory blocks. For each if-statement of the form

```
if x then A
else B
```

the compiler computes a *memory-hard bit* b_i which is extracted from the block $X[i]$ (the index can also depend on the statement for randomization) and alters the statement as

```
if x ⊕ bi then A
else B
```

for $b_i = 0$ and

```
if x ⊕ bi then B
else A
```

for $b_i = 1$. This guarantees that the program will have to run \mathcal{F} at least once (the bits b_i can be cached if this if-statement is used multiple times, ex. in a loop).

Accessing the memory block from a random memory location for each conditional statement in practice would slow down the program too much, so compiler can perform a tradeoff depending on the length of the program, the number of conditional statements in it and according to a tunable degree of required memory-hardness for a program. Memory-hard bits could be mixed into opaque predicates or other code obfuscation constructs like code-flattening logic.

We note that in order for a program to run correctly, the user needs to supply correct password for \mathcal{F} , even though the source code of the program is public. A smart decompiler, however, when supplied with the password, can obtain clean version of the program by running \mathcal{F} only once.

Our schemes described in the further text use the amalgamation principle only, so we leave the research directions in obfuscation for future work.

3 Egalitarian computing in applications

In this section we outline several applications, where memory-hard functions are actively used in order to achieve egalitarian computing.

3.1 Password hashing with a memory-hard function

The typical setting for the password hashing is as follows. A user selects a password P and submit it to the authentication server with his identifier U . The server hashes P and unique salt S with some function \mathcal{F} , and stores $(U, S, F(P, S))$ in the password file. The common threat is the password file theft, so that an attacker can try the passwords from his dictionary file D and check if any of them yields the stolen hash. The unique S ensures that the hashes are tried one-by-one.

Following massive password cracking attacks that use special hardware [23, 30], the security community initiated the Password Hashing Competition [3] to select the hash function that withstands the most powerful adversaries. The Argon2 hash function [10] has been recently selected as the winner. We stress that the use of memory-hard function for password hashing does not make the dictionary attacks infeasible, but it makes them much more expensive in terms of the single trial cost.

Definition and properties of Argon2 We use Argon2 in our new schemes described in Sections 4 and 5. Here we outline the key elements of the Argon2 design that are used in our scheme. For more details and their rationale we refer the reader to [10].

Argon2 takes P , S , and possibly some additional data U as inputs. It is parametrized by the memory size M , number of iterations t , and the available parallelism l . It fills M blocks of memory $X[1], X[2], \dots, X[M]$ (1 KB each) and then overwrites them $(t - 1)$ times. Each block $X[i]$ is generated using internal compression function F , which takes $X[i-1]$ and $X[\phi(i)]$ as inputs. For $t = 1$ this works as follows, where H is a cryptographic hash

function (Blake2b).

$$\begin{aligned} X[1] &= H(P, S); \\ X[i] &= F(X[i-1], X[\phi(i)]), i > 1; \\ Out &\rightarrow H(X[M]). \end{aligned} \quad (2)$$

The indexing function $\phi(i)$ is defined separately for each of two versions of Argon2: 2d and 2i. The Argon2d version, which we use, compute it as a function of the previous block $X[i-1]$.

The authors proved [10] that all the blocks are generated distinct assuming certain collision-resistant-like properties of F . They also reported the performance of 0.7 cpb on the Haswell CPU with 4 threads, and 1.6 cpb with 1 thread.

Tradeoff security of Argon2 Using the tradeoff algorithm published in [9], the authors report the values $C(\alpha)$ and $D(\alpha)$ up to $\alpha = 1/7$ with $t = 1$. It appears that $C(\alpha)$ is exponential in α , whereas $D(\alpha)$ is linear.

α	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{4}$	$\frac{1}{5}$	$\frac{1}{6}$	$\frac{1}{7}$
$C(\alpha)$	1.5	4	20.2	344	4660	2^{18}
$D(\alpha)$	1.5	2.8	5.5	10.3	17	27

Table 1: Time and computation penalties for the ranking tradeoff attack for Argon2d.

3.2 Proofs of work

A *proof-of-work scheme* is a challenge-response protocol, where one party (Prover) has to prove (maybe probabilistically) that it has performed a certain amount of computation following a request from another party (Verifier). It typically relies on a computational problem where a solution is assumed to have fixed cost, such as the preimage search in the Bitcoin protocol and other cryptocurrencies. Other applications may include spam protection, where a proof-of-work is a certificate that is easy to produce for ordinary sender, but hard to generate in large quantities given a botnet (or more sophisticated platform).

The proof-of-work algorithm must have a few properties to be suitable for cryptocurrencies:

- It must be *amortization-free*, i.e. producing q outputs for \mathcal{B} should be q times as expensive;
- The solution must be *short* enough and verified quickly using *little memory* in order to prevent DoS attacks on the verifier.

- The time-space tradeoffs must be *steep* to prevent any price-performance reduction.
- The time and memory parameters must be *tunable independently* to sustain constant mining rate.
- To avoid a clever prover getting advantage over the others the advertised algorithm must be the most efficient algorithm to date (*optimization-freeness*).
- The algorithm must be *progress-free* to prevent centralization: the mining process must be stochastic so that the probability to find a solution grows steadily with time and is non-zero for small time periods.
- Parallelized implementations must be limited by the memory bandwidth.

As demonstrated in [11], almost any hard problem can be turned into a proof-of-work, even though it is difficult to fulfill all these properties. The well-known hard and NP-complete problems are natural candidates, since the best algorithms for them run in (sub)exponential time, whereas the verification is polynomial. The proof-of-work scheme Equihash [11] is built on the *generalized-birthday*, or k -XOR, problem, which looks for a set of n -bit strings that XOR to zero. The best existing algorithm is due to Wagner [34]. This problem is particularly interesting, as the time-space tradeoff steepness can be adjusted by changing k , which does not hold, e.g., in hard knapsacks.

Drawbacks of existing PoW We briefly discuss existing alternatives here. The first PoW schemes by Dwork and Naor [14] were just computational problems with fast verification such as the square root computation, which do not require large memory explicitly. The simplest scheme of this kind is Hashcash [7], where a partial preimage to a cryptographic hash function is found (the so called *difficulty test*). Large memory comes into play in [13], where a random array is shared between the prover and the verifier thus allowing only large-memory verifiers. This condition was relaxed in [15], where superconcentrators [28] are used to generate the array, but the verifier must still hold large memory in the initialization phase. Superconcentrators were later used in the Proof-of-Space construction [16], which allows fast verification. However, the scheme [16] if combined with the difficulty test is vulnerable to cheating (see Section 4.4 for more details) and thus can not be converted to a progress-free PoW. We note that the superconcentrators make both [15] and [16] very slow.

Ad-hoc but faster schemes started with scrypt [27], but fast verification is possible only with rather low

amount of memory. Using more memory (say, using Argon2 [10]) with a difficulty test but verifying only a subset of memory is prone to cheating as well (Section 4.4).

The scheme [11] is quite promising, but the reference implementation reported is quite slow, as it takes about 30 seconds to get a proof that certifies the memory allocation of 500 MB. As a result, the algorithm is not truly progress-free: the probability that the solution is found within the first few seconds is actually zero. It can be argued that this would stimulate centralization among the miners. In addition, the memory parameter does not have sufficient granularity and there is no correlation between the allocated memory and the minimal time needed to find the proof.

Finally, we mention schemes Momentum [21] and Cuckoo cycle [32], which provide fast verification due to their combinatorial nature. They rely on the memory requirements for the collision search (Momentum) or graph cycle finding (Cuckoo). However, Momentum is vulnerable to a sublinear time-space tradeoff [11], whereas the first version of the Cuckoo scheme was recently broken in [6].

We summarize the properties of the existing proof-of-work constructions in Table 2. The AT cost is estimated for the parameters that enable 1-second generation time on a PC.

4 MTP: Proofs of work and time-lock puzzles based on memory-hard function

In this section we present a novel proof-of-work algorithm MTP (for Merkle Tree Proof) with fast verification, which in particular solves the progress-free problem of [11]. Our approach is based on the memory-hard function, and the concrete proposal involves Argon2.

Since fast memory-hard functions \mathcal{F} such as Argon2 perform a lengthy chain of computations, but do not solve any NP-like problem, it is not fast to verify that Y is the output of F . Checking some specific (say, last) blocks does not help, as explained in detail in the further text. We thus have to design a scheme that lower bounds the time-area product for the attacker, even if he computes a slightly modified function.

4.1 Description of MTP

Consider a memory-hard function \mathcal{F} that satisfies Equation (2) (for instance, Argon2) with a single pass over the memory producing T blocks and a cryptographic hash function H (possibly used in \mathcal{F}). We propose the following non-interactive protocol for the Prover (Figure 1) in Algorithm 1, where L and d are security parameters. The average number of calls to F is $T + 2^d L$.

Algorithm 1 MTP: Merkle-tree based Proof-of-Work. Prover's algorithm

Input: Challenge I , parameters L, d .

1. Compute $\mathcal{F}(I)$ and store its T blocks $X[1], X[2], \dots, X[T]$ in the memory.
2. Compute the root Φ of the Merkle hash tree (see Appendix A).
3. Select nonce N .
4. Compute $Y_0 = H(\Phi, N)$ where G is a cryptographic hash function.
5. For $1 \leq j \leq L$:

$$i_j = Y_{j-1} \pmod{T}; \\ Y_j = H(Y_{j-1}, X[i_j]).$$

6. If Y_L has d trailing zeros, then (Φ, N, \mathcal{Z}) is the proof-of-work, where \mathcal{Z} is the opening of $2L$ blocks $\{X[i_j - 1], X[\phi(i_j)]\}$. Otherwise go to Step 3.

Output: Proof (Φ, N, \mathcal{Z}) .

The verifier, equipped with \mathcal{F} and H , runs Algorithm 2.

Algorithm 2 MTP: Verifier's algorithm

Input: Proof (Φ, N, \mathcal{Z}) , parameters L, d .

1. Compute $Y_0 = H(\Phi, N)$.
2. Verify all block openings using Φ .
3. Compute from \mathcal{Z} for $1 \leq j \leq L$:

$$X[i_j] = F(X[i_j - 1], X[\phi(i_j)]); \\ Y_j = G(Y_{j-1}, X[i_j]).$$

4. Check whether Y_L has t trailing zeros.

Output: Yes/No.

4.2 Cheating strategies

Let the computation-space tradeoff for \mathcal{H} and the default memory value T be given by functions $C(\alpha)$ and $D(\alpha)$ (Section 2).

Memory savings Suppose that a cheating prover wants to reduce the AT cost by using αT memory for some $\alpha < 1$. First, he computes $\mathcal{F}(I)$ and Φ , making $C(\alpha)T$

Scheme	AT cost	Speed	Verification		Tradeoff	Paral-sm	Progress -free
			Fast	M/less			
Dwork-Naor I [14]	Low	High	Yes	Yes	Memoryless	Yes	Yes
Dwork-Naor II [13]	High	Low	Yes	No	Memoryless	Constr.	Yes
Dwork-Naor III [15]	Medium	Low	Yes	No	Exponential	Constr.	Yes
Hashcash/Bitcoin [7]	Low	High	Yes	Yes	Memoryless	Yes	Yes
Pr.-of-Space [16]+Diff.test	High	Low	Yes	Yes	Exponential	No	No
Litecoin	Medium	High	Yes	Yes	Linear	No	Yes
Argon2-1GB + Diff.test	High	High	No	No	Exponential	No	Yes
Momentum [21]	Medium	High	Yes	Yes	Attack [11, 33]	Yes	Yes
Cuckoo cycle [32]	Medium [6]	Medium	Yes	Yes	Linear [6]	Yes	Yes
Equihash [11]	High	Medium	Yes	Yes	Exponential	Constr.	Yes
MTP	High	High	Yes	Yes	Exponential	Constr.	Yes

Table 2: Review of existing proofs of work. Litecoin utilizes scrypt with 128KB of RAM followed by the difficulty test). M/less – memoryless; constr. – constrained.

calls to F . Then for each N he has to get or recompute L blocks using only αT stored blocks. The complexity of this step is equal to the complexity of recomputing random L blocks during the first computation of \mathcal{F} . A random block is recomputed by a tree of average size $C(\alpha)$ and depth $D(\alpha)$. Therefore, to compute the proof-of-work, a memory-saving prover has to make $C(\alpha)(T + 2^d L)$ calls to F , so his amount of work grows by $C(\alpha)$.

Block modification The second cheating strategy is to compute a different function $\mathcal{F}' \neq \mathcal{F}$. More precisely, the cheater produces some blocks $X[i']$ (which we call *inconsistent* as in [16]) not as specified by Equation (2) (e.g. by simply computing $X[i'] = H(i')$). In contrast to the verifiable computation approach, our protocol allows a certain number of inconsistent blocks. Suppose that the number of inconsistent blocks is εT , then the chance that no inconsistent block is detected by L opened blocks is

$$\gamma = (1 - \varepsilon)^L.$$

Therefore, the probability for a proof-of-work with εM inconsistent blocks to pass the opening test is γ . In other words, the cheater's time is increased by the factor $1/\gamma$. We note that it does not make sense to alter the blocks after the Merkle tree computation, as any modified block would fail the opening test.

Overall cheating penalties Let us accumulate the two cheating strategies into one. Suppose that a cheater

stores αT blocks and additionally allows εT inconsistent blocks. Then he makes at least

$$\frac{C(\alpha + \varepsilon)(T + 2^d L)}{\gamma} \quad (3)$$

calls to F . The concrete values are determined by the penalty function $C()$, which depends on \mathcal{F} .

4.3 Parallelism

Both honest prover and cheater can parallelize the computation for 2^t different nonces. However, the latency of cheater's computation will be higher, since each block generates a recomputation tree of average depth $D(\alpha + \varepsilon)$.

4.4 Why simpler approach does not work: grinding attack

Now we can explain in more details why the composition of \mathcal{F} and the difficulty test is not a good proof-of-work even if some internal blocks of \mathcal{H} are opened. Suppose that the proof is accepted if $H(X[T])$ has certain number d of trailing zeros. One would expect that a prover has to try 2^d distinct I on average and thus call \mathcal{F} 2^t times to find a solution. However, a cheating prover can simply try 2^d values for $X[T]$ and find one that passes the test in just 2^d calls to H . Although $X[T]$ is now inconsistent, it is unlikely to be selected among L blocks to open, so the cheater escapes detection easily. Additionally checking $X[T]$ would not resolve the problem since a cheater

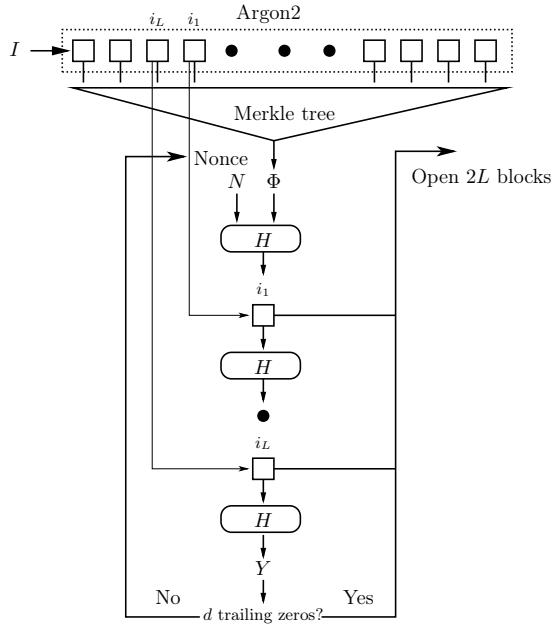

Figure 1: MTP: Merkle-tree based Proof-of-Work with light verification.

would then modify the previous block, or $X[\phi(T)]$, or an earlier block and then propagate the changes. A single inconsistent block is just too difficult to catch².

4.5 MTP-Argon2

As a concrete application, we suggest a cryptocurrency proof-of-work based on Argon2d with 4 parallel lanes. We aim to make this PoW unattractive for botnets, so we suggest using 2 GB of RAM, which is very noticeable (and thus would likely alarm the user), while being bearable for the regular user, who consciously decided to use his desktop for mining. On our 1.8 GHz machine a single call to 2-GB Argon2d runs in 0.5 seconds, but the Merkle tree computation is more expensive, as we have to hash 2 GB of data splitted into 1 KB blocks. We suggest using Blake2b for H , as it is already used in Argon2d, but restrict to 128-bit output, so that the total running time is about 3 seconds. In this case a single opening has $16 \cdot 21$ bytes of hashes, or 1.3 KB in total.

We suggest $L = 70$, so that the entire proof consists of 140 blocks and their openings, or 180 KB in total. Let us figure out the cheating advantage. The $C()$ and $D()$ functions are given in Table 1). Assuming certain ratio between the area needed to implement Blake2b and

²We have not seen any formal treatment of this attack in the literature, but it appears to be known in the community. It is mentioned in [26] and [4].

the area needed for DRAM, we get the following lower bound on the ASIC-equipped cheater.

Proposition 1 For $L = 70$ and 2 GB of RAM the time-area product can be reduced by the factor of 12 at most, assuming that each Blake2b core occupies an equivalent of 2^{16} bytes.

Proof. Assuming that each core occupies 2^{16} bytes, we obtain $\beta = 2^{-15}$ in terms of Equation (1). Since the cheater has the success chance $\gamma = (1 - \varepsilon)^L$, Equation (1) is modified as follows:

$$AT_\alpha = AT_1 \frac{\alpha D(\alpha + \varepsilon) + C(\alpha + \varepsilon)/2^{15}}{(1 - \varepsilon)^L}. \quad (4)$$

Consider three options:

- $\alpha, \varepsilon < 1/12$. Then $C(\alpha + \varepsilon) \geq 4660$ (Table 1) and we have

$$AT_\alpha \geq AT_1 \cdot \frac{4660}{32768} \geq AT_1 \cdot 0.12.$$

- $\alpha < 1/12, 1/6 \geq \varepsilon > 1/12$. Then $C(\alpha + \varepsilon) \geq 20$, $(1 - \varepsilon)^L > 1/441$, and we have

$$AT_\alpha \geq AT_1 \cdot \frac{20 \cdot 441}{32768} \geq AT_1 \cdot 0.27.$$

- $\alpha < 1/12, 1/6 \leq \varepsilon$. Then $(1 - \varepsilon)^L > 2^{15}$, and the time-area product increases.
- $\alpha > 1/12$. Then $AT_\alpha \geq AT_1 \cdot 1/12$.

This ends the proof.

We conclude that a cheater can gain at most 12x-advantage, whereas he can still be detected in the future by memory-rich verifiers. Tradeoffs are also not helpful when implementing this Proof-of-Work on ASIC. Altogether, our proposal should reduce the relative efficiency of potential ASIC mining rigs and allow more egalitarian mining process. Even if someone decides to use large botnets (10,000 machines and more), all the botnets machines would have to use the same 2 GB of memory, otherwise they would suffer large penalty. We note that if $\varepsilon = 0$, i.e. the prover is honest, then his maximal advantage is $\max \frac{1}{\alpha D(\alpha)} \leq 2$.

4.6 MTP as a tool for time-lock puzzles and timestamping

The paradigm of inherently sequential computation was developed by [12] in the application to CPU benchmarking and [29] for timestamping, i.e. to certify that the document was generated certain amount of time in the past. Rivest et al. suggested *time-lock puzzles* for this purpose.

In our context, a time-lock puzzle solution is a proof-of-work that has lower bound on the running time assuming unlimited parallelism.

The verifier in [20, 29] selects a prime product $N = pq$ and asks the prover to compute the exponent $2^{2^D} \pmod{N}$ for some $D \approx N$. It is conjectured that the prover who does not know the factors can not exponentiate faster than do D consecutive squarings. In turn, the verifier can verify the solution by computing the exponent 2^D modulo $\phi(N)$, which takes $\log(D)$ time. So far the conjecture has not been refuted, but the scheme inherently requires a secret held by the verifier, and thus is not suitable for proofs-of-work without secrets, as in cryptocurrencies.

Time-lock puzzles without secrets were suggested by Mahmoody et al. [22]. Their construction is a graph of hash computations, which is based on depth-robust graphs similarly to [16]. The puzzle is a deterministic graph such that removing any constant fraction of nodes keeps its depth above the constant fraction of the original one (so the parallel computation time is lower bounded). A Merkle tree is put atop of it with its root determining a small number of nodes to open. Therefore, a cheater who wants to compute the graph in less time has to subvert too many nodes and is likely to be caught. As [16], the construction by Mahmoody et al., if combined with the difficulty filter, is subject to the grinding attack described above.

The MTP-Argon2 construction can be viewed as a time-lock puzzle and an improvement over these schemes. First, the difficulty filter is explicitly based on the grinding attack, which makes it a legitimate way to solve the puzzle. Secondly, it is much faster due to high speed of Argon2d. The time-lock property comes from the fact that the computation chain can not be parallelized as the graph structure is not known before the computation.

Suppose that MTP-Argon2 is parallelized by the additional factor of R so that each core computes a chain of length about T/R . Let core j compute j -th (out of R) chain, chronologically. Then at step i each core has computed i blocks and has not computed $T/R - i$ blocks, so the probability that core j requests a block that has not been computed is

$$\frac{(j-1)(T/R-i)}{(j-1)T/R+i} \leq \frac{(j-1)(T/R-i)}{jT/R}.$$

Summing by all i , we obtain that core j misses at least $\frac{T(1-1/j)}{2R}$, so the total fraction of inconsistent blocks is about $0.5 - \frac{\ln R}{2R}$. Therefore, ϵ quickly approaches 0.5, which is easily detectable. We thus conclude that a parallel implementation of MTP-Argon2 is likely to fail the Merkle tree verification.

5 Memory-hard encryption on low-entropy keys

5.1 Motivation

In this section we approach standard encryption from the memory-hardness perspective. A typical approach to hard-drive encryption is to derive the master key from the user password and then use it to encrypt chunks of data in a certain mode of operation such as XTS [24]. The major threat, as to other password-based security schemes, are low-entropy passwords. An attacker, who gets access to the hard drive encrypted with such password, can determine the correct key and then decrypt within short time.

A countermeasure could be to use a memory-hard function for the key derivation, so that the trial keys can be produced only on memory-rich machines. However, the trial decryption could still be performed on special memoryless hardware given these keys. We suggest a more robust scheme which covers this type of adversaries and eventually requires that the entire attack code have permanent access to large memory.

5.2 Requirements

We assume the following setting, which is inspired by typical disk-encryption applications. The data consists of multiple chunks $Q \in \mathcal{Q}$, which can be encrypted and decrypted independently. The only secret that is available to the encryption scheme \mathcal{E} is the user-input password $P \in \mathcal{P}$, which has sufficiently low entropy to be memorized (e.g., 6 lowercase symbols). The encryption syntax is then as follows:

$$\mathcal{E} : \mathcal{P} \times \mathcal{S} \times \mathcal{Q} \rightarrow \mathcal{C},$$

where $S \in \mathcal{S}$ is associated data, which may contain salt, encryption nonce or IV, chunk identifier, time, and other secondary input; and $C \in \mathcal{C}$ is ciphertext. S serves both to simplify ciphertext identification (as it is public) and to ensure certain cryptographic properties. For instance, unique salt or nonce prevents repetition of ciphertexts for identical plaintexts. We note that in some settings due to storage restriction the latter requirement can be dropped. Decryption then is naturally defined and we omit its formal syntax.

In our proposal we do not restrict the chunk size. Even though it can be defined for chunks as small as disk sectors, the resistance to cracking attacks will be higher for larger chunks, up to a megabyte long.

A typical attack setting is as follows. An attacker obtains the encrypted data via some malicious channel or installs malware and then tries different passwords to decrypt it. For the sake of simplicity, we assume that the

plaintext contains sufficient redundancy so that a successful guess can be identified easily. Therefore, the adversary tries D passwords from his dictionary $\mathcal{D} \subset \mathcal{P}$. Let T be the time needed for the fastest decryption operation that provides partial knowledge of plaintext sufficient to discard or remember the password, and A_0 be the chip area needed to implement this operation. Then the total amount of work performed by the adversary is

$$W = D \cdot T \cdot A_0.$$

At the same time, the time to encrypt T' for a typical user should not be far larger than T . Our goal is to maximize W with keeping T' the same or smaller.

The memory-hard functions seem to serve perfectly for the purpose of maximizing W . However, it remains unclear how to combine such function \mathcal{F} with \mathcal{E} to get *memory-hard encryption* (MHE).

Now we formulate some additional features that should be desirable for such a scheme:

- The user should be able to choose the requested memory size A independently of the chunk length $|Q|$. Whereas the chunk length can be primarily determined by the CPU cache size, desirable processing speed, or the hard drive properties, the memory size determines the scheme’s resistance to cracking attacks.
- The memory can be allocated independently for each chunk or reused. In the former case the user can not allocate too much memory as the massive decryption would be too expensive. However, for the amounts of memory comparable to the chunk size the memory-hard decryption should take roughly as much as memoryless decryption. If the allocated memory is reused for distinct chunks, much more memory can be allocated as the allocation time can be amortized. However, the decryption latency would be quite high. We present both options in the further text.
- Full ciphertext must be processed to decrypt a single byte. This property clearly makes T larger since the adversary would have to process an entire chunk to check the password. At the same time, for disk encryption it should be fine to decrypt in the “all-or-nothing” fashion, as the decryption time would still be smaller than the user could wait.
- Encryption should be done in one pass over data. It might sound desirable that the decryption should be done in one pass too. However, this would contradict the previous requirement. Indeed, if the decryption can be done in one pass, then the first bytes

of the plaintext can be determined without the last bytes of the ciphertext³.

- Apart from the memory parameter, the total time needed to allocate this memory should be tunable too. It might happen that the application does not have sufficient memory but does have time. In this case, the adversary can be slowed down by making several passes over the memory during its initialization (the memory-hard function that we consider support this feature).

Our next and final requirement comes from adversary’s side. When the malware is used, the incoming network connection and memory for this malware can be limited. Thus, it would be ideal for the attacker if the memory-intensive part can be delegated to large machines under attacker’s control, such as botnets. If we just derived the secret-key K for encryption as the output of the memory-hard hash function \mathcal{F} , this would be exactly this case. An adversary would then run \mathcal{F} for dictionary D on his own machine, produce the set \mathcal{K} of keys, and supply them to malware (recall that due to low entropy there would be only a handful of these keys). Thus the final requirement should be the following:

- During decryption, it should be impossible to delegate the entire memory-hard computation to the external device without accessing the ciphertext. Therefore, there could be no memory-hard precomputation.

5.3 Our scheme

Our scheme is based on a recent proposal by Zaverucha [35], who addresses similar properties in the scheme based on Rivest’s All-or-Nothing transform (ANT). However, the scheme in [35] does not use an external memory-hard function, which makes it memory requirements inevitably bound to the chunk size. Small chunks but large memory is impossible in [35].

Our proposal is again based on the All-or-Nothing transformation, though we expect that similar properties can be obtained with deterministic authenticated encryption scheme as a core primitive. The chunk length q (measured in blocks using by \mathcal{F}) and memory size $M \geq q$ are the parameters as well as some blockcipher E (possibly AES). First, we outline the scheme where the memory is allocated separately for each chunk. The reader may also refer to Figure 2.

The underlying idea is to use both the header and the body blocks to produce the ciphertext. In turn, to recompute the body blocks both the ciphertext and the header must be available during trial decryption.

³The similar argument is made for the online authenticated ciphers

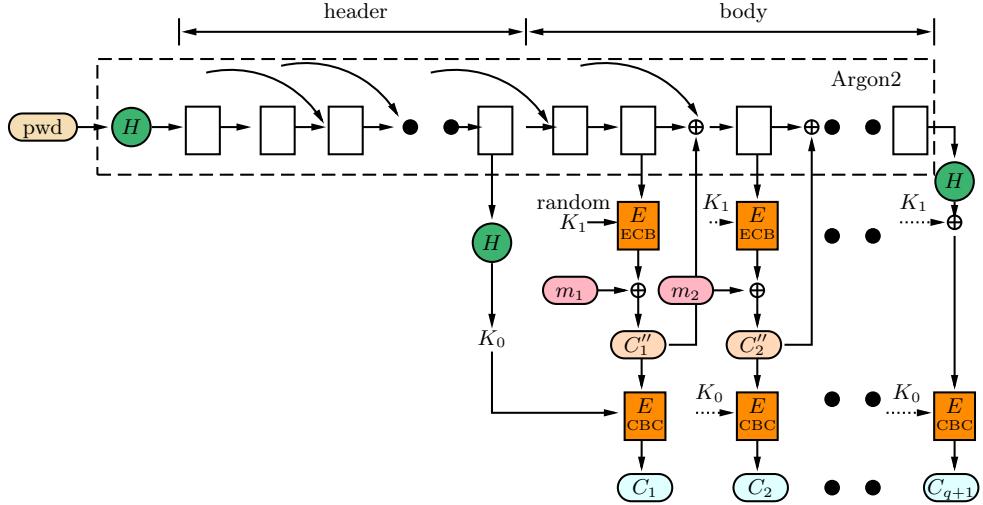

Figure 2: MHE: Disk encryption using memory-hard function Argon2.

The version of the MHE scheme which allocates the same memory for multiple chunks is very similar. The S input is ignored at the beginning, so that the header memory blocks do not depend on the data. Instead, we set $K_0 = H(X_0, S)$, so that the body blocks are affected by S and M , and thus are different for every chunk. In this case the body blocks have to be stored separately and should not overwrite the header blocks for $t > 1$.

Let us verify that the scheme in Algorithm 3 satisfies the properties we listed earlier:

- The allocated memory size M can be chosen independently of the chunk length q (as long as $M > q$).
- The body memory blocks are allocated and processed for each chunk independently. In addition, the header blocks are also processed independently for each chunk in the single-chunk version.
- In order to decrypt a single byte of the ciphertext, an adversary would have to obtain K_1 , which can be done only by running \mathcal{F} up to the final block, which requires all C''_i , which are in turn must be derived from the ciphertext blocks.
- Encryption needs one pass over data, and decryption needs two passes over data.
- The total time needed to allocate and fill the header is tunable.
- The computation of the body memory blocks during decryption can not be delegated, as it requires knowledge both of the header and the ciphertext. It

in [18].

might be possible to generate the header on an external machine, but then random access to its blocks to decrypt the ciphertext is required.

We note that properties 1, 5, and 6 are not present in [35].

Security First, we address traditional CPA security. We do not outline the full proof here, just the basic steps. We assume that the adversary does not have access to the internals of Argon2, and that blockcipher E is a secure PRF. Next, we assume collision-resistance of the compression function F used in \mathcal{F} . Given that, we prove that all the memory blocks are distinct, which yields the CPA security for C' . From the latter we deduce the CPA security for the final ciphertext. We note that in the case when the collision-resistance of F can not be guaranteed, we may additionally require that X_i undergo hashing by a cryptographic hash function H' before encryption, so that the plaintext blocks are still distinct. All these properties hold up to the birthday bound of the blockcipher.

Next, we figure out the tradeoff security. The genuine decrypting user is supposed to spend M memory blocks for \mathcal{F} and q memory blocks to store the plaintext and intermediate variables (if the ciphertext can be overwritten, then these q blocks are not needed). Suppose that an adversary wants to use αM memory for header and body. Then each missing block, if asked during decryption, must be recomputed making $C(\alpha)$ calls to F . The best such strategy for Argon2, described in [9], yields $C(\alpha)$ that grows exponentially in $1/\alpha$. For example, using $1/5$ of memory, an adversary would have to make 344 times as many calls to F , which makes a memory-reducing encryption cracking inefficient even on special hardware.

Algorithm 3 Memory-hard encryption with independent memory allocation (for each chunk).

Input: Password P , memory size M , associated data S , chunk Q , number of iterations t , memory-hard function \mathcal{F} (preferably Argon2), blockcipher E , cryptographic hash function H (e.g. SHA-3).

1. Run \mathcal{F} on (P, S) with input parameters M and t but fill only $M - q$ blocks (the *header*) in the last iteration. Let X_0 be the last memory block produced by \mathcal{F} .
2. Produce $K_0 = H(X_0)$ — the first session key.
3. Generate a random session key K_1 .
4. Generate the remaining blocks X_1, X_2, \dots, X_q (*body*) for \mathcal{F} as follows. We assume that each chunk M consists of smaller blocks m_1, m_2, \dots, m_q of length equal to the block size of \mathcal{F} . For each $i \geq 1$:
 - Encrypt X_{i-1} by E in the ECB mode under K_1 and get the intermediate ciphertext block C'_i .
 - Add the chunk data: $C''_i = C'_i \oplus m_i$.
 - Encrypt C''_i under K_0 in the CBC mode and produce the final ciphertext block C_i .
 - Modify the memory: $X_{i-1} \leftarrow X_{i-1} \oplus C''_i$.
 - Generate the block X_i according to the specification of \mathcal{F} . In Argon2, the modified X_{i-1} and some another block $X[\phi(X_{i-1})]$ would be used.
5. After the entire chunk is encrypted, encrypt also the key K_1 :

$$C_{t+1} = E_{K_0}(H(X_t) \oplus K_1).$$

Output: C_1, \dots, C_{t+1} .

Performance We suggest taking $l = 4$ in Argon2 in order to fill the header faster using multiple cores, which reportedly takes 0.7 cpb (about the speed of AES-GCM and AES-XTS). The body has to be filled sequentially as the encryption process is sequential. As AES-CBC is about 1.3 cpb, and we use two of it, the body phase should run at about 4 cpb. In a concrete setting, suppose that we tolerate 0.1 second decryption time (about 300 Mcycles) for the 1-MB chunk. Then we can take the header as large as 256 MB, as it would be processed in 170 Mcycles + 4 Mcycles for the body phase.

6 Conclusion

We have introduced the new paradigm of egalitarian computing, which suggests amalgamating arbitrary computation with a memory-hard function to enhance the security against off-line adversaries equipped with powerful tools (in particular with optimized hardware). We have reviewed password hashing and proofs of work as applications where such schemes are already in use or are planned to be used. We then introduce two more schemes in this framework. The first one is MTP, the progress-free proof-of-work scheme with fast verification based on the memory-hard function Argon2, the winner of the Password Hashing Competition. The second scheme pioneers the memory-hard encryption — the security enhancement for password-based disk encryption, also based on Argon2.

A Merkle hash trees

We use Merkle hash trees in the following form. A prover P commits to T blocks $X[1], X[2], \dots, X[T]$ by computing the hash tree where the blocks $X[i]$ are at leaves at depth $\log T$ and nodes compute hashes of their branches. For instance, for $T = 4$ and hash function G prover P computes and publishes

$$\Phi = G(G(X[1], X[2]), G(X[3], X[4])).$$

Prover stores all blocks and all intermediate hashes. In order to prove that he knows, say, $X[5]$ for $T = 8$, (or to *open* it) he discloses the hashes needed to reconstruct the path from $X[5]$ to Φ :

$$\begin{aligned} \text{open}(X[5]) &= (X[5], X[6], g_{78} = G(X[7], X[8])), \\ &\quad g_{1234} = G(G(X[1], X[2]), G(X[3], X[4])), \Phi), \end{aligned}$$

so that the verifier can make all the computations. If G is collision-resistant, it is hard to open any block in more than one possible way.

Post-quantum key exchange – a new hope*

Abstract

At IEEE Security & Privacy 2015, Bos, Costello, Naehrig, and Stebila proposed an instantiation of Peikert’s ring-learning-with-errors-based (Ring-LWE) key-exchange protocol (PQCrypto 2014), together with an implementation integrated into OpenSSL, with the affirmed goal of providing post-quantum security for TLS. In this work we revisit their instantiation and stand-alone implementation. Specifically, we propose new parameters and a better suited error distribution, analyze the scheme’s hardness against attacks by quantum computers in a conservative way, introduce a new and more efficient error-reconciliation mechanism, and propose a defense against backdoors and all-for-the-price-of-one attacks. By these measures and for the same lattice dimension, we more than double the security parameter, halve the communication overhead, and speed up computation by more than a factor of 8 in a portable C implementation and by more than a factor of 27 in an optimized implementation targeting current Intel CPUs. These speedups are achieved with comprehensive protection against timing attacks.

1 Introduction

The last decade in cryptography has seen the birth of numerous constructions of cryptosystems based on lattice problems, achieving functionalities that were previously unreachable (e.g., fully homomorphic cryptogra-

phy [38]). But even for the simplest tasks in asymmetric cryptography, namely public-key encryption, signatures, and key exchange, lattice-based cryptography offers an important feature: resistance to all known quantum algorithms. In those times of *quantum nervousness* [73, 74], the time has come for the community to deliver and optimize concrete schemes, and to get involved in the standardization of a lattice-based cipher-suite via an open process.

For encryption and signatures, several competitive schemes have been proposed; examples are NTRU encryption [50, 83], Ring-LWE encryption [67] as well as the signature schemes BLISS [31], PASS [48] or the proposal by Bai and Galbraith presented in [8]. To complete the lattice-based cipher-suite, Bos et al. [20] recently proposed a concrete instantiation of the key-exchange scheme of Peikert’s improved version of the original protocol of Ding, Xie and Lin [52, 77]. Bos et al. proved its practicality by integrating their implementation as additional cipher-suite into the transport layer security (TLS) protocol in OpenSSL. In the following we will refer to this proposal as BCNS.

Unfortunately, the performance of BCNS seemed rather disappointing. We identify two main sources for this inefficiency. First the analysis of the failure probability was far from tight, resulting in a very large modulus $q \approx 2^{32}$. As a side effect, the security is also significantly lower than what one could achieve with Ring-LWE for a ring of rank $n = 1024$. Second the Gaussian sampler, used to generate the secret parameters, is fairly inefficient and hard to protect against timing attacks. This second source of inefficiency stems from the fundamental misconception that high-quality Gaussian noise is crucial for encryption based on LWE¹, which has also made various other implementations [29, 79] slower and more complex than they would have to be.

*This work was initiated while Thomas Pöppelmann was a Ph.D. student at Ruhr-University Bochum with support from the European Union H2020 SAFCrypto project (grant no. 644729). This work has furthermore been supported by TÜBITAK under 2214-A Doctoral Research Program Grant, by the European Commission through the ICT program under contract ICT-645622 (PQCRIPTO), and by the Netherlands Organisation for Scientific Research (NWO) through Veni 2013 project 13114 and through a Free Competition Grant. ¹This is very different for lattice-based signatures or trapdoors, where distributions need to be meticulously crafted to prevent any leak of information on a secret basis.

1.1 Contributions

In this work, we propose solutions to the performance and security issues of the aforementioned BCNS proposal [20]. Our improvements are possible through a combination of multiple contributions:

- Our first contribution is an improved analysis of the failure probability of the protocol. To push the scheme even further, inspired by analog error-correcting codes, we make use of the lattice D_4 to allow error reconciliation beyond the original bounds of [77]. This drastically decreases the modulus to $q = 12289 < 2^{14}$, which improves both efficiency and security.
- Our second contribution is a more detailed security analysis against quantum attacks. We provide a lower bound on all known (or even pre-supposed) quantum algorithms solving the shortest-vector problem (SVP), and deduce the potential performance of a quantum BKZ algorithm. According to this analysis, our improved proposal provides 128 bits of post-quantum security with a comfortable margin.
- We furthermore propose to replace the almost-perfect discrete Gaussian distribution by something relatively close, but much easier to sample, and prove that this can only affect the security marginally.
- We replace the fixed parameter \mathbf{a} of the original scheme by a freshly chosen random one in each key exchange. This incurs an acceptable overhead but prevents backdoors embedded in the choice of this parameter and all-for-the-price-of-one attacks.
- We specify an encoding of polynomials in the number-theoretic transform (NTT) domain which allows us to eliminate some of the NTT transformations inside the protocol computation.
- To demonstrate the applicability and performance of our design we provide a portable reference implementation written in C and a highly optimized vectorized implementation that targets recent Intel CPUs and is compatible with recent AMD CPUs. We describe an efficient approach to lazy reduction inside the NTT, which is based on a combination of Montgomery reductions and short Barrett reductions.

Availability of software. We place all software described in this paper into the public domain and make it available online at <https://cryptojedi.org/papers/#newhope>.

org/crypto/#newhope and <https://github.com/troeppelmann/newhope>.

Full version of the paper. The full version of this paper contains various appendices in addition to the material presented in this proceedings version. The full version is available online at <https://eprint.iacr.org/2015/1092/> and at <https://cryptojedi.org/papers/#newhope>.

Acknowledgments. We are thankful to Mike Hamburg and to Paul Crowley for pointing out mistakes in a previous version of this paper, and we are thankful to Isis Lovecraft for thoroughly proofreading the paper and for suggesting the name JARJAR for the low-security variant of our proposal.

2 Lattice-based key exchange

Let \mathbb{Z} be the ring of rational integers. We define for an $x \in \mathbb{R}$ the rounding function $\lfloor x \rfloor = \lfloor x + \frac{1}{2} \rfloor \in \mathbb{Z}$. Let \mathbb{Z}_q , for an integer $q \geq 1$, denote the quotient ring $\mathbb{Z}/q\mathbb{Z}$. We define $\mathcal{R} = \mathbb{Z}[X]/(X^n + 1)$ as the ring of integer polynomials modulo $X^n + 1$. By $\mathcal{R}_q = \mathbb{Z}_q[X]/(X^n + 1)$ we mean the ring of integer polynomials modulo $X^n + 1$ where each coefficient is reduced modulo q . In case χ is a probability distribution over \mathcal{R} , then $x \xleftarrow{\$} \chi$ means the sampling of $x \in \mathcal{R}$ according to χ . When we write $\mathbf{a} \xleftarrow{\$} \mathcal{R}_q$ this means that all coefficients of \mathbf{a} are chosen uniformly at random from \mathbb{Z}_q . For a probabilistic algorithm \mathcal{A} we denote by $y \xleftarrow{\$} \mathcal{A}$ that the output of \mathcal{A} is assigned to y and that \mathcal{A} is running with randomly chosen coins. We recall the discrete Gaussian distribution $D_{\mathbb{Z}, \sigma}$ which is parametrized by the Gaussian parameter $\sigma \in \mathbb{R}$ and defined by assigning a weight proportional to $\exp(\frac{-x^2}{2\sigma^2})$ to all integers x .

2.1 The scheme of Peikert

In this section we briefly revisit the passively secure key-encapsulation mechanism (KEM) that was proposed by Peikert [77] and instantiated in [20] (BCNS). Peikert’s KEM scheme is defined by the algorithms (Setup, Gen, Encaps, Decaps) and after a successful protocol run both parties share an ephemeral secret key that can be used to protect further communication (see Protocol 1).

The KEM scheme by Peikert closely resembles a previously introduced Ring-LWE encryption scheme [66] but due to a new error-reconciliation mechanism, one \mathcal{R}_q component of the ciphertext can be replaced by a more compact element in \mathcal{R}_2 . This efficiency gain is possible due to the observation that it is not necessary to transmit an explicitly chosen key to establish a secure

ephemeral session key. In Peikert’s scheme, the reconciliation just allows both parties to derive the session key from an approximately agreed pseudorandom ring element. For Alice, this ring element is $\mathbf{us} = \mathbf{ass}' + \mathbf{e}'$ s and for Bob it is $\mathbf{v} = \mathbf{bs}' + \mathbf{e}'' = \mathbf{ass}' + \mathbf{es}' + \mathbf{e}''$. For a full explanation of the reconciliation we refer to the original paper [77] but briefly recall the cross-rounding function $\langle \cdot \rangle_2$ defined as $\langle v \rangle_2 := \lfloor \frac{4}{q} \cdot v \rfloor \pmod{2}$ and the randomized function $\text{dbl}(v) := 2v - \bar{e}$ for some random \bar{e} where $\bar{e} = 0$ with probability $\frac{1}{2}$, $\bar{e} = 1$ with probability $\frac{1}{4}$, and $\bar{e} = -1$ with probability $\frac{1}{4}$. Let $I_0 = \{0, 1, \dots, \lfloor \frac{q}{2} \rfloor - 1\}$, $I_1 = \{-\lfloor \frac{q}{2} \rfloor, \dots, -1\}$, and $E = [-\frac{q}{4}, \frac{q}{4}]$ then the reconciliation function $\text{rec}(w, b)$ is defined as

$$\text{rec}(w, b) = \begin{cases} 0, & \text{if } w \in I_b + E \pmod{q} \\ 1, & \text{otherwise.} \end{cases}$$

If these functions are applied to polynomials this means they are applied to each of the coefficients separately.

Parameters: q, n, χ	
KEM. $\text{Setup}()$:	
$\mathbf{a} \xleftarrow{\$} \mathcal{R}_q$	
Alice (server)	Bob (client)

Protocol 1: Peikert’s KEM mechanism.

2.2 The BCNS proposal

In a work by Bos, Costello, Naehrig, and Stebila [20] (BCNS), Peikert’s KEM [77] was phrased as a key-exchange protocol (see again Protocol 1), instantiated for a concrete parameter set, and integrated into OpenSSL (see Section 8 for a performance comparison). Selection of parameters was necessary as Peikert’s original work does not contain concrete parameters and the security as well as error estimation are based on asymptotics. The authors of [20] chose a dimension $n = 1024$, a modulus $q = 2^{32} - 1$, $\chi = D_{\mathbb{Z}, \sigma}$ and the Gaussian parameter $\sigma = 8/\sqrt{2\pi} \approx 3.192$. It is claimed that these parameters provide a classical security level of at least 128 bits considering the distinguishing attack [62] with distinguishing advantage less than 2^{-128} and $2^{81.9}$ bits of security

against an optimistic instantiation of a quantum adversary. The probability of a wrong key being established is less than $2^{-2^{17}} = 2^{-131072}$. The message \mathbf{b} sent by Alice is a ring element and thus requires at least $\log_2(q)n = 32$ kbits while Bob’s response (\mathbf{u}, \mathbf{r}) is a ring element R_q and an element from R_2 and thus requires at least 33 kbits. As the polynomial $\mathbf{a} \in \mathcal{R}_q$ is shared between all parties this ring element has to be stored or generated on-the-fly. For timings of their implementation we refer to Table 2. We would also like to note that besides its aim for securing classical TLS, the BCNS protocol has already been proposed as a building block for Tor [84] on top of existing elliptic-curve infrastructure [41].

2.3 Our proposal: NEWHOPE

In this section we detail our proposal and modifications of Peikert’s protocol². For the same reasons as described in [20] we opt for an unauthenticated key-exchange protocol; the protection of stored transcripts against future decryption using quantum computers is much more urgent than post-quantum authentication. Authenticity will most likely be achievable in the foreseeable future using proven pre-quantum signatures and attacks on the signature will not compromise previous communication. Additionally, by not designing or instantiating a lattice-based authenticated key-exchange protocol (see [33, 85]) we reduce the complexity of the key-exchange protocol and simplify the choice of parameters. We actually see it as an advantage to decouple key exchange and authentication as it allows a protocol designer to choose the optimal algorithm for both tasks (e.g., an ideal-lattice-based key exchange and a hash-based signature like [16] for authentication). Moreover, this way the design, security level, and parameters of the key-exchange scheme are not constrained by requirements introduced by the authentication part.

Parameter choices. A high-level description of our proposal is given in Protocol 2 and as in [20, 77] all polynomials except for $\mathbf{r} \in \mathcal{R}_4$ are defined in the ring $\mathcal{R}_q = \mathbb{Z}_q[X]/(X^n + 1)$ with $n = 1024$ and $q = 12289$. We decided to keep the dimension $n = 1024$ as in [20] to be able to achieve appropriate long-term security. As polynomial arithmetic is fast and also scales better (doubling n roughly doubles the time required for a polynomial multiplication), our choice of n appears to be acceptable from a performance point of view. We chose the modulus $q = 12289$ as it is the smallest prime for which it holds that $q \equiv 1 \pmod{2n}$ so that the number-theoretic transform (NTT) can be realized efficiently and that we can transfer polynomials in NTT encoding (see Section 7).

²For the TLS use-case and for compatibility with BNCS [20] the key exchange is initiated by the server. However, in different scenarios the roles of the server and client can be exchanged.

As the security level grows with the noise-to-modulus ratio, it makes sense to choose the modulus as small as possible, improving compactness and efficiency together with security. The choice is also appealing as the prime is already used by some implementations of Ring-LWE encryption [29, 63, 81] and BLISS signatures [31, 78]; thus sharing of some code (or hardware modules) between our proposal and an implementation of BLISS would be possible.

Noise distribution and reconciliation. Notably, we also change the distribution of the LWE secret and error and replace discrete Gaussians by the centered binomial distribution ψ_k of parameter $k = 16$ (see Section 4). The reason is that it turned out to be challenging to implement a discrete Gaussian sampler efficiently *and* protected against timing attacks (see [20] and Section 5). On the other hand, sampling from the centered binomial distribution is easy and does not require high-precision computations or large tables as one may sample from ψ_k by computing $\sum_{i=0}^k b_i - b'_i$, where the $b_i, b'_i \in \{0, 1\}$ are uniform independent bits. The distribution ψ_k is centered (its mean is 0), has variance $k/2$ and for $k = 16$ this gives a standard deviation of $\xi = \sqrt{16/2}$. Contrary to [20, 77] we hash the output of the reconciliation mechanism, which makes a distinguishing attack irrelevant and allows us to argue security for the modified error distribution.

Moreover, we generalize Peikert’s reconciliation mechanism using an analog error-correction approach (see Section 5). The design rationale is that we only want to transmit a 256-bit key but have $n = 1024$ coefficients to encode data into. Thus we encode one key bit into four coefficients; by doing so we achieve increased error resilience which in turn allows us to use larger noise for better security.

Short-term public parameters. NEWHOPE does not rely on a globally chosen public parameter \mathbf{a} as the efficiency increase in doing so is not worth the measures that have to be taken to allow trusted generation of this value and the defense against backdoors [13]. Moreover, this approach avoids the rather uncomfortable situation that all connections rely on a single instance of a lattice problem (see Section 3) in the flavor of the “Logjam” DLP attack [1].

No key caching. For ephemeral Diffie-Hellman key-exchange in TLS it is common for servers to cache a key pair for a short time to increase performance. For example, according to [24], Microsoft’s SChannel library caches ephemeral keys for 2 hours. We remark that for the lattice-based key exchange described in [77], for the key exchange described in [20], and also for the key exchange described in this paper, such short-term caching would be disastrous for security. Indeed, it is crucial that

both parties use fresh secrets for each instantiation (thus the performance of the noise sampling is crucial). As short-term key caching typically happens on higher layers of TLS libraries than the key-exchange implementation itself, we stress that particular care needs to be taken to eliminate such caching when switching from ephemeral (elliptic-curve) Diffie-Hellman key exchange to post-quantum lattice-based key exchange. This issue is discussed in more detail in [32].

One could enable key caching with a transformation from the CPA-secure key exchange to a CCA-secure key exchange as outlined by Peikert in [77, Section 5]. Note that such a transform would furthermore require changes to the noise distribution to obtain a failure probability that is negligible in the cryptographic sense.

3 Preventing backdoors and all-for-the-price-of-one attacks

One serious concern about the original design [20] is the presence of the polynomial \mathbf{a} as a fixed system parameter. As described in Protocol 2, our proposal includes pseudorandom generation of this parameter for every key exchange. In the following we discuss the reasons for this decision.

Backdoor. In the worst scenario, the fixed parameter \mathbf{a} could be backdoored. For example, inspired by NTRU trapdoors [50, 83], a dishonest authority may choose mildly small \mathbf{f}, \mathbf{g} such that $\mathbf{f} = \mathbf{g} = 1 \bmod p$ for some prime $p \geq 4 \cdot 16 + 1$ and set $\mathbf{a} = \mathbf{g}\mathbf{f}^{-1} \bmod q$. Then, given $(\mathbf{a}, \mathbf{b} = \mathbf{a}\mathbf{s} + \mathbf{e})$, the attacker can compute $\mathbf{b}\mathbf{f} = \mathbf{a}\mathbf{f}\mathbf{s} + \mathbf{f}\mathbf{e} = \mathbf{g}\mathbf{s} + \mathbf{f}\mathbf{e} \bmod q$, and, because $\mathbf{g}, \mathbf{s}, \mathbf{f}, \mathbf{e}$ are small enough, compute $\mathbf{g}\mathbf{s} + \mathbf{f}\mathbf{e}$ in \mathbb{Z} . From this he can compute $\mathbf{t} = \mathbf{s} + \mathbf{e} \bmod p$ and, because the coefficients of \mathbf{s} and \mathbf{e} are smaller than 16, their sums are in $[-2 \cdot 16, 2 \cdot 16]$: knowing them modulo $p \geq 4 \cdot 16 + 1$ is knowing them in \mathbb{Z} . It now only remains to compute $(\mathbf{b} - \mathbf{t}) \cdot (\mathbf{a} - 1)^{-1} = (\mathbf{a}\mathbf{s} - \mathbf{s}) \cdot (\mathbf{a} - 1)^{-1} = \mathbf{s} \bmod q$ to recover the secret \mathbf{s} .

One countermeasure against such backdoors is the “nothing-up-my-sleeve” process, which would, for example, choose \mathbf{a} as the output of a hash function on a common universal string like the digits of π . Yet, even this process may be partially abused [13], and when not strictly required it seems preferable to avoid it.

All-for-the-price-of-one attacks. Even if this common parameter has been honestly generated, it is still rather uncomfortable to have the security of all connections rely on a single instance of a lattice problem. The scenario is an entity that discovers an unforeseen cryptanalytic algorithm, making the required lattice reduction still very costly, but say, not impossible in a year of computation, given its outstanding computational power. By finding *once* a good enough basis of the lattice $\Lambda =$

Parameters: $q = 12289 < 2^{14}$, $n = 1024$	
Error distribution: ψ_{16}	
Alice (server)	Bob (client)
$seed \xleftarrow{\$} \{0, 1\}^{256}$	
$\mathbf{a} \leftarrow \text{Parse}(\text{SHAKE-128}(seed))$	
$\mathbf{s}, \mathbf{e} \xleftarrow{\$} \psi_{16}^n$	$\mathbf{s}', \mathbf{e}', \mathbf{e}'' \xleftarrow{\$} \psi_{16}^n$
$\mathbf{b} \leftarrow \mathbf{a}\mathbf{s} + \mathbf{e}$	$\xrightarrow{(\mathbf{b}, seed)}$
$\mathbf{v}' \leftarrow \mathbf{u}\mathbf{s}$	$\xleftarrow{(\mathbf{u}, \mathbf{r})}$
$v \leftarrow \text{Rec}(\mathbf{v}', \mathbf{r})$	$\mathbf{a} \leftarrow \text{Parse}(\text{SHAKE-128}(seed))$
$\mu \leftarrow \text{SHA3-256}(v)$	$\mathbf{u} \leftarrow \mathbf{a}\mathbf{s}' + \mathbf{e}'$
	$\mathbf{v} \leftarrow \mathbf{b}\mathbf{s}' + \mathbf{e}''$
	$\mathbf{r} \xleftarrow{\$} \text{HelpRec}(\mathbf{v})$
	$v \leftarrow \text{Rec}(\mathbf{v}, \mathbf{r})$
	$\mu \leftarrow \text{SHA3-256}(v)$

Protocol 2: Our Scheme. For the definitions of HelpRec and Rec see Section 5. For the definition of encodings and the definition of Parse see Section 7.

$\{(a, 1)x + (q, 0)y \mid x, y \in \mathcal{R}\}$, this entity could then compromise *all* communications, using for example Babai’s decoding algorithm [7].

This idea of massive precomputation that is only dependent on a fixed parameter \mathbf{a} and then afterwards can be used to break all key exchanges is similar in flavor to the 512-bit “Logjam” DLP attack [1]. This attack was only possible in the required time limit because most TLS implementations use fixed primes for Diffie-Hellman. One of the recommended mitigations by the authors of [1] is to avoid fixed primes.

Against all authority. Fortunately, all those pitfalls can be avoided by having the communicating parties generate a fresh \mathbf{a} at each instance of the protocol (as we propose). If in practice it turns out to be too expensive to generate \mathbf{a} for every connection, it is also possible to cache \mathbf{a} on the server side³ for, say a few hours without significantly weakening the protection against all-for-the-price-of-one attacks. Additionally, the performance impact of generating \mathbf{a} is reduced by sampling \mathbf{a} uniformly directly in NTT format (recalling that the NTT is a one-to-one map), and by transferring only a short 256-bit seed for \mathbf{a} (see Section 7).

A subtle question is to choose an appropriate primitive to generate a “random-looking” polynomial \mathbf{a} out of a short seed. For a security reduction, it seems to the authors that there is no way around the (non-programmable) random oracle model (ROM). It is argued in [34] that such a requirement is in practice an overkill, and that any pseudorandom generator (PRG) should also work. And while it is an interesting question how such a reasonable pseudo-random generator would interact with our lattice assumption, the cryptographic

notion of a PRG is *not* helpful to argue security. Indeed, it is an easy exercise⁴ to build (under the NTRU assumption) a “backdoored” PRG that is, formally, a legitimate PRG, but that makes our scheme insecure.

Instead, we prefer to base ourselves on a standard cryptographic hash-function, which is the typical choice of an “instantiation” of the ROM. As a suitable option we see Keccak [19], which has recently been standardized as SHA3 in FIPS-202 [72], and which offers extendable-output functions (XOF) named SHAKE. This avoids costly external iteration of a regular hash function and directly fits our needs.

We use SHAKE-128 for the generation of \mathbf{a} , which offers 128-bits of (post-quantum) security against collisions and preimage attacks. With only a small performance penalty we could have also chosen SHAKE-256, but we do not see any reason for such a choice, in particular because neither collisions nor preimages lead to an attack against the proposed scheme.

4 Choice of the error distribution

On non-Gaussian errors. In works like [20, 29, 81], a significant algorithmic effort is devoted to sample from a discrete Gaussian distribution to a rather high precision. In the following we argue that such effort is not necessary and motivate our choice of a centered binomial ψ_k as error distribution.

Indeed, we recall that the original worst-case to average-case reductions for LWE [80] and Ring-

³But recall that the secrets $\mathbf{s}, \mathbf{e}, \mathbf{s}', \mathbf{s}', \mathbf{e}''$ have to be sampled fresh for every connection.

⁴Consider a secure PRG p , and parse its output $p(\text{seed})$ as two small polynomial (\mathbf{f}, \mathbf{g}) : an NTRU secret-key. Define $p'(\text{seed}) = \mathbf{g}\mathbf{f}^{-1} \bmod q$: under the decisonal NTRU assumption, p' is still a secure PRG. Yet revealing the seed does reveal (\mathbf{f}, \mathbf{g}) and provides a backdoor as detailed above.

LWE [67] state hardness for *continuous Gaussian* distributions (and therefore also trivially apply to *rounded Gaussian*, which differ from discrete Gaussians). This also extends to discrete Gaussians [21] but such proofs are not necessarily intended for direct implementations. We recall that the use of discrete Gaussians (or other distributions with very high-precision sampling) is only crucial for signatures [65] and lattice trapdoors [39], to provide zero-knowledgeness.

The following Theorem states that choosing ψ_k as error distribution in Protocol 2 does not significantly decrease security compared to a rounded Gaussian distribution with the same standard deviation $\sigma = \sqrt{16/2}$.

Theorem 4.1 *Let ξ be the rounded Gaussian distribution of parameter $\sigma = \sqrt{8}$, that is, the distribution of $\lfloor \sqrt{8} \cdot x \rfloor$ where x follows the standard normal distribution. Let \mathcal{P} be the idealized version of Protocol 2, where the distribution ψ_{16} is replaced by ξ . If an (unbounded) algorithm, given as input the transcript of an instance of Protocol 2 succeeds in recovering the pre-hash key v with probability p , then it would also succeed against \mathcal{P} with probability at least*

$$q \geq p^{9/8}/26.$$

Proof See Appendix B in the full version of this paper.

As explained in Section 6, our choice of parameters leaves a comfortable margin to the targeted 128 bits of post-quantum security, which accommodates for the slight loss in security indicated by Theorem 4.1. Even more important from a practical point of view is that no known attack makes use of the difference in error distribution; what matters for attacks are entropy and standard deviation.

Simple implementation. We remark that sampling from the centered binomial distribution ψ_{16} is rather trivial in hardware and software, given the availability of a uniform binary source. Additionally, the implementation of this sampling algorithm is much easier to protect against timing attacks as no large tables or data-dependent branches are required (cf. to the issues caused by the table-based approach used in [20]).

5 Improved error-recovery mechanism

In most of the literature, Ring-LWE encryption allows to encrypt one bit per coordinate of the ciphertext. It is also well known how to encrypt multiple bits per coordinate by using a larger modulus-to-error ratio (and therefore decreasing the security for a fixed dimension n). However, in the context of exchanging a symmetric key (of, say, 256 bits), we end up having a message space larger

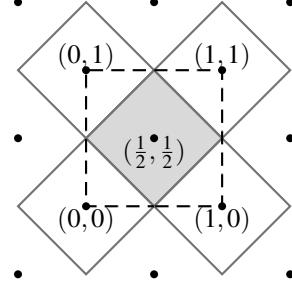

Figure 1: The lattice \tilde{D}_2 with Voronoi cells

than necessary and thus want to encrypt *one bit in multiple coordinates*.

In [79] Pöppelmann and Güneysu introduced a technique to encode one bit into two coordinates, and verified experimentally that it led to a better error tolerance. This allows to either increase the error and therefore improve the security of the resulting scheme or to decrease the probability of decryption failures. In this section we propose a generalization of this technique in dimension 4. We start with an intuitive description of the approach in 2 dimensions and then explain what changes in 4 dimensions. Appendices C and D in the full version of this paper give a thorough mathematical description together with a rigorous analysis.

Let us first assume that both client and server have the same vector $\mathbf{x} \in [0, 1)^2 \subset \mathbb{R}^2$ and want to map this vector to a single bit. Mapping polynomial coefficients from $\{0, \dots, q-1\}$ to $[0, 1)$ is easily accomplished through a division by q .

Now consider the lattice \tilde{D}_2 with basis $\{(0, 1), (\frac{1}{2}, \frac{1}{2})\}$. This lattice is a scaled version of the root lattice D_2 , specifically, $\tilde{D}_2 = \frac{1}{2} \cdot D_2$. Part of \tilde{D}_2 is depicted in Figure 1; lattice points are shown together with their Voronoi cells and the possible range of the vector \mathbf{x} is marked with dashed lines. Mapping \mathbf{x} to one bit is done by finding the closest-vector $v \in \tilde{D}_2$. If $v = (\frac{1}{2}, \frac{1}{2})$ (i.e., \mathbf{x} is in the grey Voronoi cell), then the output bit is 1; if $v \in \{(0, 0), (0, 1), (1, 0), (1, 1)\}$ (i.e., \mathbf{x} is in a white Voronoi cell) then the output bit is 0.

This map may seem like a fairly complex way to map from a vector to a bit. However, recall that client and server only have a noisy version of \mathbf{x} , i.e., the client has a vector \mathbf{x}_c and the server has a vector \mathbf{x}_s . Those two vectors are close, but they are not the same and can be on different sides of a Voronoi cell border.

Error reconciliation. The approach described above now allows for an efficient solution to solve this agreement-from-noisy-data problem. The idea is that one of the two participants (in our case the client) sends as a *reconciliation vector* the difference of his vector \mathbf{x}_c

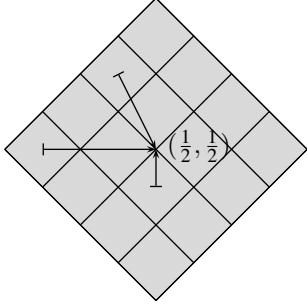

Figure 2: Splitting of the Voronoi cell of $(\frac{1}{2}, \frac{1}{2})$ into $2^{rd} = 16$ sub-cells, some with their corresponding difference vector to the center

and the center of its Voronoi cell (i.e., the point in the lattice). The server adds this difference vector to \mathbf{x}_s and thus moves away from the border towards the center of the correct Voronoi cell. Note that an eavesdropper does not learn anything from the reconciliation information: the client tells the difference to a lattice point, but not whether this is a lattice point producing a zero bit or a one bit.

This approach would require sending a full additional vector; we can reduce the amount of reconciliation information through r -bit discretization. The idea is to split each Voronoi cell into 2^{dr} sub-cells and only send in which of those sub-cells the vector x_c is. Both participants then add the difference of the center of the sub-cell and the lattice point. This is illustrated for $r = 2$ and $d = 2$ in Figure 2.

Blurring the edges. Figure 1 may suggest that the probability of \mathbf{x} being in a white Voronoi cell is the same as for \mathbf{x} being in the grey Voronoi cell. This would be the case if \mathbf{x} actually followed a continuous uniform distribution. However, the coefficients of \mathbf{x} are discrete values in $\{0, \frac{1}{q}, \dots, \frac{q-1}{q}\}$ and with the protocol described so far, the bits of \mathbf{v} would have a small bias. The solution is to add, with probability $\frac{1}{2}$, the vector $(\frac{1}{2q}, \frac{1}{2q})$ to \mathbf{x} before running the error reconciliation. This has close to no effect for most values of \mathbf{x} , but, with probability $\frac{1}{2}$ moves \mathbf{x} to another Voronoi cell if it is very close to one side of a border. Appendix E in the full version of this paper gives a graphical intuition for this trick in two dimensions and with $q = 9$. The proof that it indeed removes all biases in the key is given in Lemma C.2. in the full version of this paper.

From 2 to 4 dimensions. When moving from the 2-dimensional case considered above to the 4-dimensional case used in our protocol, not very much needs to change. The lattice \tilde{D}_2 becomes the lattice \tilde{D}_4 with basis $\mathbf{B} = (\mathbf{u}_0, \mathbf{u}_1, \mathbf{u}_2, \mathbf{g})$, where \mathbf{u}_i are the canonical basis vectors of

\mathbb{Z}^4 and $\mathbf{g}' = (\frac{1}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2})$. The lattice \tilde{D}_4 is a rotated and scaled version of the root lattice D_4 . The Voronoi cells of this lattice are no longer 2-dimensional ‘‘diamonds’’, but 4-dimensional objects called icositetrachoron or 24-cells [61]. Determining in which cell a target point lies in is done using the closest vector algorithm $\text{CVP}_{\tilde{D}_4}$, and a simplified version of it, which we call `Decode`, gives the result modulo \mathbb{Z}^4 .

As in the 2-dimensional illustration in Figure 2, we are using 2-bit discretization; we are thus sending $r \cdot d = 8$ bits of reconciliation information per key bit.

Putting all of this together, we obtain the `HelpRec` function to compute the r -bit reconciliation information as

$$\text{HelpRec}(\mathbf{x}; b) = \text{CVP}_{\tilde{D}_4} \left(\frac{2^r}{q} (\mathbf{x} + b\mathbf{g}') \right) \bmod 2^r,$$

where $b \in \{0, 1\}$ is a uniformly chosen random bit. The corresponding function $\text{Rec}(\mathbf{x}, \mathbf{r}) = \text{Decode}(\frac{1}{q}\mathbf{x} - \frac{1}{2^r}\mathbf{Br})$ computes one key bit from a vector \mathbf{x} with 4 coefficients in \mathbb{Z}_q and a reconciliation vector $\mathbf{r} \in \{0, 1, 2, 3\}^4$. The algorithms $\text{CVP}_{\tilde{D}_4}$ and `Decode` are listed as Algorithm 1 and Algorithm 2, respectively.

Algorithm 1 $\text{CVP}_{\tilde{D}_4}(\mathbf{x} \in \mathbb{R}^4)$

Ensure: An integer vector \mathbf{z} such that \mathbf{Bz} is a closest vector to \mathbf{x} : $\mathbf{x} - \mathbf{Bz} \in \mathcal{V}$

- 1: $\mathbf{v}_0 \leftarrow \lfloor \mathbf{x} \rfloor$
 - 2: $\mathbf{v}_1 \leftarrow \lfloor \mathbf{x} - \mathbf{g}' \rfloor$
 - 3: $k \leftarrow (\|\mathbf{x} - \mathbf{v}_0\|_1 < 1) ? 0 : 1$
 - 4: $(\mathbf{v}_0, \mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)^t \leftarrow \mathbf{v}_k$
 - 5: **return** $(\mathbf{v}_0, \mathbf{v}_1, \mathbf{v}_2, k)^t + v_3 \cdot (-1, -1, -1, 2)^t$
-

Algorithm 2 $\text{Decode}(\mathbf{x} \in \mathbb{R}^4 / \mathbb{Z}^4)$

Ensure: A bit k such that $k\mathbf{g}'$ is a closest vector to $\mathbf{x} + \mathbb{Z}^4$: $\mathbf{x} - k\mathbf{g}' \in \mathcal{V} + \mathbb{Z}^4$

- 1: $\mathbf{v} = \mathbf{x} - \lfloor \mathbf{x} \rfloor$
 - 2: **return** 0 if $\|\mathbf{v}\|_1 \leq 1$ and 1 otherwise
-

Finally it remains to remark that even with this reconciliation mechanism client and server do not always agree on the same key. Lemma D in the full version of this paper provides a detailed analysis of the failure probability of the key agreement and shows that it is smaller than 2^{-60} .

6 Post-quantum security analysis

In [20] the authors chose Ring-LWE for a ring of rank $n = 1024$, while most previous instantiations of the Ring-LWE encryption scheme, like the ones in [29, 42, 63, 79],

chose substantially smaller rank $n = 256$ or $n = 512$. It is argued that it is unclear if dimension 512 can offer post-quantum security. Yet, the concrete post-quantum security of LWE-based schemes has not been thoroughly studied, as far as we know. In this section we propose such a (very pessimistic) concrete analysis. In particular, our analysis reminds us that the security depends as much on q and its ratio with the error standard deviation ζ as it does on the dimension n . That means that our effort of optimizing the error recovery and its analysis not only improves efficiency but also offers superior security.

Security level over-shoot? With all our improvements, it would be possible to build a scheme with $n = 512$ (and $k = 24$, $q = 12289$) and to obtain security somewhat similar to the one of [20, 42], and therefore further improve efficiency. We call this variant JARJAR and details are provided in Appendix A of the full version of this paper. Nevertheless, as history showed us with RSA-512 [28], the standardization and deployment of a scheme awakens further cryptanalytic effort. In particular, NEWHOPE could withstand a dimension-halving attack in the line of [36, Sec 8.8.1] based on the Gentry-Szydlo algorithm [40, 60] or the subfield approach of [2]. Note that so far, such attacks are only known for principal ideal lattices or NTRU lattices, and there are serious obstructions to extend them to Ring-LWE, but such precaution seems reasonable until lattice cryptanalysis stabilizes.

We provide the security and performance analysis of JARJAR in Appendix A of the full version of this paper mostly for comparison with other lower-security proposals. We strongly recommend NEWHOPE for any immediate applications, and advise against using JARJAR until concrete cryptanalysis of lattice-based cryptography is better understood.

6.1 Methodology: the core SVP hardness

We analyze the hardness of Ring-LWE as an LWE problem, since, so far, the best known attacks do not make use of the ring structure. There are many algorithms to consider in general (see the survey [3]), yet many of those are irrelevant for our parameter set. In particular, because there are only $m = n$ samples available one may rule out BKW types of attacks [53] and linearization attacks [6]. This essentially leaves us with two BKZ [26, 82] attacks, usually referred to as primal and dual attacks that we will briefly recall below.

The algorithm BKZ proceeds by reducing a lattice basis using an SVP oracle in a smaller dimension b . It is known [47] that the number of calls to that oracle remains polynomial, yet concretely evaluating the number of calls is rather painful, and this is subject to new heuristic ideas [25, 26]. We choose to ignore this polynomial

factor, and rather evaluate only the *core SVP hardness*, that is the cost of *one call* to an SVP oracle in dimension b , which is clearly a pessimistic estimation (from the defender's point of view).

6.2 Enumeration versus quantum sieve

Typical implementations [23, 26, 35] use an enumeration algorithm as this SVP oracle, yet this algorithm runs in super-exponential time. On the other hand, the sieve algorithms are known to run in exponential time, but are so far slower in practice for accessible dimensions $b \approx 130$. We choose the latter to predict the core hardness and will argue that for the targeted dimension, enumerations are expected to be greatly slower than sieving.

Quantum sieve. A lot of recent work has pushed the efficiency of the original lattice sieve algorithms [69, 75], improving the heuristic complexity from $(4/3)^{b+o(b)} \approx 2^{0.415b}$ down to $\sqrt{3/2}^{b+o(b)} \approx 2^{0.292b}$ (see [10, 55]). The hidden sub-exponential factor is known to be much greater than one in practice, so again, estimating the cost ignoring this factor leaves us with a significant pessimistic margin.

Most of those algorithms have been shown [54, 56] to benefit from Grover's quantum search algorithm, bringing the complexity down to $2^{0.265b}$. It is unclear if further improvements are to be expected, yet, because all those algorithms require classically building lists of size $\sqrt{4/3}^{b+o(b)} \approx 2^{0.2075b}$, it is very plausible that the best quantum SVP algorithm would run in time greater than $2^{0.2075b}$.

Irrelevance of enumeration for our analysis. In [26], predictions of the cost of solving SVP classically using the most sophisticated heuristic enumeration algorithms are given. For example, solving SVP in dimension 100 requires visiting about 2^{39} nodes, and 2^{134} nodes in dimension 250. Because this enumeration is a backtracking algorithm, it does benefit from the recent quasi-quadratic speedup [70], decreasing the quantum cost to about at least 2^{20} to 2^{67} operations as the dimension increases from 100 to 250.

On the other hand, our best-known attack bound $2^{0.265b}$ gives a cost of 2^{66} in dimension 250, and the best plausible attack bound $2^{0.2075b} \approx 2^{39}$. Because enumeration is super-exponential (both in theory and practice), its cost will be worse than our bounds in dimension larger than 250 and we may safely ignore this kind of algorithm.⁵

⁵The numbers are taken from the latest full version of [26] available at http://www.di.ens.fr/~ychen/research/Full_BKZ.pdf.

6.3 Primal attack

The primal attack consists of constructing a unique-SVP instance from the LWE problem and solving it using BKZ. We examine how large the block dimension b is required to be for BKZ to find the unique solution. Given the matrix LWE instance $(\mathbf{A}, \mathbf{b} = \mathbf{As} + \mathbf{e})$ one builds the lattice $\Lambda = \{\mathbf{x} \in \mathbb{Z}^{m+n+1} : (\mathbf{A} - \mathbf{I}_m) - \mathbf{b}\mathbf{x} = \mathbf{0} \bmod q\}$ of dimension $d = m+n+1$, volume q^m , and with a unique-SVP solution $\mathbf{v} = (\mathbf{s}, \mathbf{e}, 1)$ of norm $\lambda \approx \zeta\sqrt{n+m}$. Note that the number of used samples m may be chosen between 0 and $2n$ in our case and we numerically optimize this choice.

Success condition. We model the behavior of BKZ using the geometric series assumption (which is known to be optimistic from the attacker’s point of view), that finds a basis whose Gram-Schmidt norms are given by $\|\mathbf{b}_i^*\| = \delta^{d-2i-1} \cdot \text{Vol}(\Lambda)^{1/d}$ where $\delta = ((\pi b)^{1/b} \cdot b/2\pi e)^{1/2(b-1)}$ [3, 25]. The unique short vector \mathbf{v} will be detected if the projection of \mathbf{v} onto the vector space spanned by the last b Gram-Schmidt vectors is shorter than \mathbf{b}_{d-b}^* . Its projected norm is expected to be $\zeta\sqrt{b}$, that is the attack is successful if and only if

$$\zeta\sqrt{b} \leq \delta^{2b-d-1} \cdot q^{m/d}. \quad (1)$$

6.4 Dual attack

The dual attack consists of finding a short vector in the dual lattice $\mathbf{w} \in \Lambda' = \{(\mathbf{x}, \mathbf{y}) \in \mathbb{Z}^m \times \mathbb{Z}^n : \mathbf{A}^t \mathbf{x} = \mathbf{y} \bmod q\}$. Assume we have found a vector (\mathbf{x}, \mathbf{y}) of length ℓ and compute $z = \mathbf{v}^t \cdot \mathbf{b} = \mathbf{v}^t \mathbf{As} + \mathbf{v}^t \mathbf{e} = \mathbf{w}^t \mathbf{s} + \mathbf{v}^t \mathbf{e} \bmod q$ which is distributed as a Gaussian of standard deviation $\ell\zeta$ if (\mathbf{A}, \mathbf{b}) is indeed an LWE sample (otherwise it is uniform mod q). Those two distributions have maximal variation distance bounded by⁶ $\epsilon = 4 \exp(-2\pi^2\tau^2)$ where $\tau = \ell\zeta/q$, that is, given such a vector of length ℓ one has an advantage ϵ against decision-LWE.

The length ℓ of a vector given by the BKZ algorithm is given by $\ell = \|\mathbf{b}_0\|$. Knowing that Λ' has dimension $d = m+n$ and volume q^n we get $\ell = \delta^{d-1} q^{n/d}$. Therefore, obtaining an ϵ -distinguisher requires running BKZ with block dimension b where

$$-2\pi^2\tau^2 \geq \ln(\epsilon/4). \quad (2)$$

Note that small advantages ϵ are not relevant since the agreed key is hashed: an attacker needs an advantage of at least $1/2$ to significantly decrease the search space of the agreed key. He must therefore amplify his success

⁶A preliminary version of this paper contained a bogus formula for ϵ leading to under-estimating the cost of the dual attack. Correcting this formula leads to better security claim, and almost similar cost for the primal and dual attacks.

Attack	m	b	Known Classical	Known Quantum	Best Plausible
BCNS proposal [20]: $q = 2^{32} - 1$, $n = 1024$, $\zeta = 3.192$					
Primal	1062	296	86	78	61
Dual	1055	296	86	78	61
NTRUENCRYPT [49]: $q = 2^{12}$, $n = 743$, $\zeta \approx \sqrt{2/3}$					
Primal	613	603	176	159	125
Dual	635	600	175	159	124
JARJAR: $q = 12289$, $n = 512$, $\zeta = \sqrt{12}$					
Primal	623	449	131	119	93
Dual	602	448	131	118	92
NEWHOPE: $q = 12289$, $n = 1024$, $\zeta = \sqrt{8}$					
Primal	1100	967	282	256	200
Dual	1099	962	281	255	199

Table 1: Core hardness of NEWHOPE and JARJAR and selected other proposals from the literature. The value b denotes the block dimension of BKZ, and m the number of used samples. Cost is given in \log_2 and is the smallest cost for all possible choices of m and b . Note that our estimation is very optimistic about the abilities of the attacker so that our result for the parameter set from [20] *does not* indicate that it can be broken with $\approx 2^{80}$ bit operations, given today’s state-of-the-art in cryptanalysis.

probability by building about $1/\epsilon^2$ many such short vectors. Because the sieve algorithms provide $2^{0.2075b}$ vectors, the attack must be repeated at least R times where

$$R = \max(1, 1/(2^{0.2075b} \epsilon^2)).$$

This makes the conservative assumption that all the vectors provided by the Sieve algorithm are as short as the shortest one.

6.5 Security claims

According to our analysis, we claim that our proposed parameters offer at least (and quite likely with a large margin) a post-quantum security of 128 bits. The cost of the primal attack and dual attacks (estimated by our script `scripts/PQsecurity.py`) are given in Table 1. For comparison we also give a lower bound on the security of [20] and do notice a significantly improved security in our proposal. Yet, because of the numerous pessimistic assumption made in our analysis, we do not claim any quantum attacks reaching those bounds.

Most other RLWE proposals achieve considerably lower security than NEWHOPE; for example, the highest-security parameter set used for RLWE encryption in [42] is very similar to the parameters of JARJAR. The situation is different for NTRUENCRYPT, which has been instantiated with parameters that achieve about 128 bits of security according to our analysis⁷.

⁷For comparison we view the NTRU key-recovery as an homoge-

Specifically, we refer to NTRUENCRYPT with $n = 743$ as suggested in [49]. A possible advantage of NTRUENCRYPT compared to NEWHOPE is somewhat smaller message sizes, however, this advantage becomes very small when scaling parameters to achieve a similar security margin as NEWHOPE. The large downside of using NTRUENCRYPT for ephemeral key exchange is the cost for key generation. The implementation of NTRUENCRYPT with $n = 743$ in eBACS [17] takes about an order of magnitude longer for key generation alone than NEWHOPE takes in total. Also, unlike our NEWHOPE software, this NTRUENCRYPT software is not protected against timing attacks; adding such protection would presumably incur a significant overhead.

7 Implementation

In this section we provide details on the encodings of messages and describe our portable reference implementation written in C, as well as an optimized implementation targeting architectures with AVX vector instructions.

7.1 Encodings and generation of a

The key-exchange protocol described in Protocol 1 and also our protocol as described in Protocol 2 exchange messages that contain mathematical objects (in particular, polynomials in \mathcal{R}_q). *Implementations* of these protocols need to exchange messages in terms of byte arrays. As we will describe in the following, the choice of encodings of polynomials to byte arrays has a serious impact on performance. We use an encoding of messages that is particularly well-suited for implementations that make use of quasi-linear NTT-based polynomial multiplication.

Definition of NTT and NTT^{-1} . The NTT is a tool commonly used in implementations of ideal lattice-based cryptography [29, 42, 63, 79]. For some background on the NTT and the description of fast software implementations we refer to [46, 68]. In general, fast quasi-logarithmic algorithms exist for the computation of the NTT and a polynomial multiplication can be performed by computing $\mathbf{c} = \text{NTT}^{-1}(\text{NTT}(\mathbf{a}) \circ \text{NTT}(\mathbf{b}))$ for $\mathbf{a}, \mathbf{b}, \mathbf{c} \in \mathcal{R}$. An NTT targeting ideal lattices defined in $\mathcal{R}_q = \mathbb{Z}_q[X]/(X^n + 1)$ can be implemented very efficiently if n is a power of two and q is a prime for which it holds that $q \equiv 1 \pmod{2n}$. This way a primitive n -th root of unity ω and its square root γ exist. By multiplying coefficient-wise by powers of $\gamma = \sqrt{\omega} \pmod{q}$ before

neous Ring-LWE instance. We do not take into account the combinatorial vulnerabilities [51] induced by the fact that secrets are ternary. We note that NTRU is a potentially a weaker problem than Ring-LWE: it is in principle subject to a subfield-lattice attack [2], but the parameters proposed for NTRUENCRYPT are immune.

the NTT computation and after the reverse transformation by powers of γ^{-1} , no zero padding is required and an n -point NTT can be used to transform a polynomial with n coefficients.

For a polynomial $\mathbf{g} = \sum_{i=0}^{1023} g_i X^i \in \mathcal{R}_q$ we define

$$\begin{aligned} \text{NTT}(\mathbf{g}) &= \hat{\mathbf{g}} = \sum_{i=0}^{1023} \hat{g}_i X^i, \text{ with} \\ \hat{g}_i &= \sum_{j=0}^{1023} \gamma^j g_j \omega^{ij}, \end{aligned}$$

where we fix the n -th primitive root of unity to $\omega = 49$ and thus $\gamma = \sqrt{\omega} = 7$. Note that in our implementation we use an in-place NTT algorithm which requires bit-reversal operations. As an optimization, our implementations skips these bit-reversals for the forward transformation as all inputs are only random noise. This optimization is transparent to the protocol and for simplicity omitted in the description here.

The function NTT^{-1} is the inverse of the function NTT. The computation of NTT^{-1} is essentially the same as the computation of NTT, except that it uses $\omega^{-1} \pmod{q} = 1254$, multiplies by powers of $\gamma^{-1} \pmod{q} = 8778$ after the summation, and also multiplies each coefficient by the scalar $n^{-1} \pmod{q} = 12277$ so that

$$\begin{aligned} \text{NTT}^{-1}(\hat{\mathbf{g}}) &= \mathbf{g} = \sum_{i=0}^{1023} g_i X^i, \text{ with} \\ g_i &= n^{-1} \gamma^{-i} \sum_{j=0}^{1023} \hat{g}_j \omega^{-ij}. \end{aligned}$$

The inputs to NTT^{-1} are *not* just random noise, so inside NTT^{-1} our software has to perform the initial bit reversal, making NTT^{-1} slightly more costly than NTT.

Definition of Parse. The public parameter \mathbf{a} is generated from a 256-bit seed through the extendable-output function SHAKE-128 [72, Sec. 6.2]. The output of SHAKE-128 is considered as an array of 16-bit, unsigned, little-endian integers. Each of those integers is used as a coefficient of \mathbf{a} if it is smaller than $5q$ and rejected otherwise. The first such 16-bit integer is used as the coefficient of X^0 , the next one as coefficient of X^1 and so on. Earlier versions of this paper described a slightly different way of rejection sampling for coefficients of \mathbf{a} . The more efficient approach adopted in this final version was suggested independently by Gueron and Schlieker in [45] and by Yawning Angel in [5]. However, note that a reduction modulo q of the coefficients of \mathbf{a} as described in [45] and [5] is not necessary; both our implementations can handle coefficients of \mathbf{a} in $\{0, \dots, 5q - 1\}$.

Due to a small probability of rejections, the amount of output required from SHAKE-128 depends on the seed –

what is required is $n = 1024$ coefficients that are smaller than $5q$. The minimal amount of output is thus 2 KB; the average amount is ≈ 2184.5 bytes. The resulting polynomial \mathbf{a} (denoted as $\hat{\mathbf{a}}$) is considered to be in NTT domain. This is possible because the NTT transforms uniform noise to uniform noise.

Using a variable amount of output from SHAKE-128 leaks information about \mathbf{a} through timing information. This is not a problem for most applications, since \mathbf{a} is public. As pointed out by Burdges in [22], such a timing leak of public information can be a problem when deploying NEWHOPE in anonymity networks like Tor. Appendix F in the full version of this paper describes an alternative approach for Parse, which is slightly more complex and slightly slower, but does not leak any timing information about \mathbf{a} .

The message format of $(\mathbf{b}, \text{seed})$ and (\mathbf{u}, \mathbf{r}) . With the definition of the NTT, we can now define the format of the exchanged messages. In both $(\mathbf{b}, \text{seed})$ and (\mathbf{u}, \mathbf{r}) the polynomial is transmitted in the NTT domain (as in works like [79, 81]). Polynomials are encoded as an array of 1792 bytes, in a compressed little-endian format. The encoding of seed is straight-forward as an array of 32 bytes, which is simply concatenated with the encoding of \mathbf{b} . Also the encoding of \mathbf{r} is fairly straight-forward: it packs four 2-bit coefficients into one byte for a total of 256 bytes, which are again simply concatenated with the encoding of \mathbf{u} . We denote these encodings to byte arrays as `encodeA` and `encodeB` and their inverses as `decodeA` and `decodeB`. For a description of our key-exchange protocol including encodings and with explicit NTT and NTT^{-1} transformations, see Protocol 3.

7.2 Portable C implementation

This paper is accompanied by a C reference implementation described in this section and an optimized implementation for Intel and AMD CPUs described in the next section. The main emphasis in the C reference implementation is on simplicity and portability. It does not use any floating-point arithmetic and outside the Keccak (SHA3-256 and SHAKE-128) implementation only needs 16-bit and 32-bit integer arithmetic. In particular, the error-recovery mechanism described in Section 5 is implemented with fixed-point (i.e., integer-) arithmetic. Furthermore, the C reference implementation does not make use of the division operator (/) and the modulo operator (%). The focus on simplicity and portability does not mean that the implementation is not optimized at all. On the contrary, we use it to illustrate various optimization techniques that are helpful to speed up the key exchange and are also of independent interest for implementers of other ideal-lattice-based schemes.

NTT optimizations. All polynomial coefficients are represented as unsigned 16-bit integers. Our in-place NTT implementation transforms from bit-reversed to natural order using Gentleman-Sande butterfly operations [27, 37]. One would usually expect that each NTT is preceded by a bit-reversal, but all inputs to NTT are noise polynomials that we can simply consider as being already bit-reversed; as explained earlier, the NTT^{-1} operation still involves a bit-reversal. The core of the NTT and NTT^{-1} operation consists of 10 layers of transformations, each consisting of 512 butterfly operations of the form described in Listing 2.

Montgomery arithmetic and lazy reductions. The performance of operations on polynomials is largely determined by the performance of NTT and NTT^{-1} . The main computational bottleneck of those operations are 5120 butterfly operations, each consisting of one addition, one subtraction and one multiplication by a precomputed constant. Those operations are in \mathbb{Z}_q ; recall that q is a 14-bit prime. To speed up the modular-arithmetic operations, we store all precomputed constants in Montgomery representation [71] with $R = 2^{18}$, i.e., instead of storing ω^i , we store $2^{18}\omega^i \pmod{q}$. After a multiplication of a coefficient g by some constant $2^{18}\omega^i$, we can then reduce the result r to $g\omega^i \pmod{q}$ with the fast Montgomery reduction approach. In fact, we do not always fully reduce modulo q , it is sufficient if the result of the reduction has at most 14 bits. The fast Montgomery reduction routine given in Listing 1a computes such a reduction to a 14-bit integer for any unsigned 32-bit integer in $\{0, \dots, 2^{32} - q(R-1) - 1\}$. Note that the specific implementation does not work for *any* 32-bit integer; for example, for the input $2^{32} - q(R-1) = 1073491969$ the addition $a=a+u$ causes an overflow and the function returns 0 instead of the correct result 4095. In the following we establish that this is not a problem for our software.

Aside from reductions after multiplication, we also need modular reductions after addition. For this task we use the “short Barrett reduction” [9] detailed in Listing 1b. Again, this routine does not fully reduce modulo q , but reduces any 16-bit unsigned integer to an integer of at most 14 bits which is congruent modulo q .

In the context of the NTT and NTT^{-1} , we make sure that inputs have coefficients of at most 14 bits. This allows us to avoid Barrett reductions after addition on every second level, because coefficients grow by at most one bit per level and the short Barrett reduction can handle 16-bit inputs. Let us turn our focus to the input of the Montgomery reduction (see Listing 2). Before subtracting $a[j+d]$ from t we need to add a multiple of q to avoid unsigned underflow. Coefficients never grow larger than 15 bits and $3 \cdot q = 36867 > 2^{15}$, so adding $3 \cdot q$ is sufficient. An upper bound on the

Parameters: $q = 12289 < 2^{14}$, $n = 1024$ Error distribution: ψ_{16}^n

expression $((\text{uint32_t})t + 3 * 12289 - a[j+d])$ is obtained if t is $2^{15} - 1$ and $a[j+d]$ is zero; we thus obtain $2^{15} + 3 \cdot q = 69634$. All precomputed constants are in $\{0, \dots, q - 1\}$, so the expression $(W * ((\text{uint32_t})t + 3 * 12289 - a[j+d]))$, the input to the Montgomery reduction, is at most $69634 \cdot (q - 1) = 855662592$ and thus safely below the maximum input that the Montgomery reduction can handle.

Listing 1 Reduction routines used in the reference implementation.

(a) Montgomery reduction ($R = 2^{18}$).

```
uint16_t mred(uint32_t a) {
    uint32_t u;
    u = (a * 12287);
    u &= ((1 << 18) - 1);
    a += u * 12289;
    return a >> 18;
}
```

(b) Short Barrett reduction.

```
uint16_t bred(uint16_t a) {
    uint32_t u;
    u = ((uint32_t)a * 5) >> 16;
    a -= u * 12289;
    return a;
}
```

Fast random sampling. As a first step before performing any operations on polynomials, both Alice and Bob need to expand the seed to the polynomial \mathbf{a} using SHAKE-128. The implementation we use is based on the “simple” implementation by Van Keer for the Kec-

Listing 2 The Gentleman-Sande butterfly inside odd levels of our NTT computation. All $a[j]$ and W are of type `uint16_t`.

```
W = omega[jTwiddle++];
t = a[j];
a[j] = bred(t + a[j+d]);
a[j+d] = mred(W * ((uint32_t)t + 3*12289 - a[j+d]));
```

cak permutation and slightly modified code taken from the “TweetFIPS202” implementation [18] for everything else.

The sampling of centered binomial noise polynomials is based on a fast PRG with a random seed from `/dev/urandom` followed by a quick summation of 16-bit chunks of the PRG output. Note that the choice of the PRG is a purely local choice that every user can pick independently based on the target hardware architecture and based on routines that are available anyway (for example, for symmetric encryption following the key exchange). Our C reference implementation uses ChaCha20 [12], which is fast, trivially protected against timing attacks, and is already in use by many TLS clients and servers [57, 58].

7.3 Optimized AVX2 implementation

Intel processors since the “Sandy Bridge” generation support Advanced Vector Extensions (AVX) that operate on vectors of 8 single-precision or 4 double-precision

floating-point values in parallel. With the introduction of the “Haswell” generation of CPUs, this support was extended also to 256-bit vectors of integers of various sizes (AVX2). It is not surprising that the enormous computational power of these vector instructions has been used before to implement very high-speed crypto (see, for example, [14, 16, 43]) and also our optimized reference implementation targeting Intel Haswell processors uses those instructions to speed up multiple components of the key exchange.

NTT optimizations. The AVX instruction set has been used before to speed up the computation of lattice-based cryptography, and in particular the number-theoretic transform. Most notably, Güneysu, Oder, Pöppelmann and Schwabe achieve a performance of only 4480 cycles for a dimension-512 NTT on Intel Sandy Bridge [46]. For arithmetic modulo a 23-bit prime, they represent coefficients as double-precision integers.

We experimented with multiple different approaches to speed up the NTT in AVX. For example, we vectorized the Montgomery arithmetic approach of our C reference implementation and also adapted it to a 32-bit-signed-integer approach. In the end it turned out that floating-point arithmetic beats all of those more sophisticated approaches, so we are now using an approach that is very similar to the approach in [46]. One computation of a dimension-1024 NTT takes 8448 cycles, unlike the numbers in [46] this does include multiplication by the powers of γ and unlike the numbers in [46], this excludes a bit-reversal.

Fast sampling. Intel Haswell processors support the AES-NI instruction set and for the local choice of noise sampling it is obvious to use those. More specifically, we use the public-domain implementation of AES-256 in counter mode written by Dolbeau, which is included in the SUPERCOP benchmarking framework [17]. Transformation from uniform noise to the centered binomial is optimized in AVX2 vector instructions operating on vectors of bytes and 16-bit integers.

For the computation of SHAKE-128 we use the same code as in the C reference implementation. One might expect that architecture-specific optimizations (for example, using AVX instructions) are able to offer significant speedups, but the benchmarks of the eBACS project [17] indicate that on Intel Haswell, the fastest implementation is the “simple” implementation by Van Keer that our C reference implementation is based on. The reasons that vector instructions are not very helpful for speeding up SHAKE (or, more generally, Keccak) are the inherently sequential nature and the 5×5 dimension of the state matrix that makes internal vectorization hard.

Error recovery. The 32-bit integer arithmetic used by the C reference implementation for HelpRec and Rec

is trivially 8-way parallelized with AVX2 instructions. With this vectorization, the cost for HelpRec is only 3404 cycles, the cost for Rec is only 2804 cycles.

8 Benchmarks and comparison

In the following we present benchmark results of our software. All benchmark results reported in Table 2 were obtained on an Intel Core i7-4770K (Haswell) running at 3491.953 MHz with Turbo Boost and Hyperthreading disabled. We compiled our C reference implementation with `gcc-4.9.2` and flags `-O3 -fomit-frame-pointer -march=corei7-avx -msse2avx`. We compiled our optimized AVX implementation with `clang-3.5` and flags `-O3 -fomit-frame-pointer -march=native`.

As described in Section 7, the sampling of \mathbf{a} is not running in constant time; we report the median running time and (in parentheses) the average running time for this generation, the server-side key-pair generation and client-side shared-key computation; both over 1000 runs. For all other routines we report the median of 1000 runs. We built the software from [20] on the same machine as ours and—like the authors of [20]—used `openssl speed` for benchmarking their software and converted the reported results to approximate cycle counts as given in Table 2.

Comparison with BCNS and RSA/ECDH. As previously mentioned, the BCNS implementation [20] also uses the dimension $n = 1024$ but the larger modulus $q = 2^{32} - 1$ and the Gaussian error distribution with Gaussian parameter $\sigma = 8/\sqrt{2\pi} = 3.192$. When the authors of BCNS integrated their implementation into SSL it only incurred a slowdown by a factor of 1.27 compared to ECDH when using ECDSA signatures and a factor of 1.08 when using RSA signatures with respect to the number of connections that could be handled by the server. As a reference, the reported cycle counts in [20] for a `nistp256` ECDH on the client side are 2 160 000 cycles (0.8 ms @2.77 GHz) and on the server side 3 221 288 cycles (1.4 ms @2.33 GHz). These numbers are obviously not state of the art for ECDH software. Even on the `nistp256` curve, which is known to be a far-from-optimal choice, it is possible to achieve cycle counts of less than 300 000 cycles for a variable-basepoint scalar multiplication on an Intel Haswell [44]. Also OpenSSL optionally includes fast software for `nistp256` ECDH by Kasper and Langley and we assume that the authors of [20] omitted enabling it. Compared to BCNS, our C implementation is more than 8 times faster and our AVX implementation even achieves a speedup factor of more than 27. At this performance it is in the same ballpark as state-of-the-art ECDH software, even when TLS switches to faster 128-bit secure ECDH key exchange

Table 2: Intel Haswell cycle counts of our proposal as compared to the BCNS proposal from [20].

Key gen + shared key (client)	≈ 3995977	384994 (385146)	110986 (111169)
Shared key (server)	≈ 481937	86280	19422

^a Includes reading a seed from `/dev/urandom`

^b Includes one bit reversal

^c Excludes reading a seed from `/dev/urandom`, which is shared across multiple calls to the noise generation

based on Curve25519 [11], as recently specified in RFC 7748 [59].

In comparison to the BCNS proposal we see a large performance advantage from switching to the binomial error distribution. The BCNS software uses a large pre-computed table to sample from a discrete Gaussian distribution with a high precision. This approach takes 1042700 cycles to samples one polynomial in constant time. Our C implementation requires only 32684 cycles to sample from the binomial distribution. Another factor is that we use the NTT in combination with a smaller modulus. Polynomial multiplication in [20] is using Nussbaumer’s symbolic approach based on recursive negacyclic convolutions [76]. The implementation in [20] only achieves a performance of 342800 cycles for a constant-time multiplication. Additionally, the authors of [20] did not perform pre-transformation of constants (e.g., \mathbf{a}) or transmission of coefficients in FFT/Nussbaumer representation.

Follow-Up Work. We would like to refer the reader to follow-up work in which improvements to NEWHOPE and its implementation were proposed based on a preprint version of this work [4]. In [45] Gueron and Schlieker introduce faster pseudorandom bytes generation by changing the underlying functions, a method to decrease the rejection rate during sampling (see Section 7.1), and a vectorization of the sampling step. Longa and Naehrig [64] optimize the NTT and present new modular reduction techniques and are able to achieve a speedup of factor-1.90 for the C implementation and a factor-1.25 for the AVX implementation compared to the preprint [4] (note that this version has updated numbers).

An alternative NTRU-based proposal and implementation of a lattice-based public-key encryption scheme, which could also be used for key exchange, is given by Bernstein, Chuengsatiansup, Lange, and van Vredendaal in [15], but we leave a detailed comparison to future work. An efficient authenticated lattice-based key exchange scheme has recently been proposed by del Pino, Lyubashevsky, and Pointcheval in [30].

Abstract

Incorrect error handling in security-sensitive code often leads to severe security vulnerabilities. Implementing correct error handling is repetitive and tedious especially in languages like C that do not support any exception handling primitives. This makes it very easy for the developers to unwittingly introduce error handling bugs. Moreover, error handling bugs are hard to detect and locate using existing bug-finding techniques because many of these bugs do not display any obviously erroneous behaviors (*e.g.*, crash and assertion failure) but cause subtle inaccuracies.

In this paper, we design, implement, and evaluate EPEX, a tool that uses error specifications to identify and symbolically explore different error paths and reports bugs when any errors are handled incorrectly along these paths. The key insights behind our approach are: (i) real-world programs often handle errors only in a limited number of ways and (ii) most functions have simple and consistent error specifications. This allows us to create a simple oracle that can detect a large class of error handling bugs across a wide range of programs. We evaluated EPEX on 867,000 lines of C Code from four different open-source SSL/TLS libraries (OpenSSL, GnuTLS, mbedTLS, and wolfSSL) and 5 different applications that use SSL/TLS API (Apache httpd, cURL, Wget, LYNX, and Mutt). EPEX discovered 102 new error handling bugs across these programs—at least 53 of which lead to security flaws that break the security guarantees of SSL/TLS. EPEX has a low false positive rate (28 out of 130 reported bugs) as well as a low false negative rate (20 out of 960 reported correct error handling cases).

1 Introduction

Error handling is an important aspect of software development. Errors can occur during a program’s exe-

cution due to various reasons including network packet loss, malformed input, memory allocation failure, *etc.* Handling these errors correctly is crucial for developing secure and robust software. For example, in case of a recoverable error, a developer must ensure that the affected program invokes the appropriate error recovery code. In contrast, if an error is critical, the program must display an appropriate error message and fail in a safe and secure manner. Error handling mistakes not only cause incorrect results, but also often lead to security vulnerabilities with disastrous consequences (*e.g.*, CVE-2014-0092, CVE-2015-0208, CVE-2015-0288, CVE-2015-0285, and CVE-2015-0292). More worryingly, an attacker can often remotely exploit error handling vulnerabilities by sending malformed input, triggering resource allocation failures through denial-of-service attacks *etc.*

To understand how incorrect error handling can lead to severe security vulnerabilities in security-sensitive code, consider the bug in GnuTLS (versions before 3.2.12), a popular Secure Sockets Layer (SSL) and Transport Layer Security (TLS) library used for communicating securely over the Internet, that caused CVE-2014-0092. Listing 1 shows the relevant part of the affected X.509 certificate verification code. The function `_gnutls_verify_certificate2` called another function `check_if_ca` to check whether the issuer of the input certificate is a valid Certificate Authority (CA). `check_if_ca` returns `< 0` to indicate an error (lines 4 and 5 of Listing 1). However, as line 16 shows, `_gnutls_verify_certificate2`, the caller function, only handles the case where the return value is 0 and ignores the cases where `check_if_ca` returns negative numbers as errors. This missing error check makes all applications using GnuTLS incorrectly classify an invalid certificate issuer as valid. This bug completely breaks the security guarantees of all SSL/TLS connections setup using GnuTLS and makes them vulnerable to man-in-the-middle attacks. In summary,

Listing 1: GnuTLS error handling bug (CVE-2014-0092). The lines marked in color gray show an error path and the red lines highlight the source of error handling bug.

```

1 int check_if_ca (...)

2 { ...
3     result = ...;
4     if (result < 0) {
5         goto cleanup;
6     }
7     ...
8     result = 0;
9 }

10 cleanup:
11     return result;
12 }

13 int _gnutls_verify_certificate2 (...)

14 { ...
15     if (check_if_ca (...) == 0) {
16         result = 0;
17         goto cleanup;
18     }
19     ...
20     result = 1;
21 }

22 cleanup:
23     return result;
24 }
```

this bug renders all protections provided by GnuTLS useless.

Developers often introduce error handling bugs unwittingly, as adding error checking code is repetitive and cumbersome (especially in languages like C that do not provide any exception handling primitives). Moreover, a large number of errors in real systems cannot be handled correctly at their source due to data encapsulation and, therefore, must be propagated back to the relevant module. For example, if a protocol implementation receives a malformed packet that cannot be parsed correctly, the parsing error must be appropriately transformed and propagated to the module implementing the protocol state machine in order to ignore the packet and recover gracefully. Implementing correct error propagation in real-world software is non-trivial due to their complex and intertwined code structure.

Automated detection of error handling bugs can help developers significantly improve the security and robustness of critical software. However, there are three major challenges that must be tackled in order to build such a tool: (i) **error path exploration**. Error handling code is only triggered in corner cases that rarely occur during regular execution. This severely limits the ability of dynamic analysis/testing to explore error paths. Moreover, error handling code is usually buried deep inside a program and, therefore, is hard to reach using off-the-shelf symbolic execution tools due to path explosion; (ii) **lack of an error oracle**. Error handling bugs often result

in silent incorrect behavior like producing wrong output, causing memory corruption, *etc.* as shown in the previous example. Therefore, accurately separating incorrect error handling behavior from the correct ones is a hard problem; and (iii) **localizing error handling bugs**. Finally, the effects of error handling bugs are usually manifested far away from their actual sources. Accurately identifying the origin of these bugs is another significant problem.

Our contributions. In this paper, we address all these three problems as discussed below. We design, implement, and evaluate EPEX, a novel algorithm that can automatically detect error-handling bugs in sequential C code.

Identification and scalable exploration of error paths.

As low-level languages like C do not provide any exception handling primitives, the developers are free to use any arbitrary mechanism of their choice for communicating errors. However, we observe that real-world C programs follow simple error protocols for conveying error information across different modules. For example, distinct and non-overlapping integer values are used throughout a C program to indicate erroneous or error-free execution. Integer values like 0 or 1 are often used to communicate error-free execution and negative integers typically indicate errors. Moreover, functions that have related functionality tend to return similar error values. For example, most big number functions in OpenSSL return 0 on error. These observations allow us to create simple error specifications for a given C program, indicating the range of values that a function can return on error. Given such specifications as input, our algorithm performs under-constrained symbolic execution at the corresponding call-sites to symbolically explore only those paths that can return error values and ignores the rest of the paths. Such path filtering minimizes the path exploration problem often plaguing off-the-shelf symbolic execution tools.

Design of an error oracle. We observe that when an error occurs, most C programs usually handle the scenario in one of the following simple ways: (i) propagate an appropriate error value (according to the corresponding error protocol) upstream, (ii) stop the program execution and exit with an error code, or (iii) display/log a relevant error message. We leverage this behavior to create a simple program-independent error oracle. In particular, our algorithm checks whether errors are handled following any of the above three methods along each identified error path; if not, we mark it as a potential bug.

Accurate bug localization. Our error oracle also helps us accurately localize the error handling bugs as it allows our algorithm to detect the bugs at their source. As a side-effect, we can precisely identify buggy error handling code and thus drastically cut down developers' ef-

fort in fixing these bugs.

Implementation and large-scale evaluation. Using our algorithm, we design and implement a tool, EPEX, and evaluate it. EPEX’s analysis is highly parallelizable and scales well in practice. EPEX can be used to find error-handling bugs in any C program as long as the above mentioned assumptions hold true. We evaluated EPEX on a total of 867,000 lines of C code [56] from 4 different open-source SSL/TLS libraries (OpenSSL, GnuTLS, mbedTLS, and wolfSSL) and 5 different applications using SSL/TLS APIs (cURL, Wget, Apache httpd, mutt, and LYNX). EPEX discovered 102 new error handling bugs across these programs—at least 53 of which lead to critical security vulnerabilities that break the security guarantees of SSL/TLS. We also found that EPEX has both low false positive (28 out of 130 reported bugs) and false negative rates (20 out of 960 reported correct error handling cases). Thus, EPEX has a 78% precision and 83% recall on our tested programs. Several of our tested programs (*e.g.*, PolarSSL, cURL, and Apache httpd) have been regularly checked with state-of-the-art static analysis tools like Coverity, Fortify, etc. The fact that none of these bugs were detected by these tools also demonstrates that EPEX can detect bugs that the state-of-the-art bug finding tools miss.

The rest of this paper is organized as follows. We present a brief overview of error handling conventions in C programs in Section 2. We describe our platform- and language-independent technique for detecting error handling bugs in Section 3. The details of implementing our algorithm in Clang and the results are presented in Sections 4 and 5 respectively. We survey the related work in Section 6 and present several directions for future work in Section 7. Section 8 concludes our paper.

2 Error handling in C programs

C does not support exception handling primitives like `try-catch`. In C, a fallible function, which may fail due to different errors, *e.g.*, memory allocation failure or network error, usually communicates errors to the caller function either through return values or by modifying arguments that are passed by reference. While there are no restrictions on the data types/values that can be used to communicate errors, C programmers, in general, create an informal, program-specific error protocol and follow it in all fallible functions of a program to communicate errors. An error protocol consists of a range of error-indicating and non-error-indicating values for different data types. For example, a program may use an error protocol where any negative integer value indicates an error and 0 indicates an error-free execution. Similarly, an error protocol may also use a NULL pointer or a boolean value of `false` to indicate errors. The existence of such

		Error Range	Non-Error Range
Libraries	OpenSSL	$e \leq 0$	$e = 1$
	GnuTLS	$-403 \leq e \leq -1$	$e = 0$
	mbedTLS	$e < 0$	$e = 0$
	wolfSSL	$-213 \leq e \leq -1$	$e \in \{0,1\}$
Applications	httpd [51]	$1 \leq e \leq 720000$	$e = 0$
	curl	$1 \leq e \leq 91$	$e = 0$
	lynx	$-29999 \leq e \leq -1$	$e \geq 0$
	mutt	$e = -1$	$e \geq 0$
	wget	$e = -1$	$e = 0$

e represents the return values of fallible functions

Table 1: Error protocols of the tested libraries/applications

error handling protocols makes it easier for us to create error specifications for different functions of a program.

For example, consider the C programs that we studied in this work. Table 1 shows their error protocols. Fallible functions in OpenSSL usually return 0 or a negative integer to indicate errors and 1 to indicate error-free execution. In contrast, GnuTLS uses negative integers between -1 and -403 to indicate errors and 0 to indicate error-free execution. In spite of the variety of protocols, in all the cases, error-indicating and non-error-indicating ranges for fallible functions do not overlap, to avoid ambiguities.

3 Methodology

In this section, we introduce the details of EPEX (**E**rror **P**ath **E**xplorer), a tool for automatically detecting different types of error handling bugs in sequential C programs. Our key intuition is that if an error is returned by a function in a program path, that error must be handled correctly along that path according to the program’s error convention. Given a function under test, say FT , EPEX identifies possible *error paths*—the paths along which FT returns error values, and ensures that the error values are handled correctly along the error paths at the call site; if not, EPEX reports bugs due to missing error-handling.

3.1 Overview

An overview of EPEX’s workflow for an individual API function is presented in Figure 1. EPEX takes five inputs: the signature of the fallible function under test (FT), the caller functions of FT ($FT_{callers}$), a specification defining a range of error values that FT can return ($FT_{errSpec}$), a range of return values that are used to indicate error-free execution according to the test program’s error protocol ($Global_{nerrSpec}$), and a set of error logging functions used by the program (Loggers). The list of fallible functions,

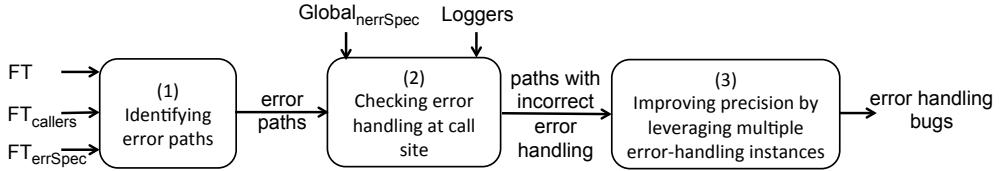

Figure 1: EPEX workflow

their error specifications, and list of error logging functions are created manually, while their caller functions are automatically identified by EPEX. EPEX then works in three steps.

In Step-I, by performing under-constrained symbolic execution at $FT_{callers}$, EPEX identifies the error paths along which FT returns an error value, based on $FT_{errSpec}$. For example, in Listing 1, `check_if_ca`'s error specification says the function will return ≤ 0 on error. Hence, Step-I symbolically executes `_gnutls_verify_certificate2` function and marks the path along the `if` branch in the `check_if_ca` function as an error path (marked in color gray).

Next, in Step-II, EPEX checks if the call site of FT handles the error values correctly. In particular, EPEX checks that if FT returns an error, the error value is handled by the caller in one of the following ways: it (i) pushed the error upstream by returning a correct error value from the caller function, (ii) stopped the program execution with a non-zero error code, or (iii) logged the error by calling a program-specific logging function. If none of these actions take place in an error path, EPEX reports an error handling bug. For instance, in case of Listing 1, the error path returns < 0 at the call site, `_gnutls_verify_certificate2` (line 16). However, the error value is not handled at the call site; in fact it is reset to 1 (line 21), which is a non-error value as per $Global_{nerrSpec}$. Thus, in this case, an error path will return a non-error value. EPEX reports such cases as the potential error-handling bugs (marked in red).

Finally, in Step-III, EPEX checks how error handling code is implemented in other call sites of FT. For example, if all other FT call sites ignore an error value, EPEX does not report a bug even if the error value is not handled properly at the call site under investigation. As $FT_{errSpec}$ may be buggy or symbolic execution engines may be imprecise, this step helps EPEX reduce false positives. The final output of EPEX is a set of program error paths—FT signature, call-site location, and error paths in the caller functions along with EPEX's diagnosis of correct and buggy error handling. We present the detailed algorithm in the rest of this section.

Algorithm 1: EPEX workflow

```

1 EPEX (FT, FTerrSpec, FTcallers, GlobalnerrSpec, Loggers)
Input : function FT, error spec FTerrSpec, callers of FT
        FTcallers, global non-error spec GlobalnerrSpec,
        error logging functions Loggers
Output: Bugs
2
3 Bugs  $\Leftarrow \emptyset$ 
4 shouldHandle  $\Leftarrow \text{False}$ 
5 for each caller  $c \in FT_{callers}$  do
6   for each argument  $a \in c.inputArguments$  do
7     |  $a.isSymbolic \Leftarrow \text{True}$ 
8   end
9   for each path  $p \in c.Paths$  do
10    | isErrPath  $\Leftarrow \text{False}$ 
11    | errPts  $\Leftarrow \emptyset$ 
12    | for each program point  $s \in p$  do
13      |   /* Step-I : identifying error paths */
14      |   | if  $s$  calls FT then
15      |   |   | FTret  $\Leftarrow$  symbolic return value of FT
16      |   |   | isErrPath  $\Leftarrow \text{chkIfErrPath}(FT_{ret},$ 
17      |   |   |   | FTerrSpec)
18      |   |   | if isErrPath = True then
19      |   |   |   | errPts  $\Leftarrow errPts \cup s.location$ 
20      |   |   | end
21      |   | if isErrPath = True then
22      |   |   /* Step-II : checking error Handling */
23      |   |   | isHandled  $\Leftarrow \text{chkErrHandling}(s,$ 
24      |   |   |   | GlobalnerrSpec, Loggers)
25      |   |   | if (isHandled = unhandled) or
26      |   |   |   (isHandled = maybe_handled) then
27      |   |   |   | Bugs  $\Leftarrow Bugs \cup (errPts, isHandled)$ 
28      |   |   | end
29      |   | if (isHandled = handled) or (isHandled =
30      |   |   | maybe_handled) then
31      |   |   |   /* Resetting an error path */
32      |   |   |   | isErrPath  $\Leftarrow \text{False}$ 
33      |   |   |   | errPts  $\Leftarrow \emptyset$ 
34      |   |   | end
35      |   | if (isHandled = handled) then
36      |   |   | shouldHandle  $\Leftarrow \text{True}$ 
37      |   | end
38   end
39 end
40 /* Step-III : Leveraging multiple error-handling instances */
41 if shouldHandle then
42   | return Bugs
43 else
44   | return  $\emptyset$ 
45 end

```

3.2 Step-I: identifying error paths

We define *error paths* to be the program paths in which a function call fails and returns error values. To identify the error paths for a function, EPEX first has to know the error values that a function can return; EPEX takes such information as input (see Section 2 for details). Then the program paths along which the function returns the error values are identified as error paths. The call sites of the failed function are treated as error points (errPts in Algorithm 1). For example, in Listing 1, the program path containing an if-branch (highlighted gray) is an error path; line 16 of `_gnutls_verify_certificate2` is an error point along that error path. Note that an error path can have one or more error points. Given a function under test, say FT, and its caller functions FT_{caller} , the goal of Step-I is to explore all possible error paths going through FT and mark the corresponding error points.

Algorithm 2: Step-I: Identifying error paths

```

1 chkIfErrPath (FTret, FTerrSpec)
  Input : FTret, FTerrSpec
  Output: isErrPath, FTret

2
3 if FTret  $\wedge$  FTerrSpec is satisfiable then
4   /* Error path is possible */
5   if FTret  $\wedge$   $\neg$  FTerrSpec is satisfiable then
6     /* Force the error path, if needed */
7     FTret  $\Leftarrow$  FTret  $\wedge$  FTerrSpec
8   return True
9 else
10  /* Error path is impossible */
11  return False
12 end
```

Exploring error paths. First, EPEX performs under-constrained symbolic execution at each caller function in $FT_{callers}$, and monitors each method call to check if FT is called. If EPEX finds such a call, then right after returning from symbolically executing FT, EPEX checks if the path conditions involving the symbolic return value (FT_{ret}) satisfy its error specifications ($FT_{errSpec}$), as mentioned in the input spec (see Algorithm 2), *i.e.* if $FT_{ret} \wedge FT_{errSpec}$ is satisfiable. This helps EPEX identify two main cases:

- **Error path possible.** If $FT_{ret} \wedge FT_{errSpec}$ is satisfiable, the error path is possible. But while continuing to analyze the error path, EPEX must make sure the constraints make the error path inevitable, so it checks if $FT_{ret} \wedge \neg FT_{errSpec}$ is satisfiable, and if so, sets FT_{ret} to $FT_{ret} \wedge FT_{errSpec}$, so that the constraints force the error path to be taken.
- **Error path impossible.** When $FT_{ret} \wedge FT_{errSpec}$ is unsatisfiable, EPEX considers it as not an error path

and stops tracking it any further.

Algorithm 2 illustrates this process. If a path is considered to be an error path, EPEX notes the corresponding call-site locations in the source code as error points and continues tracking the path in Step-II. In Listing 1, the buggy path has `check_if_ca` return a negative value, which means that it is certainly an error path, and the algorithm returns True, without having to further restrict the constraints.

3.3 Step-II: checking error handling

If a path is marked as an error path in Step-I (*isErrPath* = *True* in Algorithm 1), this step checks whether the error is handled properly along the error path in the caller function. As the symbolic execution engine explores different error paths, we propagate the error path state (*e.g.*, *isErrPath*, FT, and errPts) to any new path forked from conditional branches. We let the rest of the symbolic execution proceed normally unless one of the following happens (see Algorithm 3):

At return point. If EPEX encounters a return statement along an error path, it checks whether the error value is pushed upstream. To do that, Step-II takes program-wide specifications for non-error values ($Global_{nerrSpec}$) as input and checks the constraints on the returned variable of FT_{caller} against $Global_{nerrSpec}$ to determine whether FT_{caller} is returning an error value along the error path. If the returned variable can only contain a non-error value, EPEX marks the corresponding path to be *unhandled*; if it may have a non-error value or an error value, EPEX marks it as *maybe_handled*; and if it cannot have any non-error values, EPEX marks the path as *handled*.

Although both *maybe_handled* and *unhandled* indicate potential bugs, we differentiate between them because in Line 27 of Algorithm 1, we no longer count the path as an error path in the case of *maybe_handled*, since we have already found where the error could be handled; the same error value does not have to be checked repeatedly.

At exit point. A call to libc function `exit` (or other related function like `_exit`) ends the execution of a path. In such a case, EPEX checks the constraints on the symbolic argument to the exit function along an error path: if the symbolic argument can have only error or non-error indicating value, EPEX marks the path as *handled* or *unhandled* respectively. If the argument may have both error and non-error indicating values, EPEX marks the path as *maybe_handled*.

At logging point. The global specifications also support providing the names of the program-specific error logging functions (Loggers). In most C programs, errors are logged through special logging or alerting functions.

If an error path calls an error logging function, EPEX marks that path as *handled*.

In Listing 1, `_gnutls_verify_certificate2` sets `result` to the non-error value, 1, in the error path before returning it, so the algorithm classifies the error as *unhandled*.

Algorithm 3: Step-II: Checking error handling

```

1 chkErrHandling ( $s$ ,  $\text{Global}_{\text{nerrSpec}}$ , Loggers)
  Input : program point  $s$ , global non-error spec
            $\text{Global}_{\text{nerrSpec}}$ , error logging functions Loggers
  Output: isHandled
2
3 if ( $s$  is a top-level ret statement) or ( $s$  is a call to “exit”)
   then
4   |  $tval \leftarrow$  symbolic return value/exit argument
5   | if ( $tval \wedge \text{Global}_{\text{nerrSpec}}$  is satisfiable) and ( $tval \wedge \neg \text{Global}_{\text{nerrSpec}}$  is unsatisfiable) then
6   |   | return unhandled
7   | else if ( $tval \wedge \text{Global}_{\text{nerrSpec}}$  is unsatisfiable) and
     |   ( $tval \wedge \neg \text{Global}_{\text{nerrSpec}}$  is satisfiable) then
8   |   | return handled
9   | else if ( $tval \wedge \text{Global}_{\text{nerrSpec}}$  is satisfiable) and ( $tval \wedge \neg \text{Global}_{\text{nerrSpec}}$  is satisfiable) then
10  |   | return maybe_handled
11 else if  $s \in \text{Loggers}$  then
12   |   return handled
13 return not_checked

```

3.4 Step-III: leveraging multiple error-handling instances

As program documentation may be buggy or symbolic execution engines may be imprecise, EPEX compares the analysis results across multiple callers of the function under test (FT) to minimize false positives. Lines 34 – 45 in Algorithm 1 present this step. If EPEX finds that all the callers of FT return *unhandled* or *maybe_handled*, EPEX ignores the corresponding bugs and does not report them. However, if at least one caller sets *isHandled* to *handled*, all the buggy paths marked from Step-II (line 25 in Algorithm 1) will be reported as bugs. The underlying idea behind this step is inspired by the seminal work of Engler *et al.* [16] where deviant behaviors were shown to indicate bugs.

For example, function `gnutls_x509_trust_list_add_trust_file` adds each Certificate Authority (CA) mentioned in the input file to the list of trusted CAs. In an error-free execution, it returns the number of added CAs. It returns a negative number in case of a parsing error. However, in all the 5 instances in GnuTLS where `gnutls_x509_trust_list_add_trust_file` is called, step II indicates that error values are not handled correctly. In such cases, Step III assumes that the error values can be safely ignored and does not

report any bugs. With manual analysis we confirmed that as trusted certificate authorities can be loaded from multiple sources, such errors can indeed be ignored safely.

4 Implementation

EPEX is implemented using the Clang static analysis framework [42] (part of the LLVM project) and its underlying symbolic execution engine. The Clang analyzer core symbolically explores all feasible paths along the control flow graph of an input program and provides a platform for custom, third-party *checkers* to monitor different paths, inspect the constraints of different symbolic values along those paths, and add additional constraints if necessary. A typical checker often looks for violations of different invariants along a path (*e.g.*, division by zero). In case of a violation, the checker reports bugs. We implement EPEX as a checker inside the Clang analyzer. The rest of this section describes how EPEX is implemented as a Clang checker in detail.

Error specifications. EPEX takes a text file containing the per-function error specifications ($\text{FT}_{\text{errSpec}}$), global non-error specification ($\text{Global}_{\text{nerrSpec}}$), and global error specification ($\text{Global}_{\text{errSpec}}$) as input. Listing 2 shows a sample input file. $\text{FT}_{\text{errSpec}}$ contains five parameters: \langle function name, number of arguments, return type, lower bound of error value, upper bound of error value \rangle . The first three parameters define a function signature. The number of arguments and return type (*e.g.*, integer, boolean, *etc.*) help to disambiguate functions with identical names. The last two optional parameters represent a range of error values that the function can return. For example, error specification for function `RAND_bytes` is: \langle `RAND_bytes`, 2, int, $\geq -1, \leq 0$ \rangle (see line 2 in Listing 2). This shows `RAND_bytes` takes 2 input arguments and returns an integer value. The fourth and fifth parameters indicate that error values range from -1 to 0 . Similarly, if a function `foo` takes four arguments and it has a boolean return type where `False` indicates an error, its error spec will be \langle `foo`, 4, bool, `=False` \rangle . We also support specifications for functions returning `NULL` pointers to indicate errors.

Since most functions in a project follow the same global error convention, (*e.g.*, most OpenSSL functions return 0 to indicate error), error specifications can be simplified by providing a global lower and upper bound of errors. If the per-function error spec does not contain any error range, *i.e.* the fourth and fifth parameters are empty, the checker uses $\text{Global}_{\text{errSpec}}$. Otherwise, the function-specific bounds override $\text{Global}_{\text{errSpec}}$. For instance, OpenSSL functions `RAND_bytes` and `RAND_pseudo_bytes` specify custom lower and upper bounds $-1 \leq$ and \leq

Listing 2: Sample error specifications for OpenSSL functions

```

1  /* Per-func error spec */
2  RAND_bytes, 2, int, >=-1, <=0
3  RAND_pseudo_bytes, 2, int, >=-1, <=0
4
5  /* Per-func spec with empty error ranges
6  (global error ranges will be used) */
7  ASN1_INTEGER_set_int64, 2, int
8  ASN1_INTEGER_set, 1, int
9
10 /* Global error spec */
11 __GLOBAL_ERROR_BOUND__, int, =0, NA
12
13 /* Global non-error spec */
14 __GLOBAL_NOERR_VAL__, int, =1
15 __GLOBAL_NOERR_VAL__, ptr, !=NULL

```

0 respectively, and hence global error bounds are not valid for them. Finally, $\text{Global}_{nerr\text{Spec}}$ contains non-error bounds/values for functions with different return types (see lines 14 and 15 of Listing 2). For example, $\langle \text{__GLOBAL_NOERR_VAL}, \text{int}, = 1 \rangle$ indicates that any function with integer return type returns 1 to indicate an error-free execution. Similarly, $\langle \text{__GLOBAL_NOERR_VAL}, \text{ptr}, !=\text{NULL} \rangle$ indicates an error-free execution for the functions returning pointers will result in the return pointer to be non-null. Such $\text{Global}_{nerr\text{Spec}}$ specifications are used to ensure that the return value of the caller function of FT is pushing the errors upstream correctly.

The error specifications for all the functions under test were created manually. Since, a majority of these functions either follow the per-project global error convention or, at least, functions inside same modules have the same error ranges, *e.g.*, all the big number routines in OpenSSL return 0 on error, the overhead of manual spec generation is not very significant. In fact, it took only one man-day to generate error specs for all 256 functions that we have examined. Table 2 shows the number of specified functions for each library, and the number of unique specifications. Except for WolfSSL, where we used more individualized specifications, each library contained no more than 10 unique error specifications, so that we were able to generate 256 specifications out of only 38 unique constraints.

Table 2: Error specification counts

Library	Functions	Unique Specifications
OpenSSL	109	9
GnuTLS	58	3
mbedTLS	46	10
wolfSSL	43	16
Total	256	38

As the same set of library functions are used by multiple applications, the same error specifications can be reused for all such applications. In fact, for our test

applications, we focused on only OpenSSL API functions. We also found that fallible functions that return booleans or pointers, irrespective of the library they belong to, mostly indicate errors by returning `false` and `NULL` respectively. For functions returning integer error codes, we found that the error codes were almost always represented by a macro or enumerated type that is defined in a header file and therefore was very easy to find. Functions that use the same enumerated type/macro tend to follow the same error protocol. We show some sample error specifications for OpenSSL API functions in Listing 2.

Note that once the error specifications for a set of API functions are created manually, testing new applications using the same API is very easy; the user only needs to add application-specific non-error values (*i.e.* the values indicating error-free execution) for each new application.

Identifying error paths. For identifying error paths, as mentioned in Step-I of Section 3, EPEX checker uses the built-in callback method `checkPostCall`. `checkPostCall` is called once the analyzer core finishes tracking each function body. We overrode `checkPostCall` so that it looks for the functions mentioned in the error spec, *i.e.* checks whether the current function's name, number of arguments, and return type match the specification. In case of a match, Algorithm 2 is called to check whether the function's return value satisfies the lower and upper bounds of error values as given in its error spec; if so, the current path is marked as error path.

Checking error handling. We implemented Step-II by extending the `checkPreStmt` callback method for checking the program state before `return` statements and the `checkPreCall` callback for checking the program state before calling exit functions or any program-specific error logging functions as specified in the input spec. Inside `checkPreStmt` callback, EPEX checks whether the symbolic return value satisfies the global non-error spec (see Algorithm 3). A similar check is performed for exit functions inside `checkPreCall`.

To check the satisfiability conditions of Algorithm 2 and Algorithm 3, we use Clang's built-in constraint solver.

Outputs. EPEX can be run on any single source file (say, `foo.c`) using the command `clang -cc1 -analyze -analyzer-checker=EPEX foo.c`. For running it on large projects like OpenSSL, mbedTLS, etc. we used Clang's `scan-build` utility such that EPEX can be run as part of the regular build process. Scan-build overrides different environment variables (*e.g.*, CC, CPP) to force the build system (*e.g.*, `make`) to use a special compiler script that compiles the input source file and invokes EPEX on it. We pass the `-analyze-header` option to the clang analyzer

core to ensure that the functions defined in any included header files are also analyzed.

The output of EPEX contains one line for each analyzed error path, as shown in Table 3. Each line in the output has four components: name of the caller function, call-site of FT, candidate error-handling location (*i.e.* return instruction, exit call or error logging), and EPEX’s diagnosis about whether the error has been handled correctly or not. As each output line represents an error path and multiple error paths may pass through the same call-site, a call-site for a given FT might be repeated in the output. For example, lines 1 and 2 in Table 3 have the same call-site (ssl_lib.c:1836) but their error handling locations are different (ssl_lib.c:1899 and ssl_lib.c:1905 respectively). Note that we implement Step-III as a separate script and execute it on the output of EPEX before producing the final bug report.

Table 3: Sample EPEX output for OpenSSL function under test: RAND_pseudo_bytes.

Caller Function	Call-site	Error Handling Location	Diagnosis
SSL_CTX_new	ssl_lib.c:1836	ssl_lib.c:1899	handled
SSL_CTX_new	ssl_lib.c:1836	ssl_lib.c:1905	unhandled
dtls1_send_netsession_ticket	d1_srvr.c:1683	d1_srvr.c:1736	maybe_handled

5 Results

5.1 Study subjects

To check whether errors are handled correctly in different functions of popular SSL/TLS libraries as well as applications using them, we ran EPEX on four libraries: OpenSSL, GnuTLS, mbedTLS (formerly known as PolarSSL), and wolfSSL (formerly known as cyaSSL), and five applications that use OpenSSL: cURL, mod_ssl of the Apache HTTP server, Lynx, Mutt, and Wget (see Table 4). For the libraries, we primarily focused on the source files implementing core functionality (*e.g.*, src, lib sub-directories, *etc.*) as opposed to the test files, as detecting bugs in the test code may not be a high priority. All the applications but the HTTP server were small enough to run EPEX on the entire program, although it eventually only produced results for the source files that used the OpenSSL library. For Httpd we only checked mod_ssl. The second column of Table 4 shows the modules investigated by EPEX for each tested library.

For each library, we generate a call graph using a tool named `GNU cflow`¹. From the call graph, we choose top functions that are frequently called by other functions within the same library. Note that here we did not distinguish between internal library functions and

library functions exposed to the outer world as APIs. We further filtered out functions based on their return types—functions returning integer, boolean, and pointers are chosen because Clang’s symbolic analysis engine can currently only handle these types. In addition, we only selected those functions that can fail and return at least one error value. For the applications, we tested all the OpenSSL APIs that the applications are using. We found such APIs by simply using `grep`. Further, we only chose those APIs for which documentations are available, and the APIs that could return errors as integers, booleans or pointers. The third column of Table 4 shows the number of functions tested for a studied program.

Table 4: Study subjects

Projects	Modules	#Functions tested	#Call sites	#Error paths
OpenSSL v1.0.1p	ssl, crypto	46	507	3171

5.2 General findings

We evaluated EPEX on 195 unique program-API function pairs from 2207 call-sites, and covered 18005 error paths (see Table 4). EPEX found 102 new error-handling bugs from 4 SSL/TLS libraries and 5 applications: 48 bugs in OpenSSL, 23 bugs in GnuTLS, 19 bugs in mbedTLS, and 0 bugs in wolfSSL, 2 in cURL, 7 in httpd, 1 in Lynx, 2 in Mutt, and 0 in Wget (see Table 5). We evaluate EPEX’s performance after completion of Step-II and Step-III separately. Since we are using recent versions of real code, and finding all potential bugs in such code is an extremely difficult problem, we do not have a ground truth for bugs against which to compare the reports. Also, EPEX is not designed to detect all types of error handling bugs. For this paper, we define a bug to be any error path whose output behavior is identical to that of a non-error path, *e.g.*, no logging takes place and the same values as in the non-error paths are propagated upwards through all channels. Thus, for counting false positives and negatives, we do not consider bugs due to incomplete handling, for example, where failures are only logged, but the required cleanup is missing. Table 5 presents the detailed result. After Step-II, EPEX reported 154 bugs in the library code and 29 bugs in the application code. After a manual investigation, we found 61 of them to be false positives. Step-III reduced this false positive to 28 out of 130 reported bugs (106 in library and 24 in application code). Thus, overall, EPEX

¹<http://www.gnu.org/software/cflow/>

detected bugs with 84% precision in the library code and 50% precision in the application code with an overall precision of 78%.

In general, measuring false negatives for static analysis tools is non-trivial as it is hard to be confident about the number of bugs present in the code at any given point of time. However, for the sake of completeness, we checked false negatives by randomly selecting 100 cases at the end of Step-II, where EPEX confirmed that error handling was indeed implemented correctly. We did not find any false negatives in any of those examples, *i.e.* we did not find any bugs that were filtered out at Step-II. However, after Step-III’s optimization, among the bugs that did pass Step-II, we found 15 and 5 false negatives in Library and Application code respectively. Thus, the overall recall of EPEX was approximately 83%.

Table 5: Evaluation of EPEX

Step II		Step III		Summary	
Reported Bugs	False +ve	Reported Bugs	False +ve	True Bugs	Precision
Library					
OpenSSL	51	2	50	2	48 0.96
GnuTLS	41	15	25	1	23 0.96
mbedTLS	35	16	21	2	19 0.90
WolfSSL	27	7	10	2	0 0.80
Total	154	40	106	16	90 0.84
Application

Wget	2	1	1	1	0 0.00
Total	29	12	24	12	12 0.50
Grand Total	183	52	130	28	102 0.78

In general, EPEX performs better for libraries than applications. There are three main reasons behind this: (i) unlike libraries, applications’ error handling behavior is heavily dependent on their configuration parameters. For example, users can configure the applications to ignore certain errors. EPEX currently cannot differentiate between paths that have different values for these configuration parameters; (ii) Applications are more likely to use complex data types (*e.g.*, error code is embedded within an object) for propagating errors than libraries that are not currently supported by EPEX; and (iii) Applications prioritize user experience over internal consistency, so if the error is recoverable, they will attempt to use a fallback non-error value instead. However, none of these are fundamental limitations of our approach. EPEX can be enhanced to support such cases and improve its accuracy for applications too.

In the following section, we discuss the nature of the detected bugs and the vulnerabilities caused by them in detail with code examples from libraries in Section 5.3 and from applications in Section 5.4. All the described

bugs have been reported to the developers, who, for almost all cases, have confirmed and agreed that they should be fixed.

5.3 Bugs in libraries

From the four SSL/TLS libraries that we tested, we describe seven selected examples. They arise due to various reasons including ignoring error codes, missing checks for certain error codes, checking with a wrong value, and propagating incorrect error values upstream. These bugs affect different modules of the SSL/TLS implementations, and at least 42 of them result in critical security vulnerabilities by completely breaking the security guarantees of SSL/TLS, as discussed below.

Incorrect random number generation. EPEX found 21 instances in OpenSSL where callers of the function `RAND_pseudo_bytes` do not implement the error handling correctly. We provide two such examples below. `RAND_pseudo_bytes` returns cryptographically secure pseudo-random bytes of the desired length. An error-free execution of this function is extremely important to OpenSSL as the security guarantees of all cryptographic primitives implemented in OpenSSL depend on the unpredictability of the random numbers that `RAND_pseudo_bytes` returns. The cryptographically secure random numbers, as returned by `RAND_pseudo_bytes`, are used for diverse purposes by different pieces of OpenSSL code, *e.g.*, creating initialization vectors (IVs), non-repeatable nonces, cryptographic keys. In case of a failure, `RAND_pseudo_bytes` returns 0 or -1 to indicate any error that makes the generated random numbers insecure and unsuitable for cryptographic purposes.

Example 1.

```

1 int PEM_ASN1_write_bio(...)
2 {
3     int ret = 0;
4     ...
5     /* Generate a salt */
6     if (RAND_pseudo_bytes(iv, enc->iv_len) <
7         0)
8         goto err;
9     ...
10    ret = 1;
11    err:
12    OPENSSL_cleanse(iv, sizeof(iv));
13    ...
14    return ret;
15 }
```

Example 2.

```

1 int bnrand(...)
2 {
3     int ret = 0;
4     ...
5     if (RAND_pseudo_bytes(buf, bytes) == -1)
6         goto err;
7     ...
8     ret = 1;
9     err:
10    ...
11    return ret;
12 }
```

The above code shows two examples of incorrect error handling at different call-sites of `RAND_pseudo_bytes` in OpenSSL code. In **Example 1**, function `PEM_ASN1_write_bio` checks only if < 0 , but not if $= 0$. In **Example 2**, function `bnrand` only checks for the -1 value but not for the 0 value. `bnrand` is used by all bignum routines, which are in turn used for key generation by many cryptographic implementations like RSA. These bugs completely break the security guarantees of any cryptographic implementations (RSA, AES, *etc.*) and security protocol implementations (*e.g.*, SSL/TLS, SMIME, *etc.*) in OpenSSL that use such buggy code for random number generation. An attacker can leverage these bugs to launch man-in-the-middle attacks on SSL/TLS connections setup using OpenSSL.

The sources of errors in random number generation functions are diverse and depend on the underlying random number generation mechanism (see Listing 3 in the Appendix for a sample random number generation implementation in OpenSSL). For example, an error can occur due to memory allocation failures or module loading errors. Note that some of these failures can be triggered remotely by an attacker through denial-of-service attacks. Thus, if the errors are not handled correctly, an attacker can break the security guarantees of different cryptographic primitives by making them use insecure random numbers. We have received confirmation from OpenSSL developers about these issues.

Incorrect cryptography implementations. Here, we exhibit an example from OpenSSL demonstrating an error handling bug that EPEX found in the implementation of a cryptographic algorithm.

Insecure SRP keys. EPEX found that the function `SRP_Calc_server_key`, which is part of the SRP (Secure Remote Password) module in OpenSSL, contains an error handling bug while calling `BN_mod_exp`, as shown in the code below.

```

1  BIGNUM *SRP_Calc_server_key(BIGNUM *A,
2      BIGNUM *v,
3      BIGNUM *u, BIGNUM *b, BIGNUM *N)
4  {
5      BIGNUM *tmp = NULL, *S = NULL;
6      BN_CTX *bn_ctx;
7      ...
8      if ((bn_ctx = BN_CTX_new()) == NULL ||
9          (tmp = BN_new()) == NULL ||
10         (S = BN_new()) == NULL)
11         goto err;
12     if (!BN_mod_exp(tmp, v, u, N, bn_ctx))
13         goto err;
14     ...
15   err:
16     BN_CTX_free(bn_ctx);
17     BN_clear_free(tmp);
18     return S;
19 }
```

The `BN_mod_exp` function takes four big numbers (arbitrary-precision integers) `tmp`, `v`, `u`, `N`, and a context

`bn_ctx` as input. It then computes `v` raised to the u^{th} power modulo `N` and stores it in `tmp` (*i.e.* $tmp = v^u \% N$). However, `BN_mod_exp` can fail for different reasons including memory allocation failures. It returns 0 to indicate any such error. The call-site of `BN_mod_exp` (line 12), in fact, correctly checks for such an error and jumps to the error handling code at line 15. The error handling code frees the resources and returns `S` (line 18). However, `S` is guaranteed to be not NULL at this point as it has been allocated by calling a `BN_new` function at line 9. This leads `SRP_Calc_server_key` to return an uninitialized big number `S`. Thus, the functions upstream will not know about the error returned by `BN_mod_exp`, as `SRP_Calc_server_key` is supposed to return a NULL pointer in case of an error. This leads to silent data corruption that can be leveraged to break the security guarantees of the SRP protocol.

Incorrect X.509 certificate revocation. Here we cite two examples from mbedTLS and GnuTLS respectively showing different types of incorrect error handling bugs in implementations of two different X509 certificate revocation mechanisms: CRL (Certificate Revocation List) and OCSP (Online Certificate Status Protocol).

CRL parsing discrepancy. In mbedTLS, EPEX found that `x509_crl_get_version`, which retrieves the version of a X509 certificate revocation list, has an error handling bug while calling function `asn1_get_int` (line 7 in the code below). Function `asn1_get_int` reads an integer from an ASN1 file. It returns different negative values to indicate different errors. In case of a malformed CRL (Certificate Revocation List) file, it returns `POLARSSL_ERR ASN1_UNEXPECTED_TAG` error value. In case of such an error, line 9-13 treats the CRL version as 0 (version 1). Thus, mbedTLS parses a malformed CRL file as version 1 certificate. However, other SSL implementations (*e.g.*, OpenSSL) treat these errors differently and parse it as a version 2 certificate. We are currently discussing the exploitability of this inconsistency with the developers.

```

1  int x509_crl_get_version(unsigned char **p,
2                           const unsigned char
3                           *end,
4                           int *ver )
5  {
6      int ret;
7      if((ret = asn1_get_int(p, end, ver))!= 0)
8      {
9          if( ret ==
10             POLARSSL_ERR ASN1_UNEXPECTED_TAG )
11          {
12              *ver = 0;
13              return(0);
14          }
15      }
16      return(POLARSSL_ERR_X509_INVALID_VERSION +
17      ret);
18  }
19  return( 0 );
```

Incorrect OCSP timestamps. GnuTLS function `gnutls_ocsp_resp_get_single` is used to read the timestamp of an Online Certificate Status Protocol (OCSP) message along with other information. EPEX found an error handling bug in it while calling function `asn1_read_value`, as shown in line 5 in the following code. `asn1_read_value` reads the value of an ASN1 tag. It returns an error while failing to read the tag correctly. `gnutls_ocsp_resp_get_single` correctly checks for the error conditions (line 6), but instead of returning an error value, simply sets the `this_update` parameter to `-1`. However, further upstream, in `check_ocsp_response`, which calls the function `gnutls_ocsp_resp_get_single` (line 16), the corresponding variable `vtime` is not checked for an error value; only the return value is checked, but that is a non-error value. Further down the function, at line 22, `vtime` is used to check whether the message is too old. However, in the error path, since `vtime` is set to `-1` from line 7, the left-hand side of the conditional check will always be a positive number. Due to a large value of the variable `now` (representing current time), the conditional check will always be positive, and result in categorizing all messages to be over the OCSP validity threshold irrespective of their actual timestamp. Depending on the configuration of GnuTLS, this may result in ignoring new OCSP responses containing information on recently revoked certificates.

```

1 int
2 gnutls_ocsp_resp_get_single (... , time_t *
3   this_update)
4 {
5   ...
6   ret = asn1_read_value(resp->basicresp,
7     name, ttime, &len);
8   if (ret != ASN1_SUCCESS) {
9     *this_update = (time_t) (-1);
10  }
11  ...
12  return GNUTLS_SUCCESS;
13 }
14 static int
15 check_ocsp_response(... )
16 {
17   ...
18   ret = gnutls_ocsp_resp_get_single(... , &
19     vtime);
20   if (ret < 0) {
21     ...
22     if ((now - vtime >
23       MAX_OCSP_VALIDITY_SECS) {
24     }
25   }
26 }
```

Incorrect protocol implementations. Here we show two examples from OpenSSL where error handling bugs occur in implementations of two different protocols: Secure/Multipurpose Internet Mail Extensions (S/MIME) and Datagram Transport Layer Security (DTLS).

Faulty parsing of X.509 certificates in S/MIME

EPEX found that the OpenSSL function `cms_SignerIdentifier_cert_cmp` does not check the return value returned by function `X509_get_serialNumber`, as shown in the code below. This code is part of the OpenSSL code that handles S/MIME v3.1 mail. Here, the error point (see line 6) is at the call site of `X509_get_serialNumber`, which returns a pointer to the `ASN1_INTEGER` object that contains the serial number of the input `x509` certificate. However, in case of a malformed certificate missing the serial number, `X509_get_serialNumber` returns `NULL` to indicate an error. In this case, the caller function `cms_SignerIdentifier_cert_cmp` does not check for an error and passes the return value directly to `ASN1_INTEGER_cmp`. Thus, the second argument of `ASN1_INTEGER_cmp` (y in line number 12) is set to `NULL`, in the case of an error. At line 16, `ASN1_INTEGER_cmp` tries to read `y->type` and causes a `NULL` pointer dereference and results in a crash. This can be exploited by a remote attacker to cause a denial of service attack by supplying malformed X.509 certificates. This issue was confirmed by the corresponding developers but they believe that that it is up to the application programmer to ensure that the input certificate is properly initialized.

```

1 int cms_SignerIdentifier_cert_cmp(
2   CMS_SignerIdentifier *sid, X509 *cert)
3 {
4   if (sid->type ==
5     CMS_SIGNERINFO_ISSUER_SERIAL) {
6     ...
7     return ASN1_INTEGER_cmp(serialNumber,
8       X509_get_serialNumber(cert));
9   }
10  ...
11  return -1;
12 }
13 int ASN1_INTEGER_cmp(const ASN1_INTEGER *x,
14   const ASN1_INTEGER *y)
15 {
16   int neg = x->type & V ASN1 NEG;
17   /* Compare signs */
18   if (neg != (y->type & V ASN1 NEG)) {
19     ...
20   }
21   ...
22 }
```

Faulty encoding of X.509 certificates in DTLS. EPEX found that the function `dtls1_add_cert_to_buf` that reads a certificate from DTLS² handshake message contains an error handling bug while calling `i2d_X509` (line 8 in the code below). Function `i2d_X509` encodes the input structure pointed to by `x` into DER format. It returns a negative value to indicate an error, otherwise it returns the length of the encoded data. Here, the caller code (line 8) does not check for error cases, and thus gives no indication of whether the read data was valid or not. In case of an error, this will lead to incorrect results and silent data corruption.

²Datagram Transport Layer Security: a protocol in SSL/TLS family

```

1 static int dtls1_add_cert_to_buf(BUF_MEM *
2     buf, unsigned long *l, X509 **x)
3 {
4     int n;
5     unsigned char *p;
6     ...
7     p = (unsigned char *) &(buf->data[*l]);
8     l2n3(n, p);
9     i2d_X509(x, &p);
10    *l += n + 3;
11 }
12 }
```

5.4 Bugs in applications

Beside libraries, we used EPEX to evaluate error handling implementations in application software that use SSL/TLS library APIs. We have performed tests on 5 programs that use the OpenSSL library: cURL³, httpd⁴, Lynx⁵, Mutt⁶, and Wget⁷. Our error specification included 29 OpenSSL APIs that are used by at least one of these applications. As the results show in Table 5, even though EPEX is not as accurate for applications as for libraries, and we had to discard 2 alerts because the callers did not follow the error protocol, it still found 12 real bugs.

In case of applications, unlike libraries, Step-III of EPEX was able to compare error behavior across multiple applications and libraries that use the same API. This allowed us to detect bugs in the cases where an application developer has consistently made error handling mistakes for an API function as long as other applications using the same API function are correctly handling the errors.

In terms of security effects, the bugs that we found range from causing serious security vulnerabilities to denial-of-service attacks. We found 2 bugs in cURL random number generation modules that can be exploited to make cURL vulnerable to man-in-the-middle attacks. We also found 4 bugs in httpd, Mutt, and Lynx that will cause denial-of-service attacks. The other bugs that we found mostly lead to resource leakage. We provide one example of the cURL random number generation bug below.

cURL ignores the return value of the Pseudorandom number generator RAND_bytes. In case of an error, RAND_bytes will return an output buffer with non-random values. In that case cURL will use it for generating SSL session keys and other secrets. Note that a failure in RAND_bytes can be induced by an attacker by launching a denial of service attack and causing memory allocation failures, file descriptor exhaustion, *etc.*

```

1 int Curl_oss1_random(struct SessionHandle *
2     data, unsigned char *entropy,
3     size_t length)
4 {
5     ...
6     RAND_bytes(entropy, curlx_uztosi(length));
7     return 0; /* 0 as in no error */
8 }
```

5.5 Checking for correct error propagation

Besides producing bugs, EPEX also confirms whether a function call's error handling code correctly takes care of all possible errors. Note that EPEX only checks whether error values are propagated upstream but does not check whether other error handling tasks (e.g., freeing up all acquired resources) have been implemented correctly.

The following example shows an instance where EPEX confirmed that the error codes are correctly propagated by the error handling code. This piece of code is from GnuTLS 3.3.17.1 and contains the fix for the CVE-2014-92 vulnerability that we described in the introduction (Listing 1). EPEX confirmed that the fix indeed correctly handles the error case.

Besides fixing the bug, the updated version of the code has also been slightly refactored and reorganized as shown below. Code in **red** highlights the bug, while **green** shows the fix. The return type of function `check_if_ca` has been updated to `bool`, where returning false (0) indicates an error (see line 1 and 10). The caller function `verify_crt` is correctly checking $\neq 1$ (*i.e.* True) at line 17 to handle the error case.

```

1 int bool
2 check_if_ca(...)
3 { ...
4     if (ret < 0) {
5         gnutls_assert();
6         goto fail;
7     }
8
9     fail:
10    result = 0;
11
12    return result;
13 }
14
15 bool verify_crt(...)
16 {
17     if (check_if_ca(...) == 0 != 1) {
18         result = 0;
19         goto cleanup;
20     }
21     ...
22     cleanup:
23     ...
24     return result;
25 }
26 }
```

We also used EPEX to successfully check the fixes for other CVEs mentioned in Section 1 (CVE-2015-0208, CVE-2015-0288, CVE-2015-0285, and CVE-2015-0292).

5.6 Imprecision in EPEX Analysis

The 130 potential bugs reported by EPEX includes 28 false positives and incorrectly excludes 20. In the li-

³<http://curl.haxx.se/>

⁴<https://httpd.apache.org/>

⁵<http://lynx.invisible-island.net/>

⁶<http://www.mutt.org/>

⁷<https://www.gnu.org/software/wget/wget.html>

ibraries, most of the false positives appeared due to the limitations of underlying Clang symbolic analysis engine. The interprocedural analysis supported by Clang’s symbolic analysis engine is currently limited to the functions defined within an input source file or functions included in the file through header files. Therefore, the symbolic analyzer is not able to gather correct path conditions and return values for the functions defined in other source files. For example, in the code below, EPEX reported error since the return value of `X509_get_serialNumber` is not checked at line 5. However, inside the callee, `ASN1_STRING_dup`, the error condition is checked at line 17 and the NULL value is returned. This return value (`serial`) is further checked at line 6. Since, `ASN1_STRING_dup` is implemented in a different file, EPEX could not infer that the `ASN1_STRING_dup` call in line 5 will always return NULL if `X509_get_serialNumber` returns an error. Note that if the pattern of not checking error for `X509_get_serialNumber` calls were consistent across all call-sites, EPEX would not have reported this false positive due to Step-III in Section 3).

```

1 AUTHORITY_KEYID *v2i_AUTHORITY_KEYID(...
2 {
3     ...
4     serial = ASN1_INTEGER_dup(
5         X509_get_serialNumber(cert));
6     if (!isname || !serial) {
7         X509V3err(...);
8         goto err;
9     }
10    ...
11 }
12 ASN1_STRING *ASN1_STRING_dup(
13     const ASN1_STRING *str)
14 {
15     ASN1_STRING *ret;
16     if (!str)
17         return NULL;
18     ...
20 }
```

EPEX performed the worst in wolfSSL, mostly due to confusion arising from compile-time configuration settings affecting the function `mp_init`. EPEX raised 8 alerts for the function, but after contacting the developers, we learned that the corresponding functions can be configured, at compilation time, to be either fallible or infallible. All the reported call sites were only compiled if the functions were configured to be infallible. Therefore, our error specifications should not have marked these functions as fallible. On the other hand, in the applications, the most frequent causes are 5 instances of fallbacks, which are characteristic of applications. Still, missed checks in external functions are the second most frequent cause, at 3 cases. The remaining causes are alternative error propagation channels, and deliberate disregard for the error, due to either a conscious choice of the programmer, or a configuration parameter, as mentioned in Section 5.2.

Given the false positives due to checks by external functions, a natural solution would be to have all functions validate their input. While this is a good practice for library programmers, application programmers should not depend on functions, whose implementation they often do not control, to follow this practice. For debugging purposes, it would appear that the function receiving the invalid return value is at fault. Moreover, not all functions can cleanly handle invalid input. Comparison functions such as `ASN1_INTEGER_cmp` only return non-error values, so the only safe response would be to terminate the program, which is a drastic action that can easily be averted by checking the parameters in the first place.

5.7 Performance analysis

EPEX is integrated with the test project’s building procedure through the Clang framework. We ran all our tests on Linux servers with 4 Intel Xeon 2.67GHz processors and 100 GB of memory. The following table shows the performance numbers. EPEX’s execution time is comparable to that of other built-in, simple checkers in Clang (*e.g.*, division-by-zero) as shown in the table below.

	Regular build	Division-by-zero in-built checker	EPEX checker
wolfSSL	0.05m	3.08m	2.68m
mbedTLS	0.67m	3.72m	2.83m
GnuTLS	1.85m	13.28m	12.82m
OpenSSL	8.25m	186.9m	132.33m
cURL	0.18m	13.96m	12.95m
httpd	0.04m	4.68m	4.51m
Lynx	0.55m	71.35m	71.73m
Mutt	0.10m	13.03m	13.12m
Wget	0.03m	5.63m	5.66m

6 Related work

6.1 Automated detection of error handling bugs

Rubio-González *et al.* [45, 21] detected incorrect error handling code in the Linux file system using a static control and data-flow analysis. Their technique was designed to detect bugs caused by faulty code that either overwrite or ignore error values. In addition to these two cases, we check whether appropriate error values are propagated upstream as per global error protocol of the analyzed program. We use module-specific error specifications as opposed to hard coded error values like `-EIO`, `-ENOMEM`, *etc.* used by Rubio-González *et al.* This helps us in reducing the number of false positives significantly; for instance, unlike [45, 21], we do not report a bug when an error value is over-written by another error value that conforms to the global error protocol. Our usage of symbolic analysis further minimizes false

positives as symbolic analysis, unlike the data-flow analysis used in [45, 21], can distinguish between feasible and infeasible paths.

Acharya *et al.* [1] automatically inferred error handling specifications of APIs by mining static traces of their run-time behaviors. Then, for a different subject system, they found several bugs in error handling code that do not obey the inferred specifications. The static traces were generated by MOPS [11] that handles only control dependencies and minimal data-dependencies. As observed by Acharya *et al.*, lack of extensive data-dependency support (*e.g.*, pointer analysis, aliasing, *etc.*) introduced imprecision in their results. By contrast, our symbolic execution engine with extensive memory modeling support minimizes such issues. Further, to identify error handling code blocks corresponding to an API function, Acharya *et al.* leveraged the presence of conditional checks on the API function’s return value and/or ERNNO flag. They assumed that if such a conditional check leads to a return or exit call, then it is responsible for handling the error case. Such assumption may lead to false positives where conditional checks are performed on non-error cases. Also, as noted by Acharya *et al.*, for functions that can return multiple non-error values, they cannot distinguish them from error cases. By contrast, we create our error specifications from the program documentation and thus they do not suffer from such discrepancies.

Lawall *et al.* [31] used Coccinelle, a program matching and transformation engine, to find missing error checks in OpenSSL. By contrast, we not only look for error checks but also ensure that the error is indeed handled correctly. This allows us to find a significantly larger class of error handling problems. Also, unlike our approach, Lawall *et al.*’s method suffers from an extremely high false positive rate.

Several other approaches to automatically detect error/exception handling bugs have been proposed for Java programs [52, 53, 44, 8, 54]. However, since the error handling mechanism is quite different in Java than C (*e.g.*, the `try-catch-finally` construct is not supported in C), these solutions are not directly applicable to C code.

Static analysis has been used extensively in the past to find missing checks on security critical objects [48, 57, 49]. However, none of these tools can detect missing/incorrect error handling checks. Complementary to our work, and other static approaches, dynamic analysis methods have been developed to discover the practical effects of error handling bugs, although they do so at the cost of lower coverage of error paths, as well as unknown failure modes. Fault injection frameworks such as LFI bypass the problem of the unlikelihood of errors by injecting failures directly into fallible functions.

LFI includes a module for automatically inferring error specifications, although it is not usable in our case, since static analysis requires explicitly identifying error and non-error values, and not just differentiate between them [34].

6.2 Symbolic execution

The idea of symbolic execution was initially proposed by King *et al.* [29]. Concolic execution is a recent variant of symbolic execution where concrete inputs guide the execution [19, 10, 47]. Such techniques have been used in several recent projects for automatically finding security bugs [27, 46, 22, 20].

KLEE [9], by Cadar *et al.*, is a symbolic execution engine that has been successfully used to find several bugs in UNIX coreutils automatically. UC-KLEE [40], which integrates KLEE and lazy initialization [26], applies more comprehensive symbolic execution over a bounded exhaustive execution space to check for code equivalence; UC-KLEE has also been effective in finding bugs in different tools, including itself. Recently, Ramos *et al.* applied UC-KLEE to find two denial-of-service vulnerabilities in OpenSSL [41].

SAGE, by Godefroid *et al.* [20], uses a given set of inputs as seeds, builds symbolic path conditions by monitoring their execution paths, and systematically negates these path conditions to explore their neighboring paths, and generate input for fuzzing. SAGE has been successfully used to find several bugs (including security bugs) in different Windows applications like media players and image processors. SAGE also checks for error handling bugs, but only errors from user inputs, and not environmental failures, which are unlikely to appear when only user input is fuzzed.

Ardilla, by Kiezun *et al.* [27], automates testing of Web applications for SQL injection and cross-site scripting attacks by generating test inputs using dynamic taint analysis that leverages concolic execution and mutates the inputs using a library of attack patterns.

Existing symbolic execution tools are not well suited for finding error handling bugs for two primary reasons: (i) The existing symbolic execution tools depend on obvious faulty behaviors like crashes, assertion failures, *etc.* for detecting bugs. A large number of error handling bugs are completely silent and do not exhibit any such behavior. (ii) As the number of paths through any reasonable sized program is very large, all symbolic execution tools can only explore a fraction of those paths. The effects of most non-silent error handling bugs show up much further downstream from their source. An off-the-shelf symbolic execution tool can only detect such cases if it reaches that point. By contrast, our algorithm for identifying and exploring error paths enables EPEX

to detect completely silent and non-silent error handling bugs at their sources. This makes it easy for the developers to understand and fix these bugs.

6.3 Security of SSL/TLS implementations

Several security vulnerabilities have been found over the years in both SSL/TLS implementations and protocol specifications [15, 43, 2, 5, 7, 4, 3]. We briefly summarize some of these issues below. A detailed survey of SSL/TLS vulnerabilities can be found in [13].

Multiple vulnerabilities in certification validation implementations, a key part of the SSL/TLS protocol, were reported by Moxie Marlinspike [38, 37, 36, 35]. Similar bugs have been recently discovered in the SSL implementation on Apple iOS [24]. Another certificate validation bug (“goto fail”) was reported in Mac OS and iOS [30] due to an extra goto statement in the implementation of the SSL/TLS handshake protocol. The affected code did not ensure that the key used to sign the server’s key exchange matches the key in the certificate presented by the server. This flaw made the SSL/TLS implementations in MacOS and iOS vulnerable to active Man-In-The-Middle (MITM) attackers. This bug was caused by unintended overlapping of some parts of a non-error path and an error path. However, this is not an error handling bug like the ones we found in this paper.

Hash collisions [50] and certificate parsing discrepancies between certificate authorities (CAs) and Web browsers [25] can trick a CA into issuing a valid certificate with the wrong subject name or even a valid intermediate CA certificate. This allows an attacker to launch a successful MITM attack against any arbitrary SSL/TLS connection.

Georgiev *et al.* [18] showed that incorrect usage of SSL/TLS APIs results in a large number of certificate validation vulnerabilities in different applications. Fahl *et al.* [17] analyzed incorrect SSL/TLS API usage for Android applications. Brubaker *et al.* [6] designed Frankencerts, a mechanism for generating synthetic X.509 certificates based on a set of publicly available seed certificates for testing the certificate validation component of SSL/TLS libraries. They performed differential testing on multiple SSL/TLS libraries using Frankencerts and found several new security vulnerabilities. Chen *et al.* [12] improved the coverage and efficiency of Brubaker *et al.*’s technique by diversifying the seed certificate selection process using Markov Chain Monte Carlo (MCMC) sampling. However, all these techniques are black-box methods that only focus on the certificate validation part of the SSL/TLS implementations. By contrast, our white-box analysis is tailored to look for flawed error handling code in any sequential C code.

Flawed pseudo-random number generation can produce insecure SSL/TLS keys that can be easily compromised [32, 23]. We have also reported several bugs involving pseudo-random number generator functions in this paper, although their origins are completely different, *i.e.*, unlike [32, 23], they are caused by incorrect error handling.

7 Future work

Automated inference of error specifications. One limitation of our current implementation of EPEX is that it requires the input error specifications to be created manually by the user. Automatically generating the error specifications will significantly improve EPEX’s usability. One possible way to automatically infer the error specifications is to identify and compare the path constraints imposed along the error paths (*i.e.*, the paths along which a function can fail and return errors) across different call-sites of the same function. However, in order to do so, the error paths must first be automatically identified. This leads to a chicken-and-egg problem as the current prototype of EPEX uses the input error specifications to identify the error paths.

To solve this problem, we plan to leverage different path features that can distinguish the error paths from non-error paths. For example, error paths are often more likely to return constant values than non-error paths [33]. Error paths are also more likely to call functions like exit (with a non-zero argument) than regular code for early termination. Further, since errors invalidate the rest of the computation, the lengths of the error paths (*i.e.*, number of program statements) might be, on average, shorter than the non-error paths. An interesting direction for future research will be to train a supervised machine learning algorithm like Support Vector Machines (SVMs) [14] for identifying error paths using such different path features. The supervised machine learning algorithm can be trained using a small set of error and non-error paths identified through manually created error specifications. The resulting machine learning model can then be used to automatically identify different error paths and infer error specifications by comparing the corresponding path constraints.

Automatically generating bug fixes. As error-handling code is often repetitive and cumbersome to implement, it might be difficult for developers to keep up with EPEX and fix all the reported bugs manually. Moreover, manual fixes introduced by a developer might also be buggy and thus may introduce new error handling bugs. In order to avoid such issues, we plan to automatically generate candidate patches to fix the error handling bugs reported by EPEX. Several recent projects [55, 39, 28] have successfully generated patches

for fixing different types of bugs. Their main approach is dependent on existing test suites—they first generate candidate patches by modifying existing code and then validate the patches using existing test cases. While this generic approach can be applied in our setting, we cannot use the existing schemes as error handling bugs are, in general, hard to detect through existing test cases. Also, these approaches typically focus on bug fixes involving only one or two lines of code changes. However, the error handling bugs are not necessarily limited to such small fixes. Solving these issues will be an interesting direction for future work.

8 Conclusion

In this paper, we presented EPEX, a new algorithm and a tool that automatically explores error paths and finds error handling bugs in sequential C code. We showed that EPEX can efficiently find error handling bugs in different open-source SSL/TLS libraries and applications with few false positives; many of these detected bugs lead to critical security vulnerabilities. We also demonstrate that EPEX could also be useful to the developers for checking error handling code.

APISAN: Sanitizing API Usages through Semantic Cross-checking

Insu Yun Changwoo Min Xujie Si Yeongjin Jang Taesoo Kim Mayur Naik
Georgia Institute of Technology

Abstract

API misuse is a well-known source of bugs. Some of them (e.g., incorrect use of SSL API, and integer overflow of memory allocation size) can cause serious security vulnerabilities (e.g., man-in-the-middle (MITM) attack, and privilege escalation). Moreover, modern APIs, which are large, complex, and fast evolving, are error-prone. However, existing techniques to help finding bugs require manual effort by developers (e.g., providing specification or model) or are not scalable to large real-world software comprising millions of lines of code.

In this paper, we present APISAN, a tool that automatically infers correct API usages from source code without manual effort. The key idea in APISAN is to extract likely correct usage patterns in four different aspects (e.g., causal relation, and semantic relation on arguments) by considering semantic constraints. APISAN is tailored to check various properties with security implications. We applied APISAN to 92 million lines of code, including Linux Kernel, and OpenSSL, found 76 previously unknown bugs, and provided patches for all the bugs.

1 Introduction

Today, large and complex software is built with many components integrated using APIs. While APIs encapsulate the internal state of components, they also expose rich semantic information, which renders them challenging to use correctly in practice. Misuse of APIs in turn leads to incorrect results and more critically, can have serious security implications. For example, a misuse of OpenSSL API can result in man-in-the-middle (MITM) attacks [22, 26], and seemingly benign incorrect error handling in Linux (e.g., missing a check on `kmalloc()`) can allow DoS or even privilege escalation attacks [12]. This problem, in fact, is not limited to API usage, but pervades the usage of all functions, which we generally refer to as APIs in this paper.

Many different tools, techniques, and methodologies have been proposed to address the problem of finding or preventing API usage errors. Broadly, all existing techniques either require (1) manual effort—API-specific specifications (e.g., SSL in SSLint [26], setuid [10, 15]), code annotations (e.g., lock operations in Sparse [41]),

correct models (e.g., file system in WOODPECKER [11]), or (2) an accurate analysis of source code [6, 7], which is hard to scale to complex, real-world system software written in C/C++.

We present a fully automated system, called APISAN for finding API usage errors. Unlike traditional approaches that require API-specific specifications or models, APISAN infers the correct usage of an API from other uses of the API, regarding the majority usage pattern as a *semantic belief*, i.e., the likely correct use. Also, instead of relying on whole-program analysis, APISAN represents correct API usage in a probabilistic manner, which makes it scalable beyond tens of millions of lines of low-level system code like the Linux kernel. In APISAN, the higher the observed number of API uses, potentially even from different programs, the stronger is the belief in the inferred correct use. Once APISAN extracts such semantic beliefs, it reports deviations from the beliefs as potential errors together with a probabilistic ranking that reflects their likelihood.

A hallmark of APISAN compared to existing approaches [1, 18, 28, 29] for finding bugs by detecting contradictions in source code is that it achieves precision by considering semantic constraints in API usage patterns. APISAN infers such constraints in the form of symbolic contexts that it computes using a symbolic execution based technique. The technique, called *relaxed symbolic execution*, circumvents the path-explosion problem by limiting exploration to a bounded number of intra-procedural paths that suffice in practice for the purpose of inferring semantic beliefs.

APISAN computes a database of symbolic contexts from the source code of different programs, and infers semantic beliefs from the database by checking four key aspects: implications of function return values, relations between function arguments, causal relationships between functions, and implicit pre- and post-conditions of functions. These four aspects are specialized to incorporate API-specific knowledge for more precise ranking and deeper semantic analysis. We describe eight such cases in APISAN that are tailored to check a variety of properties with security implications, such as cryptographic protocol API misuses, integer overflow, improper locking, and NULL dereference.

Our evaluation shows that APISAN’s approach is scal-

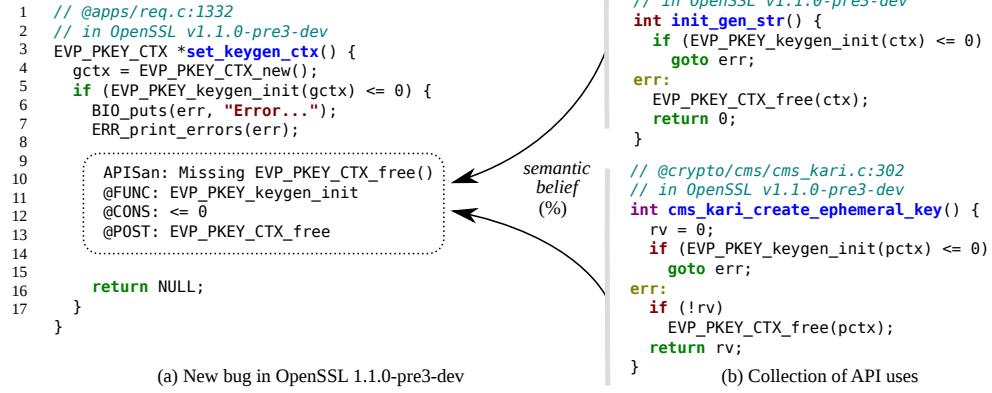

Figure 1: (a) A memory leak vulnerability found by APISAN in OpenSSL 1.1.0-pre3-dev. When a crypto key fails to initialize, the allocated context (i.e., `gctx`) should be freed. Otherwise, a memory leak will occur. APISAN first infers correct semantic usage of the API from (b) other uses of the API, and extracts a checkable rule, called a *semantic belief*, under the proper context (e.g., state: `EVP_PKEY_keygen_init() → rv <= 0 && EVP_PKEY_CTX_free()`). This newly found vulnerability has been reported and fixed in the mainstream with the patch we provided. In the above report, `@FUNC` indicates a target API, `@CONS` is a return value constraint, and `@POST` shows an expected post-action following the API.

able and effective in finding API misuses that result in critical security problems such as code execution, system hangs, or crashes. In total, we analyzed 92 million lines of code (LoC) and found 76 *previously unknown* bugs in Linux, OpenSSL, PHP, Python, and debian packages using OpenSSL (see Table 2). More importantly, we created patches for all these bugs and sent them to the mainline developers of each project. Of these, 69 bugs have been confirmed, and most have already been applied to the mainstream repositories. We are awaiting responses for the remaining reported bugs.

In short, our paper makes the following contributions:

- **New methodology.** We develop a fully automated way of finding API misuses that infers semantic beliefs from existing API uses and probabilistically ranks deviant API usages as bugs. We also formalize our approach thoroughly.
- **Practical impact.** APISAN found 76 new bugs in system software and libraries, including Linux, OpenSSL, PHP, and Python, which are 92 million LoC in total. We created patches for all bugs and most of them have already been fixed in the mainstream repositories of each project.
- **Open source tool.** We will make the APISAN framework and all its checkers publicly available online for others to readily build custom checkers on top of APISAN.

The rest of this paper is organized as follows. §2 provides an overview of APISAN. §3 describes APISAN’s design. §4 presents various checkers of APISAN. §5 describes APISAN’s implementation. §6 explains the bugs we found. §7 discusses APISAN’s limitations and potential future directions. §8 compares APISAN to previous work and §9 concludes.

2 Overview

In this section, we present an overview of APISAN, our system for finding API usage errors. These errors often have security implications, although APISAN and the principles underlying it apply to general-purpose APIs and are not limited to finding security errors in them. To find API usage errors, APISAN automatically infers semantic correctness, called *semantic beliefs*, by analyzing the source code of different uses of the API.

We motivate our approach by means of an example that illustrates an API usage error. We outline the challenges faced by existing techniques in finding the error and describe how APISAN addresses those challenges.

2.1 Running Example

Figure 1(a) shows an example of misusing the API of OpenSSL. The allocated context of a public key algorithm (`gctx` on Line 3) must be initialized for a key generation operation (`EVP_PKEY_keygen_init()` on Line 4). If the initialization fails, the allocated context should be freed by calling `EVP_PKEY_CTX_free()`. Otherwise, it results in a memory leak.

To find such errors automatically, a checker has to know the correct usage of the API. Instead of manually encoding semantic correctness, APISAN automatically infers the correct usage of an API from other uses of the API, regarding the majority usage pattern as the likely correct use. For example, considering the use of the OpenSSL API in Figure 1(a) together with other uses of the API shown in Figure 1(b), APISAN infers the majority pattern as freeing the allocated context after initialization failure (i.e., `EVP_PKEY_keygen_init() <= 0`), and thereby reports the use in Figure 1(a) as an error.

2.2 Challenges

We describe three key challenges that hinder existing approaches in finding the error in the above example.

1. Lack of specifications. A large body of work focuses on checking semantic correctness, notably dataflow analysis and model checking approaches [3, 4, 14, 17, 21, 46]. A major obstacle to these approaches is that developers should manually describe “*what is correct*,” and this effort is sometimes prohibitive in practice. To alleviate this burden, many of the above approaches check lightweight specifications, notably type-state properties [42]. These specifications are not expressive enough to capture correct API uses inferred by APISAN; for example, type-state specifications can capture finite-state rules but not rules involving a more complex state, such as the rule in the box in Figure 1(a), which states that `EVP_PKEY_CTX_free()` must be called if `EVP_PKEY_CTX_init() <= 0`. Moreover, techniques for checking such rules must track the context of the API use in order to be precise, which limits their scalability. For instance, the second example in Figure 1(b) has a constraint on `!rv`, whose tracking is necessary for precision but complicated by the presence of `goto` routines in the example.

2. Missing constraints. Engler et al. [18] find potential bugs by detecting contradictions in software in the absence of correctness semantics specified by developers. For instance, if most occurrences of a lock release operation are preceded by a lock acquire operation, then instances where the lock is released without being acquired are flagged as bugs. The premise of APISAN is similar in that the majority occurrence of an API usage pattern is regarded as likely the correct usage, and deviations are reported as bugs. However, Engler et al.’s approach does not consider semantic constraints, which can lead it to miss bugs that occur under subtle constraints, such as the one in Figure 1(a), which states that `EVP_PKEY_CTX_free()` must be called only when `EVP_PKEY_keygen_init()` fails.

3. Complex constraints. KLEE [7] symbolically executes all possible program paths to find bugs. While it is capable of tracking semantic constraints, however, it suffers from the notorious path-explosion problem; its successor, UC-KLEE [37], performs under-constrained symbolic execution that checks individual functions rather than whole programs. However, functions such as `EVP_PKEY_keygen_init()` in Figure 1 contain a function pointer, which is hard to resolve in static analysis, and cryptographic functions have extremely complex path constraints that pose scalability challenges to symbolic execution based approaches.

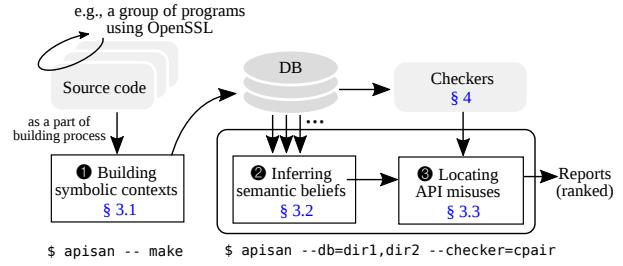

Figure 2: Overview of APISAN’s architecture and workflow. APISAN first builds symbolic contexts from existing programs’ source code and creates a database (§3.1); then APISAN infers correct usages of APIs, so-called *semantic beliefs*, in four aspects (§3.2). The inferred beliefs are used to find and rank potential API misuses to be reported as bugs (§3.3). Specific checkers are built by using the inferred beliefs and symbolic context database. If necessary, checkers incorporate domain-specific knowledge to find and rank bugs more precisely (§4).

2.3 Our Approach

APISAN’s workflow consists of three basic steps as shown in Figure 2. It first builds symbolic contexts using symbolic execution techniques on existing programs’ source code and creates a database of symbolic traces (§3.1). Then, it statistically infers correct API usages, called semantic beliefs, using the database (§3.2). Finally, it locates API misuses in the programs’ source code using the inferred beliefs and domain-specific knowledge if necessary (§3.3, §4).

We formalize our approach as a general framework, shown in Figure 5, which can be tuned using two parameters: the context checking function, which enables tailoring the checking of symbolic contexts to different API usage aspects, and an optional hint ranking function, which allows customizing the ranking of bug reports. As we will discuss shortly, our framework provides several built-in context checking functions, allowing common developers to use APISAN without modification.

Below, we describe how APISAN tackles the challenges outlined in the previous section.

1. Complete automation. In large and complex programs, it is prohibitive to rely on manual effort to check semantic correctness, such as manually provided specifications, models, or formal proofs. Instead, APISAN follows a fully automated approach, inferring semantic beliefs, i.e., correct API usages, from source code.

2. Building symbolic contexts. To precisely capture API usages involving a complex state, APISAN infers semantic beliefs from the results of symbolic execution. These results, represented in the form of symbolic constraints, on one hand contain precise semantic information about each individual use of an API, and on the other hand are abstract enough to compare across uses of the API even in different programs.

3. Relaxed symbolic execution. To prevent the path

explosion problem and achieve scalability, we perform *relaxed symbolic execution*. Unlike previous approaches, which try to explore as many paths as possible, APISAN explores as few paths as possible so as to suffice for the purpose of inferring semantic beliefs. In particular, our relaxed symbolic execution does not perform inter-procedural analysis, and unrolls loops.

4. Probabilistic ranking. To allow to prioritize developers’ inspection effort, APISAN ranks more likely bug reports proportionately higher. More specifically, APISAN’s ranking is probabilistic, denoting a confidence in each potential API misuse that is derived from a proportionate number of occurrences of the majority usage pattern, which itself is decided based on a large number of uses of the API in different programs. The ranking is easily extensible with domain-specific ranking policies for different API checkers.

3 Design of APISAN

The key insight behind our approach is that the “correctness” of API usages can be probabilistically measured from existing uses of APIs: that is, the more API patterns developers use in similar contexts, the more confidence we have about the correct API usage. APISAN automatically infers correct API usage patterns from existing source code without any human intervention (e.g., manual annotation or providing an API list), and ranks potential API misuses based on the extent to which they deviate from the observed usage pattern. To process complex, real-world software, APISAN’s underlying mechanisms for inferring, comparing, and contrasting API usages should be scalable, yet without sacrificing accuracy. In this section, we elaborate on our static analysis techniques based on relaxed symbolic execution (§3.1), methodologies to infer semantically correct API usages (§3.2), and a probabilistic method for ranking potential API misuses (§3.3).

3.1 Building Symbolic Contexts

APISAN performs symbolic execution to build symbolic contexts that capture rich semantic information for each function call. The key challenge of building symbolic contexts in large and complex programs is to overcome the path-explosion problem in symbolic execution.

We made two important design decisions for our symbolic execution to achieve scalability yet extract accurate enough information about symbolic contexts. First, APISAN localizes symbolic execution within a function boundary. Second, APISAN unrolls each loop once so that the results of symbolic execution can be efficiently represented as a *symbolic execution tree* with no backward edges. In this section, we provide justifications for

```

1 // @drivers/tty/synclink_gt.c:2363
2 // in Linux v4.5-rc4
3 static irqreturn_t slgt_interrupt(int dummy, void *dev_id) {
4     struct slgt_info *d = dev_id;
5     ...
6     for (i = 0; i < d->count; i++) {
7         if (d->ports[i] == NULL)
8             continue;
9     *     spin_lock(&d->ports[i]->lock);
10    ...
11    *     spin_unlock(&d->ports[i]->lock);
12 }
13 ...
14 return IRQ_HANDLED;
15 }
```

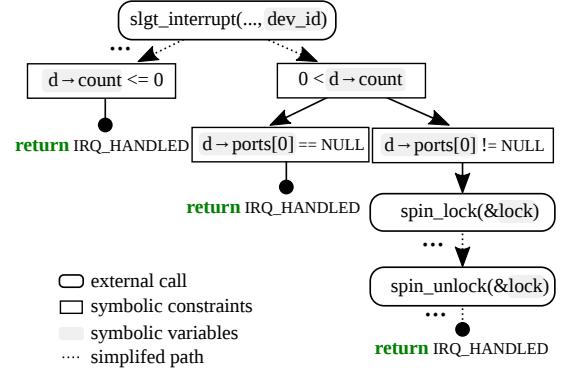

Figure 3: A typical API usage inside a loop. This code snippet comes from a `tty` device driver in the Linux v4.5-rc1. `spin_lock()` and `spin_unlock()` are used in a pair inside the loop. APISAN represents its symbolic context as a tree that contains function calls and symbolic constraints by unrolling its outer loop, as depicted at the bottom of the code snippet. Note that we use `lock` for `d->ports[0]->lock` due to space limitation.

these two design decisions within the context of finding API misuses, and provide a performance optimization that memoizes the predominant symbolic states. Finally, we precisely define the structure of symbolic execution traces computed by APISAN.

Limiting inter-procedural analysis. In APISAN, we perform symbolic execution intra-procedurally for each function. We use a fresh symbolic variable to represent each formal argument of the function, as well as the return value of each function called in its body. The symbolic constraints track C/C++ expressions over such symbolic variables, as described below. In our experience with APISAN, limiting inter-procedural analysis is reasonable for accuracy and code coverage, since most API usages can be captured within a caller function without knowing API internals.

Unrolling a loop. APISAN unrolls each loop only once to reduce the number of paths explored. While this can limit the accuracy of our symbolic execution, it does not noticeably affect the accuracy of APISAN. This is because most API usages in practice do not tend to be related to loop variables. Figure 3 (top) shows such an example in a Linux device driver. Although the symbolic context changes while executing the loop, API usages

```

(function)  $f \in \mathbb{F}$ 
(integer)  $n \in \mathbb{Z}$ , (natural)  $i \in \mathbb{N}$ 
(symbolic variable)  $\alpha ::= \langle \text{arg}, i \rangle \mid \langle \text{ret}, i \rangle$ 
(symbolic expression)  $e ::= n \mid \alpha \mid uop\ e \mid e_1\ bop\ e_2$ 
(integer range)  $r ::= [n_1, n_2]$ 
(event in trace)  $a ::= \text{call}\ f(\bar{e}) \mid \text{assume}(e, \bar{r})$ 
(trace)  $t ::= \bar{a}$ 
(database of traces)  $\mathbb{D} ::= \{ t_1, t_2, \dots \}$ 

```

Figure 4: Abstract syntax of symbolic execution traces.

of `spin_lock()` and `spin_unlock()` can be precisely captured even by unrolling the loop once. While this may not always be the case, however, we compensate for the incurred accuracy loss by collecting a larger number of API uses.

Memoizing predominant symbolic states. Another advantage of loop unrolling is that all symbolic execution traces of a function can be efficiently represented as a tree, namely, a symbolic execution tree, without having backward edges. This helps scalability because APISAN can deterministically explore the symbolic execution tree, and all intermediate results can be cached in interior nodes; most importantly, the cached results (i.e., predominant symbolic contexts) can be safely re-used because there is no control flow from a child to its ancestors. [Figure 3](#) (bottom) shows the corresponding symbolic execution tree for the function `sigt_interrupt` shown above it.

Structure of symbolic execution traces. [Figure 4](#) formally describes the structure of traces computed by APISAN using symbolic execution. Each trace t consists of a sequence of events. We refer to the i^{th} event by $t[i]$, where $1 \leq i \leq |t|$. Each event a is either a `call` to a function f with a sequence of symbolic expressions \bar{e} as arguments, or an `assume` constraint, which is a pair consisting of a symbolic expression e and its possible value ranges \bar{r} . A symbolic expression e can be a constant n , a symbolic variable α , or the result of an unary (`uop`) or binary (`bop`) operation on other symbolic expressions. Each symbolic variable α is either the return result of a function called at the i^{th} event in the trace, denoted $\langle \text{ret}, i \rangle$, or the i^{th} formal parameter of the function being symbolically executed, denoted $\langle \text{arg}, i \rangle$.

The following three traces are computed by APISAN for the code snippet in [Figure 3](#) (ignoring unseen parts)¹:

```

 $t_1 : \text{assume}(d \rightarrow \text{count}, [\text{MIN}, 0])$ 
 $t_2 : \text{assume}(d \rightarrow \text{count}, [1, \text{MAX}]);$ 
 $\quad \text{assume}(d \rightarrow \text{ports}[0], [0, 0])$ 
 $t_3 : \text{assume}(d \rightarrow \text{count}, [1, \text{MAX}]);$ 
 $\quad \text{assume}(d \rightarrow \text{ports}[0], [[\text{MIN}, -1], [1, \text{MAX}]])$ ;
 $\quad \text{call spin\_lock}(&d \rightarrow \text{ports}[0] \rightarrow \text{lock});$ 
 $\quad \text{call spin\_unlock}(&d \rightarrow \text{ports}[0] \rightarrow \text{lock})$ 

```

¹MIN and MAX stand for the minimum and maximum possible values of a related type, respectively.

3.2 Inferring Semantic Beliefs

The key challenge is to infer (most likely) correct API usages that are implicitly embedded in a large number of existing implementations. We call the inferred API usages “semantic beliefs,” not only because they are believed to be correct by a dominant number of implementations, but also because they are used in semantically similar contexts (e.g., certain state or conditions). Therefore, the more frequent the API usage patterns we observe, the stronger is the semantic belief about the correctness of API usages. APISAN infers semantic beliefs by analyzing the surrounding symbolic contexts ([§3.1](#)) without developers’ manual annotations or providing an API list.

In particular, APISAN focuses on exploring four common API context patterns.

- **Return value:** Not only does a function return the result of its computation, but it often implicates the status of the computation through the return value; for example, non-zero value in `glibc` and `PTR_ERR()` in the Linux kernel.
- **Argument:** There are semantic relations among arguments of an API; for example, the memory copy size should be smaller or equal to the buffer size.
- **Causality:** Two APIs can be causally related; for example, an acquired lock should be released at the end of critical section.
- **Conditions:** API semantics can imply certain pre- or post-conditions; for example, verifying a peer certificate is valid only if the peer certificate exists.

We give a formal description of these four patterns in [Figure 6](#) and elaborate upon them in the rest of this section. Since APISAN infers semantic beliefs, which are probabilistic in nature, there could be false positives in bug reports. APISAN addresses this problem by providing a ranking scheme for developers to check the most probable bug reports first. [Figure 5](#) formalizes this computation and [§3.3](#) presents it in further detail.

3.2.1 Implication of Return Values

Return value is usually used to return the computation result (e.g. pointer to an object) or execution status (e.g., `errno`) of a function. Especially for system programming in C, certain values are conventionally used to represent execution status. In such cases, checking the return value (execution status) properly before proceeding is critical to avoid security flaws. For instance, if a program ignores checking the return value of memory allocation (e.g., `malloc()`), it might crash later due to NULL pointer dereference. In the OpenSSL library, since the result of establishing a secure connection is passed by a return value, programs that fail to check the return value properly are vulnerable to MITM attacks [[22](#)].

$\text{SymbolicContexts}(f)$	$= \{ (t, i, C) \mid t \in \mathbb{D} \wedge i \in [1.. t] \wedge t[i] \equiv \text{call } f(*) \wedge C = \text{CONTEXTS}(t, i) \}$
$\text{Frequency}(f, c)$	$= \{ (t, i) \mid \exists C : c \in C \wedge (t, i, C) \in \text{SymbolicContexts}(f) \}$
$\text{Majority}(f)$	$= \{ c \mid \text{Frequency}(f, c) / \text{SymbolicContexts}(f) \geq \theta \}$
$\text{BugReports}(f)$	$= \{ (t, i, C) \mid (t, i, C) \in \text{SymbolicContexts}(f) \wedge C \cap \text{Majority}(f) = \emptyset \}$
$\text{BugReportScore}(f)$	$= 1 - \text{BugReports}(f) / \text{SymbolicContexts}(f) + \text{HINT}(f)$

Figure 5: The general framework of APISAN. Threshold ratio θ is used to decide whether a context c is a correct or buggy API usage. Procedures CONTEXTS and HINT are abstract; Figure 6 shows concrete instances of these procedures implemented in APISAN.

$\text{returnValueContexts} = \lambda(t, i). \{ \bar{r} \mid \exists j : t[j] \equiv \text{assume}(e, \bar{r}) \wedge \langle \text{ret}, i \rangle \in \text{retvars}(e) \}$
$\text{argRelationContexts} = \lambda(t, i). \{ (u, v) \mid t[i] \equiv \text{call } *(\bar{e}) \wedge \text{argvars}(\bar{e}[u], t) \cap \text{argvars}(\bar{e}[v], t) \neq \emptyset \}$
$\text{causalityContexts}(\bar{r}) = \lambda(t, i). \{ g \mid \exists j : t[j] \equiv \text{assume}(e, \bar{r}) \wedge \langle \text{ret}, i \rangle \in \text{retvars}(e) \wedge \exists k > j : t[k] \equiv \text{call } g(*) \}$
$\text{conditionContexts}(\bar{r}) = \lambda(t, i). \{ (g, \bar{r}') \mid \exists j : t[j] \equiv \text{assume}(e, \bar{r}) \wedge \langle \text{ret}, i \rangle \in \text{retvars}(e) \wedge \exists k > j : t[k] \equiv \text{call } g(*) \wedge \exists l : t[l] \equiv \text{assume}(e', \bar{r}') \wedge \langle \text{ret}, k \rangle \in \text{retvars}(e') \}$
$\text{defaultHint} = \lambda f. 0 \quad \text{nullDerefHint} = \lambda f. \text{if } (f\text{'s name contains } \text{alloc}) \text{ then } 0.3 \text{ else } 0$

Figure 6: Concrete instances of the CONTEXTS and HINT procedures implemented in APISAN. Function $\text{retvars}(e)$ returns all $\langle \text{ret}, i \rangle$ variables in e . Function $\text{argvars}(e, t)$ returns all $\langle \text{arg}, i \rangle$ variables in e , consulting t to recursively replace each $\langle \text{ret}, i \rangle$ variable by its associated function call symbolic expression. Both these functions are formally described in Appendix A.

Moreover, missing return value checks can lead to privilege escalation like CVE-2014-4113 [12]. Because of such critical scenarios, gcc provides a special pragma, `__attribute__((warn_unused_result))`, to enforce the checking of return values. However, it does not guarantee if a return value check is proper or not [24].

Properly checking return values seems trivial at the outset, but it is not in reality; since each API uses return values differently (e.g., `0` can be used to denote either success or failure), it is error-prone. Figure 7 shows such an example found by APISAN in Linux. In this case, `kthread_run()` returns a new `task_struct` or a non-zero error code, so the check against `0` is incorrect (Line 12).

Instead of analyzing API internals, APISAN analyzes how return values are checked in different contexts to infer proper checking of return values of an API. For an API function f , APISAN extracts all symbolic constraints on f 's return values from symbolic execution traces. After extracting all such constraints, APISAN calculates the probability of correct usage for each constraint based on occurrence count. For example, APISAN extracts how frequently the return value of `kthread_run()` is compared with `0` or `IS_ERR(p)`. APISAN reports such cases that the probability of constraints is below a certain threshold as potential bugs; the lower the probability of correctness, the more likely those cases are to be bugs.

Our framework can be easily instantiated to capture return value context by defining the context function $\text{returnValueContexts}(t, i)$, as shown in Figure 6, which extracts all checks on the return value of the function called at $t[i]$ (i.e., the i^{th} event in trace t).

3.2.2 Relations on Arguments

In many APIs, arguments are semantically inter-related. Typical examples are memory copy APIs, such as `strncpy(d, s, n)` and `memcpy(d, s, n)`; for correct operation without buffer overrun, the size of the destination

buffer d should be larger or equal to the copy length n .

APISAN uses a simple heuristic to capture possible relations between arguments. APISAN decides that two arguments are related at a function call if their symbolic expressions share a common symbolic variable. For example, the first and third arguments of `strncpy(malloc(n+1), s, n)` are considered to be related. After deciding whether a pair of arguments are related or not at each call to a function, APISAN calculates the probability of the pair of arguments being related. APISAN then classifies the calls where the probability is lower than a certain threshold as potential bugs.

Another important type of relation on arguments is the constraint on a single argument, e.g., an argument is expected to be a format string. When such constraints exist on well-known APIs like `printf()`, they can be checked by compilers. However, a compiler cannot check user-defined functions that expect a format string argument.

To capture relations on arguments, we define the context function `argRelationContexts` as shown in Figure 6. It is also straightforward to handle the format string check by extending the definition with a format check as a pair relation, such as $(-1, i)$, where -1 indicates that the pair is a special check and i denotes the i^{th} argument that is under consideration for a format check.

3.2.3 Constrained Causal Relationships

Causal relationships, also known as the a-b pattern, are common in API usage, such as `lock/unlock` and `malloc/free`. Past research [18, 29] only focuses on finding “direct” causal relationships, that is, no context constraint between two API calls. In practice, however, there are many *constrained* causal relationships as well. The conditional synchronization primitives shown in Figure 8 are one such example. In this case, there is a causal relationship between `mutex_trylock()` and `mutex_unlock()` only when `mutex_trylock()` returns a non-zero value.

```

1 // @drivers/media/usb/pvrusb2/pvrusb2-context.c:194
2 // in Linux v4.5-rc4
3 int pvr2_context_global_init(void) {
4     pvr2_context_thread_ptr = \
5         kthread_run(pvr2_context_thread_func,
6             NULL,
7             "pvrusb2-context");
8     // APISan: Incorrect return value check
9     // @FUNC: kthread_run
10    // @CONS: >= (unsigned long)-4095
11    //      < (unsigned long)-4095
12 *     return (pvr2_context_thread_ptr ? 0 : -ENOMEM);
13 }

```

Figure 7: Incorrect handling of a return value in Linux found by APISAN. `kthread_run()` returns a pointer to `task_struct` upon success or returns an error code upon failure. Because of incorrect handling of return values, this function always returns `0`, i.e., success, even in the case of error.

Both direct and constrained causality relationships can be effectively captured in the APISAN framework by defining a parametric context function $\text{causalityContexts}(\bar{r})$ shown in Figure 6, which extracts all pairs of API calls with \bar{r} as the context constraints between them. Conceptually, the parameter \bar{r} is obtained by enumerating all constraints on return values from all symbolic execution traces. In practice, however, we only check \bar{r} when necessary, for example, we only check constraints on the return value of `f()` after a call to `f()`.

3.2.4 Implicit Pre- and Post-Conditions

In many cases, there are hidden assumptions *before* or *after* calling APIs, namely, implicit pre- and post-conditions. For example, the memory allocation APIs assume that there is no integer overflow on the argument passed as allocation size, which implies that there should be a proper check before the call. Similarly, `SSL_get_verify_result()`, an OpenSSL API which verifies the certificate presented by the peer, is meaningful only when `SSL_get_peer_certificate()` returns a non-NULL certificate of a peer, though which could happen either before or after `SSL_get_verify_result()`. So the validity check of a peer certificate returned by `SSL_get_peer_certificate()` is an implicit pre- or post-condition of `SSL_get_verify_result()`.

Similar to the context checking of causal relationships, we define a parametric context function $\text{conditionContexts}(\bar{r})$ shown in Figure 6, to capture implicit pre- and post-conditions of an API call. Here, the parameter \bar{r} serves as the pre-condition, and the post-condition is extracted along with the called API.

3.3 Ranking Semantic Disbeliefs

After collecting the API usage patterns discussed above, APISAN statistically infers the majority usage patterns for each API function under each context. This computation is described in detail in Figure 5. Intuitively,

```

1 // @kernel/workqueue.c:1977
2 // in Linux v4.5-rc4
3 static bool manage_workers(struct worker *worker)
4 {
5     struct worker_pool *pool = worker->pool;
6     if (!mutex_trylock(&pool->manager_arb))
7         return false;
8     pool->manager = worker;
9     maybe_create_worker(pool);
10    pool->manager = NULL;
11    mutex_unlock(&pool->manager_arb);
12    return true;
13 }

```

Figure 8: An example usage of conditional locking in Linux. `mutex_trylock()` returns non-zero value when a lock is acquired. So `mutex_unlock()` is necessary only in this case.

APISAN labels an API usage pattern as majority (i.e., likely correct usage) if its occurrence ratio is larger than a threshold θ . In our experience, this simple approach is quite effective, though more sophisticated statistical approaches could be further applied. Each call to a function that deviates from its majority usage pattern is reported as a potential bug.

Since our approach is probabilistic in nature, a bug report found by APISAN might be a false alarm. APISAN ranks bug reports in decreasing order of their likelihood of being bugs, so that the most likely bugs have the highest priority to be investigated. Based on the observation that the more the majority patterns repeat, the more confident we are that these majority patterns are correct specifications, APISAN uses the ratio of majority patterns over “buggy” patterns as a measure of the likelihood. In addition, APISAN can also adjust the ranking with domain-specific knowledge about APIs. For example, if an API name contains a sub-string `alloc`, which indicates that it is very likely to handle memory allocation, we can customize APISAN to give more weight for its misuse in the return value checking.

4 Checking API Misuses

In this section, we demonstrate how inferred semantic beliefs described in the previous section can be used to find API misuses. In particular, we introduce eight cases, which use API-specific knowledge for more precise ranking and deeper semantic analysis.

4.1 Checking SSL/TLS APIs

A recent study shows that SSL/TLS APIs are very error-prone—especially, validating SSL certificates is “*the most dangerous code in the world*” [22]. To detect their incorrect use, specialized checkers that rely on hand-coded semantic correctness have been proposed [22, 26].

In APISAN, we easily created a SSL/TLS checker based on the constraints of return values and implicit pre- and post-conditions without manually coding seman-

```

1 // @librabbitmq/amqp_openssl.c:180
2 // in librabbitmq v0.8
3 static int
4 amqp_ssl_socket_open(void *base, const char *host,
5                      int port, struct timeval *timeout) {
6     // APISan: Missing implicit condition
7     // @FUNC : SSL_get_verify_result
8     // @CONS : == X509_V_OK
9     // @COND : SSL_get_peer_certificate != NULL
10    cert = SSL_get_peer_certificate(self->ssl);
11    result = SSL_get_verify_result(self->ssl);
12    if (X509_V_OK != result) {
13        if (!cert || X509_V_OK != result) {
14            goto error_out3;
15        }
16    }

```

Figure 9: Incorrect use of OpenSSL API found in librabbitmq, a message queuing protocol library, by APISAN. `SSL_get_verify_result()` always returns `X509_V_OK` if there is no certificate (i.e., `!cert`). So `SSL_get_peer_certificate()` needs to be validated before or after calling `SSL_get_verify_result()`.

tic correctness. In practice, as we described in §3.2.4, the sequence of API calls and relevant constraints to validate SSL certificates can be captured by using implicit pre- and post-conditions. For example, Figure 9 shows that APISAN successfully inferred valid usage of `SSL_get_verify_result()` and discovered a bug.

4.2 Checking Integer Overflow

Integer overflows remain a very important threat despite extensive research efforts for checking them. Checkers have to deal with two problems: (1) whether there is a potential integer overflow, and (2) whether such a potential integer overflow is exploitable. KINT [45], the state-of-the-art integer security checker, relies on scalable static analysis to find potential integer overflows. To decide exploitability, KINT relies on users’ annotations on untrusted data source and performs taint analysis to decide whether untrusted sources are related to an integer overflow. But if annotations are missing, KINT may miss some bugs.

Instead of annotating untrusted sources, APISAN infers *untrusted sinks* to decide that an integer overflow has security implications. The background belief is “checking sinks implies that such sinks are untrusted.” APISAN considers APIs with arguments that are untrusted sinks as *integer overflow-sensitive APIs*. To infer whether an API is integer overflow-sensitive, the checker extracts all function calls whose arguments have arithmetic operations that can result in integer overflow. The checker classifies such function calls into three categories: (1) correct check, (2) incorrect check, and (3) missing check. If an argument has a constraint that prevents integer overflow, then it is a correct check. Determining potential integer overflow is straightforward because APISAN maintains a numerical range for each symbolic variable. If such a constraint cannot prevent integer overflow, then it is an

```

1 // @fs/ext4/resize.c:193
2 // in Linux v4.5-rc4
3 static struct ext4_new_group_data
4     *alloc_flex_gd(unsigned long flexbg_size)
5 {
6     if (flexbg_size >=
7         UINT_MAX / sizeof(struct ext4_new_group_data))
8         goto out2;
9     flex_gd->count = flexbg_size;
10    // APISan: Incorrect integer overflow check
11    // @CONS: flexbg_size < UINT_MAX / 20
12    // @EXPR: flexbg_size * 40
13    flex_gd->groups =
14        kmalloc(sizeof(struct ext4_new_group_data) *
15                flexbg_size, GFP_NOFS);
16 }

```

Figure 10: An integer overflow vulnerability found in Linux by APISAN. Since `struct ext4_new_group_data` is larger than `struct ext4_new_flex_group_data`, previous overflow check can be bypassed. Interestingly, this bug was previously found by KINT and already patched [8], but APISAN found the patch is actually incorrect.

incorrect check. Finally, if there is no constraint, then it is a missing check. The checker concludes that an API is more integer overflow-sensitive if the ratio of correct checks over total checks is higher. The checker gives a higher rank to incorrect checks followed by missing checks. For example, Figure 10 shows an integer overflow vulnerability found by APISAN.

4.3 Checking Memory Leak

A memory leak can be represented as a causal relationship between memory allocation and free functions. As Figure 1 shows, APISAN can infer a constrained causal relation between such a pair of functions, which may not be captured as a direct causal relation. When a function that is presumed to be a free function is not called following a function that is presumed to be the corresponding allocation function, it is reported as a memory leak with a higher rank. In this manner, APISAN effectively captures typical usage patterns of memory allocation and free routines to report potential memory leaks.

4.4 Checking Lock and Unlock

Similar to checking memory leaks, lock checking is based on a constrained causal relationship between lock and unlock functions inferred by APISAN. It gives a higher rank to cases where there are missing unlock function calls in some of the paths. For example, Figure 11 shows that there is one missing `clk_prepare_unlock()` call among two symbolic execution paths.

4.5 Checking NULL Dereference

NULL dereference can happen by accessing a pointer returned by a memory allocation function, such as `malloc()` and `kmalloc()`, without validation. Checking NULL

```

1 // @drivers/clk/clk.c:2672
2 // in Linux v4.5-rc4
3 void clk_unregister(struct clk *clk) {
4     clk_prepare_lock();
5     if (clk->core->ops == &clk_nodrv_ops) {
6         pr_err("%s: unregistered clock: %s\n", __func__,
7                clk->core->name);
8         // APISan: Missing clk_prepare_unlock()
9         // @FUNC: clk_prepare_lock
10        // @CONS: None
11        // @POST: clk_prepare_unlock
12        return;
13    }
14    clk_prepare_unlock();
15 }

```

Figure 11: A missing unlock bug in Linux found by APISAN. It shows a common pattern of violating a causal relation.

dereference is based on the return value inference of APISAN. It collects how frequently the return value of a function is compared against NULL. Based on this information, it can find missing NULL checks. In addition, it gives a higher rank to cases where the function name contains common keywords for allocation such as alloc or new.

4.6 Checking Return Value Validation

Checking a return value of a function properly is more important than checking a return value itself. If the return value is incorrectly checked, the caller is likely to believe that the callee succeeded. Moreover, it is quite usual that incorrect checks fail only in rare cases, so that finding such incorrect checks is much more difficult than completely omitted checks. APISAN can find bugs of this kind, such as the one shown in Figure 7, by comparing constraints of return value checks.

4.7 Checking Broken Argument Relation

We can find potential bugs by inferring and finding broken relations between arguments. However, detecting a broken relation does not mean that it is always a bug, because there might be an implicit relation between two arguments that cannot be captured by APISAN (e.g., complex pointer aliasing of the buffer). This lack of information is complemented by a ranking policy that incorporates domain-specific knowledge, for example, a broken argument relation is ranked higher if either argument has a sizeof() operator.

4.8 Checking Format String

Incorrect use of format strings is one frequent source of security vulnerabilities [39]. Modern compilers (e.g., gcc) give compile-time warnings for well-known APIs such as printf(). However, in the case of programs that have their own printf-like functions (e.g., PHP), compilers cannot detect such errors.

To infer whether a function argument is a format string, we use a simple heuristic: if the majority of symbolic expressions for an argument is a constant string and contains well-known format codes (e.g, %s), then the argument is considered as a format string. For the cases where a symbolic variable is used as a format string argument, the corresponding API calls will be considered as potential bugs. Similarly, domain-specific knowledge can be applied as well. Bug reports of an API whose name contains a sub-string print is ranked higher, since it indicates that the API is very likely to take a format string as an argument.

5 Implementation

APISAN is implemented in 9K lines of code (LoC) as shown in Table 1: 6K of C/C++ for generating symbolic execution traces, which is based on Clang 3.6, and 3K of Python for checkers and libraries. We empirically chose a threshold value of **0.8** for deciding whether to label an API usage pattern as majority. Since APISAN ranks all reports in order of bug likelihood, however, the result is not sensitive to the threshold value in that the ordering of the top-ranked reports remains the same.

Component	Lines of code
Symbolic database generator	6,256 lines of C/C++
APISAN Library	1,677 lines of Python
Checkers	1,047 lines of Python
Total	8,980 lines of code

Table 1: Components and lines of code of APISAN.

6 Evaluation

To evaluate APISAN, this section attempts to answer the following questions:

- How effective is APISAN in finding previously unknown API misuses? (§6.1)
- How easy is APISAN to use by end-users and checker developers? (§6.2)
- How reasonable is APISAN’s relaxed symbolic execution in finding bugs? (§6.3)
- How effective is APISAN’s approach in ranking bugs? (§6.4)
- How effective is APISAN’s approach compared to manual checking? (§6.5)

6.1 New Bugs

We applied APISAN to Linux v4.5-rc4, OpenSSL 1.1.0-pre3-dev, PHP 7.0, Python 3.6, and all 1,204 debian packages using the OpenSSL library. APISAN generated 40,006 reports in total, and we analyzed the reports

Table 2: List of new bugs discovered by APISAN. We sent patches of all 76 new bugs; 69 bugs have been already confirmed and applied by corresponding developers (marked ✓ in the rightmost column); 7 bugs (marked P in the rightmost column) have not been confirmed yet. APISAN analyzed 92 million LoC and found one bug per 1.2 million LoC.

according to ranks. As a result, APISAN found 76 previously unknown bugs: 64 in Linux, 3 in OpenSSL, 4 in PHP, 1 in Python, and 5 in the debian packages (see Table 2 for details). We created patches for all the bugs and sent them to the mainline developers of each project. 69 bugs have been confirmed by the developers and most have already been applied to the mainline repositories. For remaining, 7 bugs, we are waiting for their response.

Security implications. All of the bugs we found have serious security implications: e.g., code execution, system crash, MITM, etc. For a few bugs including integer overflows in Python(CVE-2016-5636 [13]) and PHP, we could even successfully exploit them by chaining ROP gadgets [2, 27]. In addition, we found that the vulnerable Python module is in the whitelist of Google App Engine and reported it to Google.

6.2 Usability

End-users. APISAN can be seamlessly integrated into an existing build process. Users can generate symbolic execution databases by simply invoking the existing build command, e.g., `make`, with apisan.

```
1 # generate DB
2 $ apisan make
```

With the database, users can run various checkers, which extract semantic beliefs from the database and locate potential bugs in order of their likelihood. For eight types of API misuses described at §4, we developed five checkers: return value checker (`rvchk`), causality checker (`cpair`), argument relation checker (`args`) implicit pre- and post-condition checker (`cond`), and integer overflow checker (`intovfl`).

```
1 # run a causality checker
2 $ apisan --checker=cpair
3 @FUNC: EVP_PKEY_keygen_init
4 @CONS: ((-2147483648, 0),)
5 @POST: EVP_PKEY_CTX_free
6 @CODE: { req.c:1745 }
7 ...
```

APISAN can also be run against multiple databases generated by different project code repositories. For example, users can infer semantic beliefs from multiple programs (e.g., all packages using libssl) and similarly get a list of ranked, potential bugs. This is especially useful for relatively young projects, which lack sufficient API usages.

```
1 # check libssl misuses by using rabbitmq and hexchat repos
2 $ apisan --checker=cond --db=rabbitmq,hexchat
```

Checker developers. Developing specialized checkers is easy; APISAN provides a simple interface to access symbolic execution databases. Each of our checkers is around 200 lines of Python code as shown in §5. Providing API-specific knowledge such as manual annotations can be easily integrated in the Python script.

		UC-KLEE	APISAN
Approach	Loop Inter-procedural Constraint	best effort yes SAT	once no numerical range
Bugs (OpenSSL)	Memory leak NULL dereference Uninitialized data	5 - 6	7 (2*) 11 -

Table 3: Comparison between UC-KLEE and APISAN in approaches and bugs found in OpenSSL v1.0.2, which is used in UC-KLEE’s evaluation [37]. APISAN found 7 memory leak bugs and 11 NULL dereference vulnerabilities; two memory leak bugs (marked *) were previously unknown, and our two patches have been applied to the mainline repository.

6.3 Effect of Relaxed Symbolic Execution

One of our key design decisions is to use relaxed symbolic execution for scalability at the cost of accuracy. To evaluate the effect of this design decision, we compare APISAN against UC-KLEE, which performs best-effort accurate symbolic execution including inter-procedural analysis and best-effort loop unrolling. For comparison, we ran UC-KLEE and APISAN on OpenSSL v1.0.2, which is the version used for UC-KLEE’s evaluation. Table 3 shows a summary of the result.

APISAN found 11 NULL dereference bugs caused by missing return value checks of `OPENSSL_malloc()`, which are already fixed in the latest OpenSSL. Also, APISAN found seven memory leak bugs related to various APIs, such as `BN_CTX_new()`, `BN_CTX_start()`, and `EVP_PKEY_CTX_new()`, without any annotations. Two of these bugs were previously unknown; we sent patches which were confirmed and applied to the OpenSSL mainline. UC-KLEE found five memory leak bugs related to `OPENSSL_malloc()` with the help of users’ annotations.

Interestingly, there is no common bug between UC-KLEE and APISAN. UC-KLEE cannot find the bugs that APISAN found because of function pointers, which are frequently used for polymorphism, and path explosion in complex cryptographic operations. APISAN does not discover the five memory bugs that UC-KLEE found because of diverse usages of `OpenSSL_malloc()`. Also, APISAN could not find any uninitialized memory bugs since it does not track memory accesses.

6.4 Ranking Effectiveness

Another key design aspect of APISAN is its ranking scheme. In this section, we investigate two aspects of our ranking scheme: (1) where true-positives are located in bug reports and (2) what are typical reasons of false positives. To this end, we analyzed the results of the return value checker (`rvchk`) on Linux v4.5-rc4.

True positives. If true-positive reports are highly ranked, developers can save effort in investigating bug reports. An

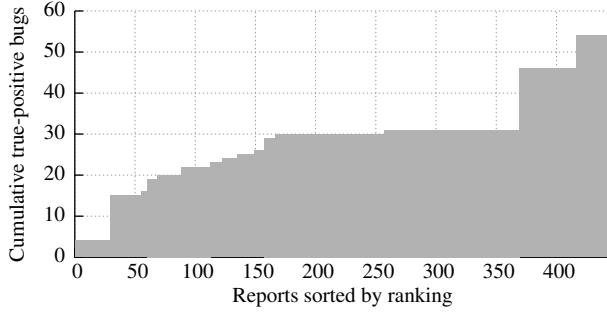

Figure 12: Cumulative true-positive bugs in Linux v4.5-rc4 reported by our return value checker (rvchk). We investigated top 445 bug reports out of 2,876 reports in total. Most new bugs are highly ranked.

author audited the top 445 reports out of 2,876 reports for two days and found 54 new bugs. As shown in Figure 12, most new bugs are highly ranked. This shows that our ranking scheme is effective to save developers’ effort by letting them investigate the highest-ranked reports first.

False positives. To understand what causes false positives, we manually investigated all false positive cases in the top 445 reports, and found a few frequent reasons: diverse patterns of return value checking, wrapper functions delegating return value checking to callers, and semantically correct, but rare patterns.

Some kernel APIs, such as `snd_pcm_new()` [40], return zero on success or a negative error code on failure. In this case, there are two valid ways to check for error: comparison against zero (i.e., $\text{== } 0$) or negative value (i.e., < 0). If the majority of code follows one pattern (`snd_pcm_new() < 0`), APISAN flags the minor correct cases as bugs.

Some wrapper functions delegate return value checking to their callers. APISAN treats these cases as if return value checking is missing because APISAN does not perform inter-procedural analysis.

If a return value of a function can have multiple meanings, APISAN can decide the rare cases as bugs. For example, most functions use `strcmp()` to test if two strings are equivalent (i.e., $\text{== } 0$). But for the rare cases, which in fact use `strcmp()` to decide alphabetical order of two strings (i.e., < 0), APISAN generates false alarms.

6.5 Comparison with Manual Auditing

The other extreme to automatic bug finding is manual auditing by developers. Manual auditing would be the most accurate but is not scalable in size and cost. We compared APISAN with manual auditing to grasp how accurate APISAN is compared to the ground truth.

To this end, we manually inspected memory allocation and free functions in OpenSSL v1.1.0-pre3-dev because OpenSSL faithfully follows naming conventions: allocation functions end with `_new` or `alloc`, and free functions end with `_free`.

```

1 // @ext/standard/string.c:877
2 // in PHP v5.5.9-rc1
3 PHP_FUNCTION(wordwrap) {
4     if (linelength > 0) {
5         chk = (int)(textlen/linelength + 1);
6         // no integer overflow
7         newtext = safe_emalloc(chk, \
8             breakcharlen, textlen + 1);
9         allocated = textlen + chk * breakcharlen + 1;
10    }
11 }

```

```

1 // @ext/standard/string.c:946
2 // in PHP v7.0.0-rc1
3 PHP_FUNCTION(wordwrap) {
4     if (linelength > 0) {
5         chk = (size_t)(ZSTR_LEN(text)/linelength + 1);
6         // introduce a new integer overflow
7         newtext = zend_string_alloc( \
8             chk * breakchar_len + ZSTR_LEN(text), 0);
9         allocated = ZSTR_LEN(text) + chk * breakchar_len + 1;
10    }
11 }

```

Figure 13: An integer overflow bug introduced by changing string allocation API in PHP. While the old string allocation API, `safe_emalloc()`, internally checks integer overflow, the new API, `zend_string_alloc()` has no such check.

To determine how APISAN accurately infers the correct check of return value, we counted how many allocation functions are inferred to need NULL checking by APISAN. Among 294 allocation functions, APISAN successfully figured out that 164 allocation functions require NULL checking. To assess the accuracy of APISAN’s causal relation inference, we counted how many allocation-free functions are inferred as causal relations by APISAN. APISAN found 37 pairs out of 187 such causal relations.

The inaccuracy of APISAN mainly stems from a small number of API usages and limited symbolic execution. For example, if allocated memory is freed by a callback function, APISAN fails to detect the causal relation.

6.6 Performance

Our experiments are conducted on a 32-core Xeon server with 256GB RAM. Constructing a symbolic database for Linux kernel, a one-time task for analysis, takes roughly eight hours and generates 300 GB database. Each checker takes approximately six hours. Thus, APISAN can analyze a large system in a reasonable time bound.

6.7 Our Experience with APISAN

While investigating the bug reports generated by APISAN, we found several interesting bugs, which were introduced while fixing bugs or refactoring code to reduce potential bugs. We believe that it shows that bug fixing is the essential activity during the entire life cycle of any software, and automatic bug finding tools such as APISAN should be scalable enough for them to be integrated into the daily software development process.

Incorrect bug fixes. Interestingly, APISAN found an incorrect bug patch, which was found and patched by KINT [45]. The bug was a missing integer overflow check in ext4 file system, but the added condition was incorrect [8]. Also, the incorrect patch was present for almost four years, showing the difficulty of finding such bugs that can be reproduced only under subtle conditions. Since APISAN gives a higher rank for incorrect condition check for integer overflow, we easily found this bug.

Incorrect refactoring. While investigating PHP integer overflow bugs in Figure 13, we found that the bug was newly introduced when changing string allocation APIs; the new string allocation API, `zend_string_alloc()`, omits an internal integer overflow check, making its callers vulnerable to integer overflow.

7 Discussion

In this section, we discuss the limitations of APISAN’s approach and discuss potential future directions to mitigate the limitations.

Limitations. APISAN does not aim to be sound nor complete. In fact, APISAN has false positives (§6.4) as well as false negatives (§6.3, §6.5).

Replacing manual annotations. One practical way to reduce false negatives is to run multiple checkers on the same source code. In this case, APISAN’s inference results can be used to provide missing manual annotations required by other checkers. For example, APISAN can provide inferred integer overflow-sensitive APIs to KINT and inferred memory allocation APIs to UC-KLEE.

Interactive ranking and filtering. In our experience, the false positive reports of APISAN are repetitive since incorrect inference of an API can incur many false positive reports. Therefore, we expect that incorporating the human feedback of investigation into APISAN’s inference and ranking will significantly reduce false positives and developers’ investigation efforts.

Self regression. As we showed in §6.7, bug fixing and refactoring can introduce new bugs. APISAN’s approach is also a good fit for self-regression testing by comparing two versions of bug reports and giving higher priorities to changed results.

8 Related Work

In this section, we survey related work in bug finding, API checking, and semantic inference.

Finding bugs. Meta compilation [3, 17, 25] performs static analysis integrated with compilers to enforce domain-specific rules. RacerX [16] proposed flow-sensitive static analysis for finding deadlocks and race

conditions. LCLint [20] detects mismatches between source code and user-provided specifications. Sparse [41] is a static analysis tool to find certain types of bugs (e.g., mixing pointers to user and kernel address spaces, and incorrect lock/unlock) in the Linux kernel based on developers’ annotations. Model checking has been applied to various domains including file systems [24, 38, 48, 49], device drivers [5], and network protocols [34]. A frequent obstacle in applying these techniques is the need to specify semantic correctness, e.g., domain-specific rules and models. In contrast, APISAN statistically infers semantic correctness from source code; it is generic without requiring models or annotations, but it could incur higher false positives than techniques that use precise semantic correctness information.

Checking API usages. SSLint [26] is a static analysis tool to find misuses of SSL/TLS APIs based on predefined rules. MOPS [9] checks source code against security properties, i.e., rules of safe programming practices. Jfern [46] models common vulnerabilities into graph traversals in a code property graph. Unlike these solutions, which are highly specialized for a certain domain (or an API set) and rely on hand-coded rules, APISAN is generally applicable to any domain without manual effort.

Inferring semantics. Engler et al. [18] find deviations from the results of static analysis. Juxta [32] finds deviations by comparing multiple file systems, which follow similar specifications. APISAN’s goal is to find deviations in API usages under rich symbolic contexts. DynaMine [30] and VCCFinder [36] automatically extract bug patterns from source code repositories by analyzing bug patches. These approaches would be useful in APISAN as well.

Automatic generation of specifications has been explored by Kremenek et al. [28] for resource allocation, by PRMiner [29] for causal relations, by APIMiner [1] for partial ordering of APIs, by Daikon [19] from dynamic execution traces, by Taghdiri et al. [43] for structural properties, by PRIME [33] for temporal specifications, by Nguyen et al. [35] for preconditions of APIs, by Gruska et al. [23] for sequences of functions, by JIGSAW [44] for resource accesses, by MERLIN [31] for information flow specifications, and by Yamaguchi et al. [47] for taint-style vulnerabilities. These approaches focus on extracting one aspect of the specification. Also, some of them [1, 43] are not scalable because of the complexity of the algorithms used. On the other hand, APISAN focuses on extracting four orthogonal aspects of API usages and using them in combination to find complex bug patterns.

9 Conclusion

We proposed APISAN, a fully automated system for finding API usage bugs by inferring and contrasting semantic beliefs about API usage from source code. We applied APISAN to large, widely-used software, including the Linux kernel, OpenSSL, PHP, and Python, composed of 92 million lines of code. We found 76 previously unknown bugs of which 69 bugs have already been confirmed. Our results show that APISAN’s approach is effective in finding new bugs and is general enough to extend easily to custom API checkers based on APISAN.

A Appendix

Function $\text{retvars}(e)$ returns all $\langle \text{ret}, i \rangle$ variables in e , which is defined as follows:

$$\text{retvars}(e) = \begin{cases} \emptyset & \text{if } e \equiv n \\ \emptyset & \text{if } e \equiv \langle \text{arg}, i \rangle \\ \{\langle \text{ret}, i \rangle\} & \text{if } e \equiv \langle \text{ret}, i \rangle \\ \text{retvars}(e') & \text{if } e \equiv uop e' \\ \text{retvars}(e_1) \cup \text{retvars}(e_2) & \text{if } e \equiv e_1 \text{ bop } e_2 \end{cases}$$

Function $\text{argvars}(e, t)$ returns all $\langle \text{arg}, i \rangle$ variables in e , consulting t to recursively replace each $\langle \text{ret}, i \rangle$ variable by its associated function call symbolic expression. It is defined as follows:

$$\text{argvars}(e, t) = \begin{cases} \emptyset & \text{if } e \equiv n \\ \{\langle \text{arg}, i \rangle\} & \text{if } e \equiv \langle \text{arg}, i \rangle \\ \bigcup_{j=1}^{|e'|} \text{argvars}(e'[j], t) & \text{if } e \equiv \langle \text{ret}, i \rangle, \text{ where} \\ & t[i] \equiv \text{call*}(e') \\ \text{argvars}(e', t) & \text{if } e \equiv uop e' \\ \text{argvars}(e_1, t) \cup \text{argvars}(e_2, t) & \text{if } e \equiv e_1 \text{ bop } e_2 \end{cases}$$

Abstract

Metadata manipulation attacks represent a new threat class directed against Version Control Systems, such as the popular Git. This type of attack provides inconsistent views of a repository state to different developers, and deceives them into performing unintended operations with often negative consequences. These include omitting security patches, merging untested code into a production branch, and even inadvertently installing software containing known vulnerabilities. To make matters worse, the attacks are subtle by nature and leave no trace after being executed.

We propose a defense scheme that mitigates these attacks by maintaining a cryptographically-signed log of relevant developer actions. By documenting the state of the repository at a particular time when an action is taken, developers are given a shared history, so irregularities are easily detected. Our prototype implementation of the scheme can be deployed immediately as it is backwards compatible and preserves current workflows and use cases for Git users. An evaluation shows that the defense adds a modest overhead while offering significantly stronger security. We performed responsible disclosure of the attacks and are working with the Git community to fix these issues in an upcoming version of Git.

1 Introduction

A Version Control System (VCS) is a crucial component of any large software development project, presenting to developers fundamental features that aid in the improvement and maintenance of a project’s codebase. These features include allowing multiple developers to collaboratively create and modify software, the ability to roll back to previous versions of the project if needed, and a documentation of all actions, thus tying changes in files to their authors. In this manner, the VCS maintains a progressive history of a project and helps ensure the integrity of the software.

Unfortunately, attackers often break into projects’ VCSs and modify the source code to compromise hosts who install this software. When this happens, an attacker can introduce vulnerable changes by adding (e.g., adding a backdoor), or removing certain elements from a project’s history (e.g., a security patch) if he or she acquires write access to the repository. By doing this, attackers are usually able to compromise a large number of hosts at once [42, 27, 13, 21, 15, 4, 45, 18, 44]. For example, the Free Software Foundation’s repository was controlled by hackers for more than two months, serving potentially backdoored versions of GNU software to millions of users [16].

The existing security measures on VCSs, such as commit signing and push certificates [19, 2], provide limited protection. While these mechanisms prevent an attacker from tampering with the contents of a file, they do not prevent an attacker from modifying the repository’s metadata. Hence, these defenses fail to protect against many impactful attacks.

In this work, we reveal several new types of attacks against Git, a popular VCS. We collectively call these attacks *metadata manipulation attacks* in which Git metadata is modified to provide inconsistent and incorrect views of the state of a repository to developers. These attacks can be thought of as *reconcilable fork attacks* because the attacker can cause a developer’s version of the repository to be inconsistent just for a finite window of time — only long enough to trick a developer into committing the wrong action — and leave no trace of the attack behind.

The impact of an attack of this nature can be substantial. By modifying the right metadata, an attacker can remove security patches, merge experimental code into a production branch, withhold changes from certain users before a release, or trick users and tools into installing a different version than the one requested to the VCS. To make matters worse, the attacker only requires a few resources to achieve his or her malicious goals.

We have submitted a vulnerability disclosure to CERT and the GitHub security team describing the following scenario: an attacker capable of performing a man-in-the-middle attack between a GitHub [3] server and a developer using pip to install Django (a popular website framework) can trick the developer into installing a vulnerable version simply by replacing one metadata file with another. Even though Git verifies that the signature in Git objects is correct, it has no mechanism to ensure it has retrieved the correct object. This type of attack enables a malicious party to strike any system that can retrieve packages from Git repositories for installation, including Node’s NPM [22], Python’s pip [11], Apache Maven [34], Rust’s cargo [35], and OCaml’s OPAM [33]. As such, it could potentially affect hundreds of thousands of client devices.

To mitigate metadata manipulation attacks, we designed and implemented a client-only, backwards-compatible solution that introduces only minimal overhead. By storing signed reference state and developer information on the server, multiple developers are able to verify and share the state of the repository at all times. When our mechanism is in place, Git metadata manipulation attacks are detected. We have presented these issues to the Git developer community and prepared patches — some of which are already integrated into Git — to fix these issues in upcoming versions of Git.

In summary, we make the following contributions:

- We identify and describe metadata manipulation attacks, a new class of attacks against Git. We show these attacks can have a significant practical impact on Git repositories.
- We design a defense scheme to combat metadata manipulation attacks by having Git developers share their perception of the repository state with their peers through a signed log that captures their history of operations.
- We implement the defense scheme and study its efficiency. An evaluation shows that it incurs a smaller storage overhead than push certificates, one of Git’s security mechanisms. If our solution is integrated in Git, the network communication and end-to-end delay overhead should be negligible. Our solution does not require server side software changes and can be used today with existing Git hosting solutions, such as GitHub, GitLab, or Bitbucket.

2 Background and related work

2.1 Overview of Git

In order to understand how Git metadata manipulation attacks take place, we must first define Git-specific terminology, as well as some usage models of the tool itself.

Git is a distributed VCS that aids in the development of software projects by giving each user a local copy of the relevant development history, and by propagating changes made by developers (or their history) between such repositories. Essential to the version history of code committed to a Git repository are `commit` objects, which contain metadata about who committed the code, when it was committed, pointers to the previous commit object, (the `parent` commit) and pointers to the objects (e.g., a file) that contain the actual committed code.

Branches serve as “pointers” to specific commit objects, and to the development history that preceded each commit. They are often used to provide conceptual separation of different histories. For example, a branch titled “`update-hash-method`” will only contain objects that modify the hash method used in a project. When a developer adds a new commit to the commit chain pointed to by a branch, the branch is moved forward.

Inside Git, branches are implemented using “reference” files, that only contain the SHA1 hash of a target commit. The same format is used for Git tags, which are meant to point to a static point in the project’s history. Both tags and branches live in the `.git/refs` folder.

Git users `commit` changes to their local repositories, and employ three main commands to propagate changes between repositories: `fetch`, to retrieve commits by other developers from a remote repository; `merge`, to merge two changesets into a single history; and `push`, to send local commits from a local repository to a remote repository. Other common commands may consist of two or more of these commands performed in conjunction (e.g., `pull` is both a `fetch` and a `merge`). Consider the following example:

Alice is working on a popular software project and is using Git to track and develop her application. Alice will probably host a “blessed” copy of her repository in one provider (e.g., GitHub or Gitlab) for everyone to clone, and from which the application will eventually be built. In her computer, she will keep a `clone` (or copy) of the remote repository to work on a new feature. To work on this feature, she will create a new `branch`, `#5-handle-unicode-filenames` that will diverge from the `master` branch from now on. As she modifies files and updates the codebase, she commits – locally – and the updates will be added to the new branch in her local clone. Once Alice is done adding the feature, she will `push` her local commits to the remote server and request a colleague to review and `merge` her changes into the `master` branch. When the changes are merged, Alice’s commits will become part of the `master` history and, on the next release cycle, they will be shipped in the new version of the software.

2.1.1 Git security features

To ensure the integrity of the repository’s history, Git incorporates several security features that provide a basic defense layer:

- Each commit object contains a cryptographic hash of its parent commit. In addition, the name of the file that contains the commit object is the cryptographic hash of the file’s contents. This creates a hash chain between commits and ensures that the history of commits cannot be altered arbitrarily without being detected.
- Users have the option to cryptographically sign a commit (a digital signature is added to the commit object) using a GPG key. This allows an auditor to unequivocally identify the user who committed code and prevents users from repudiating their commits.
- A signed certificate of the references can be pushed to a remote repository. This “push certificate” solution addresses man-in-the-middle attacks where the user and a well-behaving server can vouch for the existence of a push operation.

2.2 Related work

VCS Security. Wheeler [39] provides an overview of security issues related to software configuration management (SCM) tools. He puts forth a set of security requirements, presents several threat models (including malicious developers and compromised repositories), and enumerates solutions to address these threats. Gerwitz [17] provides a detailed description of creating and verifying Git signed commits. Signing commits allows the user to detect modifications of committed data. Git incorporates protection mechanisms, such as commit signing and commit hash chaining. Unfortunately, they do not prevent the attacks we introduce in this work.

There have been proposals to protect sensitive data from hostile servers by incorporating secrecy into both centralized and distributed version control systems [1, 29]. Shirey et al. [32] analyzes the performance trade-offs of two open source Git encryption implementations. Secrecy from the server might be desirable in certain scenarios, but it is orthogonal to our goals in this work.

The “push certificate” mechanism, introduced in version 2.2.0 of Git, allows a user to digitally sign the reference that points to a pushed object. However, push certificates do not protect against most of the attacks we describe in this work. Furthermore, push certificates were designed for out-of-band auditing (*i.e.* they are not integrated into the usual workflow of Git and need to be fetched and verified by a trusted third party using out-of-band mechanisms). As a result, push certificates are rarely used in practice.

Fork Consistency. A problem that could arise in remote storage used for collaborative purposes is when the un-

trusted storage server hides updates performed by one group of users from another. In other words, the server equivocates and presents different views of the history of operations to different groups of users. The *fork consistency* property seeks to address this attack by forcing a server that has forked two groups in this way to continue this deception. Otherwise, the attack will be detected as soon as one group sees an operation performed by the other group after the moment the fork occurred.

SUNDR [26] provides fork consistency for a network file system that stores data on untrusted servers. In SUNDR, users sign statements about the complete state of all the files and exchange these statements through the untrusted server. SPORC [14] is a framework for building collaborative applications with untrusted servers that achieves fork* consistency (*i.e.*, a weaker variant of fork consistency). Our solution seeks to achieve a similar property and shares similarities with SUNDR in that Git users leverage the actual Git repository to create and share signed statements about the state of the repository. However, the intricacies and usage model of a VCS system like Git impose a different set of constraints.

Other work, such as Depot [28], focuses on recovering from forks in an automatic fashion (*i.e.*, not only detecting forks, but also repairing after they are detected). Our focus is on detecting the metadata manipulation attacks, after which the affected users can perform a manual rollback procedure to a safe point.

Caelus [25] seeks to provide the same declared history of operations to all clients of a distributed key-value cloud store. Caelus assumes that no external communication channel exists between clients, and requires them to periodically attest to the order and timing of operations by writing a signed statement to the cloud every few seconds. The attestation schedule must be pre-defined and must be known to all clients. Our setting is different, since Git developers usually communicate through multiple channels; moreover, a typical team of Git developers cannot be expected to conform to such an attestation policy in practice.

3 Threat model and security guarantees

We make the following assumptions about the threat model our scheme is designed to protect against:

- Developers use the existing Git signing mechanisms whenever performing an operation in Git to stop an attacker from tampering with files.
- An attacker cannot compromise a developer’s key or get other developers to accept that a key controlled by an attacker belongs to a legitimate developer. Alternatively, should an attacker control such a key (*e.g.*, an insider attack), he or she may not

want to have an attack attributed to him- or herself and would thus be unwilling to sign data they have tampered with using their key.

- The attacker can read and modify any files on the repository, either directly (*i.e.* a compromised repository or a malicious developer) or indirectly (*i.e.*, through MITM attacks and using Git’s interface to trick honest users into doing it).
- The attacker does not want to alert developers that an attack has occurred. This may lead to out-of-band mechanisms to validate the attacked repository [30].

This threat model covers a few common attack scenarios. First of all, an attacker could have compromised a software repository, an unfortunately common occurrence [42, 27, 13, 21, 15, 4, 45, 18, 44, 16]. Even if the repository is not compromised, an attacker could act as a man-in-the-middle by intercepting traffic destined for the repository (e.g., by forging SSL certificates [23, 31, 8, 37, 43, 7, 41, 6, 38]). However, an attacker is not limited to these strategies. As we will show later, a malicious developer can perform many of the same attacks *without using their signing key*. This means that it is feasible for a developer inside an organization to launch these attacks and not be detected.

Note that in all cases, the developers have known signing keys to commit, push, and verify information.

3.1 Security guarantees

Answering to this threat model, the goal of a successful defensive system should be to enforce the following:

- **Prevent modification of committed data:** If a file is committed, an attacker should not be able to modify the file’s contents without being detected.
- **Ensure consistent repository state:** All developers using a repository should see the same state. The repository should not be able to equivocate and provide different commits to different developers.
- **Ensure repository state freshness:** The repository should provide the latest commits to each developer.

As we will show later, Git’s existing security mechanisms fail to handle the last two properties. The existing signing mechanism for Git does enable developers to detect modification of committed data, because the changed data will not be correctly signed. However, due to weaknesses in handling the other properties, an attacker can omit security patches, merge experimental features into production, or serve versions of software with known vulnerabilities.

An attacker is successful if he or she is able to break any of these properties without being detected by the developers. So, an attacker who controls the repository could block a developer from pushing an update by pretending the repository is offline. However, since the developer receives an error, it is obvious that an attack is occurring and therefore is easy to detect. Similarly, this also precludes *irreconcilable fork attacks* where two sets of developers must be permanently segregated from that point forward. Since developers typically communicate through multiple channels, such as issue trackers, email, and task management software, it will quickly become apparent that fixes are not being merged into the master branch. (Most projects have a tightly integrated team, usually a single person, who integrates changes into the master branch, which further ensures this attack will be caught.) For these reasons, we do not focus on attacks that involve a trivial denial of service or an irreconcilable fork because they are easy to detect in practice.

4 Metadata manipulation attacks

Even when developers use Git commit signing, there is still a substantial attack surface. We have identified a new class of attacks that involve manipulation of Git metadata stored in the `.git/refs` directory of each repository. We emphasize that, unlike Git commits that can be cryptographically signed, there are no mechanisms in Git to protect this metadata. As such, the metadata can be tampered with to cause developers to perceive different states of the repository, which can coerce or trick them into performing unintended operations in the repository. We also note that a solution that simply requires users to sign Git metadata has serious limitations (as described in Sec. 5.2).

Unlike many systems where equivocation is likely to be noticed immediately by participants, Git’s use of branches hides different views of the repository from developers. In many development environments, developers only have copies of branches that they are working on stored locally on their system, which makes it easy for a malicious repository to equivocate and show different views to different developers.

In Git, a branch is represented by a file that contains the SHA1 checksum of a commit object (under benign circumstances, this object is the latest commit on that branch). We will refer to such files as *branch references*. All the branch references are stored in the directory `.git/refs/heads/`, with the name of the branch as the filename. For example, a branch “hotfix” is represented by the file `.git/refs/heads/hotfix`.

We discovered that it is straightforward for an attacker to manipulate information about branches by simply changing contents in a reference file to point to any

other commit object. *Modifying the branch reference can be easily performed with a text editor and requires no sophistication.* Specifically, we show three approaches to achieve this, all of them being captured by our adversarial model. *First*, an attacker who has compromised a Git repository and has write access to it, can directly modify the metadata files. *Second*, an attacker can perform an MITM attack by temporarily redirecting a victim’s traffic to a fake repository serving tampered metadata, and then reestablishing traffic so the victim propagates the vulnerable changes to the genuine repository (in Appendix A, we describe a proof-of-concept attack against GitHub based on this approach). *Third*, a malicious developer can take advantage of the fact that Git metadata is synchronized between local and remote repositories. The developer manipulates the Git metadata in her local repository, which is then propagated to the (main) remote repository.

It is also possible to extend these attacks for Git tags. Although a Git tag is technically a Git tag object that can be signed the same way as a commit object, an attacker can target the *reference* pointing to a tag. Tag references are stored in the directory `.git/refs/tags/` and work similarly to branch references, in that they are primarily a file containing the SHA1 of a Git tag object that points to a Git commit object. Although Git tags are conceptually different — they only represent a fixed point (e.g., a major release version) in the projects history — they can be exploited in the same way, because Git has no mechanism to protect either branch or tag references.

We have validated the attacks against a standard Git server and also the GitHub, GitLab and other popular Git hosting services.

Based on their effect on the state of the repository, we identify three types of metadata manipulation attacks:

- **Teleport Attacks:** These attacks modify a Git reference so that it points to an arbitrary object, different from the one originally intended. The reference can be a branch reference or a tag reference.
- **Rollback Attacks:** These attacks modify a Git branch reference so that it points to an older commit object from the same branch, thus providing clients with a view in which one or more of the latest branch commits are missing.
- **Deletion Attacks:** These attacks remove branch or tag references, which in turns leads to the complete removal of an entire branch, or removal of an entire release referred to by a tag.

We use the following setup to present the details of these attacks. A Git server is hosting the main repository

and several developers who have their own local repositories have permission to fetch/push from/to any branch of the main repository, including the master branch. For commit objects, we use a naming convention that captures the temporal ordering of the commits. For example, if a repository has commits C0, C1, C2, this means that they were committed in the order C0, C1, C2.

4.1 Teleport attacks

We identified two teleport attacks: *branch teleport* and *tag teleport* attacks.

Branch Teleport Attacks. These attacks modify the branch reference so that it points to an arbitrary commit object on a different branch. Although we illustrate the attacks for the master branch, they are applicable to any branch, since none of the branch reference metadata is protected.

Fig. 1(a) shows the initial state of the main Git repository, which contains two branches, “master” and “feature.” The local repository of developer 1 is in the same state as shown in Fig. 1(a). The “feature” branch implements a new feature and contains one commit, C2. The code in C2 corresponds to an unstable, potentially-vulnerable version that needs to be tested more thoroughly before being integrated into the master branch. Commit C1 is the head of the master branch. This means that the file `.git/refs/heads/master` contains the SHA1 hash of the C1 commit object.

After developer 2 pulls from the master branch of the main repository (Fig. 1(b)), the attacker changes the master branch to point to commit C2 (Fig. 1(c)). The attacker does this by simply changing the contents of the file `.git/refs/heads/master` to the SHA1 hash of the C2 commit. Any developer who clones the repository or fetches from the master branch at this point in time will be provided with the incorrect repository state, as shown in Fig. 1(c). For example, developer 2, who committed C3 into his local repository (Fig. 1(d)), now wants to push this change to the main repository. Developer 2 is notified that there were changes on the master branch since his last fetch, and needs to pull these changes. As a result, a merge commit C4 occurs between C3 and C2 in the local repository of developer 2, as shown in Fig. 1(e). The main repository looks like Fig 1(e) after developer 2 pushes his changes. If developer 1 then pulls changes from the main repository, all three repositories will appear like Fig 1(e).

Normally, the master branch should contain software that was thoroughly tested and properly audited. However, in this incorrect history, the master branch incorporates commit C2, which was in a experimental feature branch and may contain bugs. The attacker tricked a developer into performing an action that was never in-

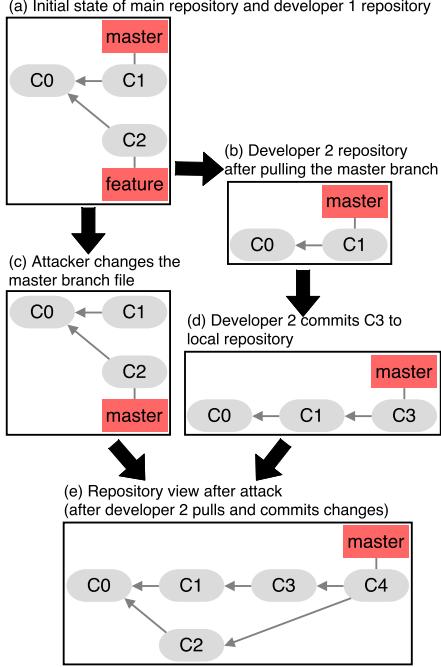

Figure 1: The Branch Teleport attack

tended, and none of the two developers are aware that the attack took place.

Tag Teleport Attacks. These attacks modify a tag reference so that it points to an arbitrary tag object. Surprisingly, a tag reference can also be made to point to a commit object, and Git commands will still work.

One can verify whether a tag is both signed and a valid tag object by using the `git tag --verify` command. However, if an attacker were to modify a tag reference to point to an older tag (e.g., if the tag for release 1.1 is replaced by the tag for the vulnerable release 1.0), the verification command is successful.

Modifying tag metadata could be especially impactful for automated systems that rely on tags to build/test and release versions of software [36, 20, 10, 12]. Furthermore, package managers such as Python’s pip, Ruby’s RubyGEMS, and Node’s NPM, among many others support the installation of software from public Git repositories and tags. Finally, Git submodules are also vulnerable, as they automatically track a tag (or branch). If a build dependency is included in a project as a part of the submodule, a package might be vulnerable via an underlying library.

4.2 Rollback attacks

These attacks modify a Git branch reference so that it points to an older commit object from the same branch. This gives clients a view in which one or more of the latest branch commits are missing. The attacker can cause commits to be missing on a permanent or on a temporary basis.

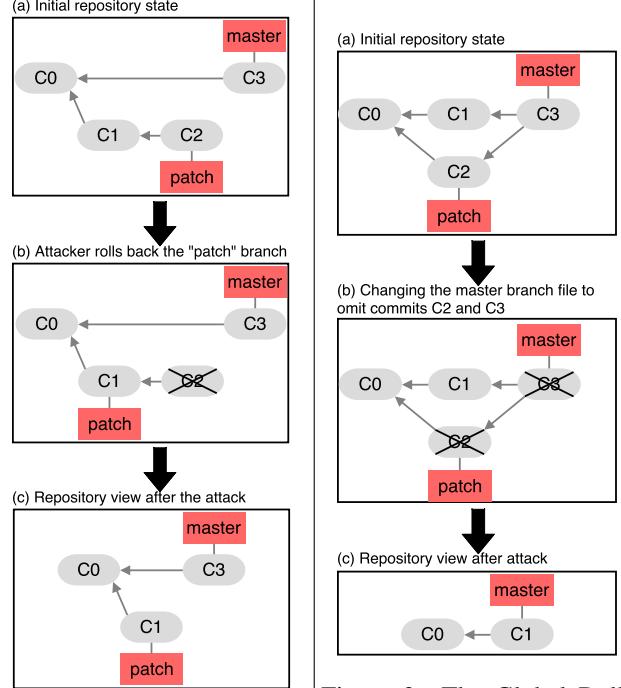

Figure 2: The Branch Rollback attack

4.2.1 Permanent rollback attacks

Based on the nature of the commits removed, we separate permanent rollback attacks in two groups: Branch Rollback attacks and Global Rollback attacks.

Branch Rollback Attacks. Consider the repository shown in Fig. 2(a), in which the order of the commits is C0, C1, C2, C3. Commits C0 and C3 are in the master branch, and commits C1 and C2 are security patches in a “patch” branch. The attacker rolls back the patch branch by making the head of such branch point to commit C1, as shown in Fig. 2(b). This can be done by simply replacing the contents of the file `.git/refs/heads/patch` with the SHA1 hash of the C1 commit. As a result, all developers that pull from the main repository after this attack will see the state shown in Fig. 2(c), in which commit C2 (that contains a security patch) has been omitted.

Note that the attack can also be used to omit commits on any branch, including commits in the master branch.

Global Rollback Attacks. As opposed to a Branch Rollback attack, which removes commits that happened prior to one that remains visible, in a Global Rollback attack, no commits remain visible after the commits that are removed. In other words, the attacker removes one or more commits that were added last to the repository.

Consider the initial state of a Git repository as illustrated in Fig. 3(a), in which C2 is a commit that fixes a security bug and has been merged into the master

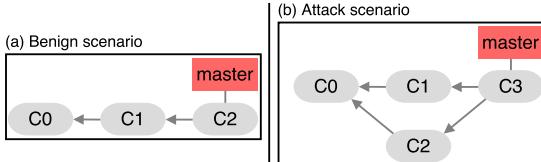

Figure 4: The Effort Duplication attack

branch. The file `.git/refs/heads/master` contains the SHA1 hash of the C3 commit object.

By simply changing the contents of the file `.git/refs/heads/master` to the SHA1 hash of the C1 commit, the attacker forges a state in which the repository contains the history of commits depicted in Fig. 3(b). This effectively removes commits C2 and C3 from the project’s history, and a developer who now clones the project will get a history of commits as shown in Fig. 3(c). This incorrect history does not contain the commit C2 that fixed the security bug.

Note that the Global Rollback attack *removed the latest two commits from the repository*. This is different than the effect of a Branch Rollback attack which *removes one or more commits that happened before a commit that remains visible*.

4.2.2 Temporary rollback attacks

Effort Duplication Attacks. The Effort Duplication attack is a variation of the Global Rollback attack, in which the attacker temporarily removes commits from the repository. This might cause developers to unknowingly duplicate coding efforts that exist in the removed commits.

Consider a main Git repository with just a master branch which contains only one commit C0. Two developers D1 and D2 have pulled from the main repository, so their local repositories also contain C0. After the following sequence of actions by D1 and D2, the repository should look as shown in Fig. 4(a):

1. D1 commits C1 to her local repository & pushes to the main repository.
2. D2 pulls from the main repository.
3. D2 commits C2 to her local repository & pushes to the main repository.

However, when D2 pulls in step 2, the attacker can temporarily withhold commit C1, keeping D2 unaware of the changes in C1. As a result, D2 works on changes that already exist in C1. The following attack scenario results in a repository shown in Fig. 4(b):

1. D1 commits C1 to her local repository & pushes to the main repository.
2. D2 pulls from the main repository, but the attacker withholds C1. Thus, D2 thinks there are no changes.
3. D2 makes changes on top of C0 and commits these changes in her local repository as commit C2. C2 duplicates (some or all of) D1’s coding effort in C1.

4. D2 tries to push changes to the main repository. This time, the attacker presents C1 to D2 (these are the changes that were withheld in step 2). Thus, D2 has to first pull changes before pushing.
5. D2 pulls changes from the main repository, and this results in a merge commit C3 between C1 and C2. As part of the merge, the developer has to solve any merge conflicts that appear from the code duplication between C1 and C2.

In this case, D2 re-did a lot of D1’s work because D1’s commit C1 was withheld by the attacker. Note that unlike a Global Rollback attack, in which commits are removed permanently from the repository, in the Effort Duplication attack commits are just removed temporarily. This is a more subtle attack, since the final state of the repository is the same for both the benign and attack cases. The effect of applying commits C1 and C2 in Fig. 4(a) on the files in the repository is the same as applying commits C1, C2, C3 in Fig. 4(b). However, D2 unknowingly (and unnecessarily) duplicated D1’s coding effort, which may have negative economic consequences. Adding to this, an attacker can slow down developers of a specific project (e.g., a competitor’s project) by delivering previously-withheld changes to them when they will cause merge conflicts and hamper their development progress.

4.3 Reference deletion attacks

Since the branch metadata is not protected, the attacker can hide an entire branch from the repository by removing a branch reference. Similarly, since the tag metadata is not protected, the attacker can remove a tag reference in order to hide a release from the repository history.

When an attacker performs a reference deletion attack, only the users who previously held a copy of the reference will be able to know of its existence. If this is not the case, a developer would be oblivious of the fact that other developers have worked on the deleted branch (similar to a fork attack), or be tricked into retrieving another version if the target tag is not available. Furthermore, some projects track work in progress by tying branch names to numbers in their issue tracker [9], so two developers could be tricked into working on the same issue by hiding a branch (similar to an effort duplication attack).

4.4 Summary of attacks

Metadata manipulation attacks may lead to inconsistent and incorrect views of the repository and also to corruption and loss of data. Ultimately, this will lead to merge conflicts, omission of bug fixes, merging experimental code into a production branch, or withholding changes from certain users before a release. All of these are problems that can impact the security and stability of

the system as a whole. Table 1 summarizes the attacks impact.

Attack	Impact
Branch Teleport	Buggy code inclusion
Branch Rollback	Critical code omission
Global Rollback	Critical code omission
Effort Duplication	Coding effort duplicated
Tag Rollback	Older version retrieved

Table 1: Impact of metadata manipulation attacks.

5 Defense framework

5.1 Design goals for a defense scheme

We designed our defense scheme against metadata manipulation attacks with the following goals in mind:

Design Goal 1 (DG1): Achieve the security goals stated in Sec. 3.1. That is, prevent modification of committed data, ensure a consistent repository state, and ensure repository state freshness.

Design Goal 2 (DG2): Preserve (as much as possible) current workflows and actions that are commonly used by developers, in order to facilitate a seamless adoption.

Design Goal 3 (DG3): Maintain compatibility with existing Git implementations. For example, Git has limited functionality when dealing with concurrency issues in a multi-user setting: it only allows atomic push of multiple branches and tags after version 2.4. Following Git’s design philosophy, backwards compatibility is paramount; a server running the latest Git version (*i.e.*, 2.9.0) can be cloned by a client with version 1.7.

5.2 Why binding references with Git objects is not enough

Adding reference information (*i.e.*, branch and tag names) inside the commit object might seem like a sufficient defense against metadata manipulation attacks. This would bind a commit to a reference and prevent an attacker from claiming that a commit object referred to in a reference belongs somewhere else.

Unfortunately, this simple approach has important drawbacks. It does not meet our *DG1* because it does not defend against rollback and effort duplication attacks. Furthermore, adding new reference information in a commit object requires updating an existing commit object. When this happens, the SHA-1 hash of the commit object will change, and the change will propagate to all new objects in the history. In other words, when a new branch is created and bound to a commit far earlier in the history, all commit objects need to be rewritten and, thus, sent back to the remote repository, which could add substantial computational and network overhead.

5.3 Our defense scheme

The fundamental cause of metadata manipulation attacks is that the server can respond to users’ fetches with an incorrect state and history of the main repository that they cannot verify. For example, the server can falsely claim that a branch points to a commit that was never on that branch or to a commit that was the location of that branch in an earlier version. Or, the server can falsely claim that the reference of a tag object points to an older tag.

In order to stop the server from falsely claiming an incorrect state of the repository, we propose that every Git user must include additional information vouching for their perceived repository state during a push or a fetch operation. To achieve this, we include two pieces of additional information on the repository:

- First, upon every push, users must append a *push entry* to a *Reference State Log (RSL)* (Sec. 5.3.1). By validating new entries in this log with each push and fetch operation, we can prevent teleport, permanent rollback, and deletion attacks.
- Second, when a Git user performs a fetch operation and receives a new version of files from the repository, the user places a random value into a *fetch nonce bag* (Sec. 5.3.2). If the Git user does not receive file updates when fetching, the user replaces her value in the bag with a new one. The bag serves to protect against temporary rollback attacks.

During our descriptions, we assume that a trusted key-chain is distributed among all developers along with the RSL. There are tools available to automate this process [24, 5], and the RSL itself can also be used to distribute trust (we elaborate more on this in Sec 6.1).

5.3.1 The Reference State Log (RSL)

For a developer to prevent the server from equivocating on the location of the references, the developer will sign a *push entry*, vouching for the location of the references at the time of a push. To do this, she must execute the `Secure_push` procedure, which has the following steps:

First, the remote RSL is retrieved, validated, and checked for the presence of new push entries (lines 3–11). If the RSL is valid and no push entries were added, a new RSL push entry is created (lines 13–14). The newly created entry will contain: (1) the new location of the reference being pushed; (2) the nonces from the fetch nonce bag; (3) a hash of the previous push entry; and (4) the developer’s signature over the newly created push entry. The newly created entry is then appended to the RSL (line 16), and the `nonce_bag` is cleared (line 15).

Once this is done, the remote RSL must be updated and local changes must be pushed to the remote reposi-

PROCEDURE: Secure_push

Input: LocalRSL; related_commits; pushed reference X
Output: result: (success/fail/invalid)

```
1: repeat
2:   result ← fail
3:   (RemoteRSL, nonce_bag) =
   Retrieve_RSL_and_nonce_bag_from_remote_repo
4:   if (RSL_Validate(RemoteRSL, nonce_bag) == false)
   then
5:     // Retrieved RemoteRSL is invalid
6:     // Must take necessary actions!
7:     return invalid
8:   if (new push entries for reference X in RemoteRSL) then
9:     // Remote repository contains changes
10:    // User must fetch changes and then retry
11:    return fail
12:   else
13:     prev_hash = hash.last_push_entry(RemoteRSL)
14:     new_RSL_Entry = create_push_Entry(prev_hash,
   nonce_bag, X)
15:     nonce_bag.clear()
16:     RemoteRSL.addEntry(new_RSL_Entry)
17:     result = Store_in_remote_repo(RemoteRSL,
   nonce_bag)
18:   if (result == success) then
19:     // The remote RSL has no new entries
20:     push related_commits
21:     LocalRSL = RemoteRSL
22:     return success
23: until (result == success)
```

tory (lines 17-20). Notice that these steps are performed under a loop, because other developers might be pushing, which is not an atomic operation in older versions of Git (this is required to meet *DG3*).

Depending on the result of the Secure_push procedure, a developer's actions correspond to the following:

- **success:** the push is successful. No further actions are required from the user (line 22).
- **fail:** the push fails because there are changes in the remote repository that must first be fetched and merged locally before the user's changes can be pushed (line 11).
- **invalid:** the RSL validation has failed. The algorithm detects a potential attack and notifies the user, who must then take appropriate measures (line 7).

Note that these actions mirror a user's actions in the case of a regular Git push operation, as suggested by *DG2*. By doing this, we effectively follow the existing Git workflows while providing better security guarantees at the same time.

5.3.2 TheNonce Bag

When retrieving the changes from a remote repository, a developer must also record her perceived state of the repository. Our scheme requires that all the user fetches be recorded in the form of a fetch *nonce bag*, *i.e.*, an unordered list of nonces. Each nonce is a random number that corresponds to a fetch from the main repository. Every time a user fetches from the main repository, she updates the nonce bag. If the user has not fetched since the last push, then she generates a new nonce and adds it to the nonce bag; otherwise, the user replaces her nonce in the nonce bag with a new nonce.

Each nonce in the nonce bag serves as a proof that a user was presented a certain RSL, preventing the server from executing an Effort Duplication attack and providing repository freshness as per *DG1*. To fetch the changes from the remote repository, a developer must execute the Secure_fetch procedure.

The first steps of the Secure_fetch procedure consist of retrieving the remote RSL, performing a regular git fetch, and ensuring that the latest push entry in the RSL points to a valid object in the newly-fetched reference (lines 4-11). Note that this check is performed inside a loop because push operations are not atomic in older versions of Git (lines 2-12). A user only needs to retrieve the entries which are new in the remote RSL and are not present in the local version of the RSL.

If this check is successful, the nonce bag must be updated and stored at the remote repository (lines 14-20). Note that all these steps are also in a loop because other developers might update the RSL or the nonce bag since it was last retrieved (lines 1-21).

Finally, the RSL is further validated for consistency (line 22), and the local RSL is updated. We chose to validate the RSL at the end of Secure_fetch and outside of the loop in order to optimize for the most common case. Once Secure_fetch is successfully executed, a developer can be confident that the state of the repository she fetched is consistent with her peers. Otherwise, the user could be the victim of one of the attacks in Sec. 4.

5.3.3 RSL validation

The RSL_Validate routine is used in Secure_push and Secure_fetch to ensure the presented RSL is valid. The aim of this routine is to check that push entries in a given RSL are correctly linked to each other, that they are signed by trusted developers, and that nonces corresponding to a user's fetches are correctly incorporated into the RSL.

First, the procedure checks that the nonce corresponding to the user's last fetch appears either in the nonce bag or was incorporated into the right push entry (*i.e.*, the first new push entry of the remote RSL) (lines 1-2). The algorithm then checks if the new push RSL entries from the

PROCEDURE: Secure_fetch**Input:** reference X to be fetched**Output:** result: (success/invalid)

```
1: repeat
2:   store_success ← false
3:   repeat
4:     (RemoteRSL, nonce_bag) =
      Retrieve_RSL_and_nonce_bag_from_remote_repo()
5:     fetch_success ← false
6:     // This is a regular “Git fetch” command.
7:     // Branch X’s reference is copied to FETCH_HEAD
8:     fetch reference X
9:     C ← RemoteRSL.latestPush(X).refPointer
10:    if (C == FETCH_HEAD) then
11:      fetch_success ← true
12:    until (fetch_success == true)
13:    // Update the nonce bag
14:    if NONCE in nonce_bag then
15:      nonce_bag.remove(NONCE)
16:    save_random_nonce_locally(NONCE)
17:    nonce_bag.add(NONCE)
18:    // Storing the nonce bag at the remote repository
19:    // might fail due to concurrency issues
20:    store_success = Store_in_remote_repo(nonce_bag)
21:    until (store_success == true)
22:    if (RSL_Validate(RemoteRSL, nonce_bag) == false)
        then
23:      // Retrieved RemoteRSL is invalid
24:      // Must take necessary actions!
25:      return invalid
26:    else
27:      LocalRSL = RemoteRSL
28:      return success
```

remote RSL are correctly linked to each other and that the first new remote push entry is correctly linked to the last push entry of the local RSL (the check is based on the prev_hash field) (lines 5-9). Finally, the signature on the last RSL push entry is verified to ensure it was signed by a trusted developer; since all RSL entries are correctly linked, only the last entry signature needs to be verified.

How to handle misbehavior? If the RSL validation fails due to a misbehaving server, the user should compare the local RSL with the remote RSL retrieved from the remote repository and determine a safe point up to which the two are consistent. The users will then manually roll back the local and remote repositories to that safe point, and decide whether or not to continue trusting the remote repository.

6 Discussion

6.1 Trust and revoke entries

Developers’ keys may be distributed using *trust/revoke RSL entries*. To use these entries, the

PROCEDURE: RSL_Validate**Input:** LocalRSL (RSL in the local repository); RemoteRSL; nonce_bag**Output:** true or false

```
1: if (NONCE not in nonce_bag) and (NONCE not in RemoteRSL.push_after(LocalRSL)) then
2:   return false
3:   // Verify that the ensuing entries are valid
4:   prev_hash = hash_last_push_entry(LocalRSL)
5:   for new_push_entry in RemoteRSL do
6:     if new_push_entry.prev_hash != prev_hash then
7:       // The RSL entries are not linked correctly
8:       return false
9:     prev_hash = hash(new_push_entry)
10:    if verify_signature(RemoteRSL.latest_push) == false then
11:      // this RSL is not signed by a trusted developer
12:      return false
13:    return true
```

repository is initialized with an authoritative root of trust (usually a core developer) who will add further entries of new developers in the group. Once developers’ public keys are added to the RSL, they are allowed to add other trust entries.

A trust entry contains information about the new developer (i.e., username and email), her public key, a hash of the previous push entry and a signature of the entry by a trusted developer. Revocation entries are similar in that they contain the key-id of the untrusted developer, the hash of the push entry, and the signature of the developer revoking trust.

6.2 Security analysis

Our defense scheme fulfills the properties described in Sec. 3.1 as follows:

- Prevent modification of committed data: The existing signing mechanism for Git handles this well. Also, RSL entries are digitally signed and chained with each other, so unauthorized modifications will be detected.
- Ensure consistent repository state: The RSL provides a consistent view of the repository that is shared by all developers.
- Ensure repository state freshness: The Nonce Bag provides repository state freshness because an attacker cannot replay nonces in the Nonce Bag. Also, if no newer push entries are provided by the repository, then the attack becomes a fork attack.

The attacks described in Section 4 are prevented because, after performing the attack, the server cannot provide a valid RSL that matches the current repository

	Possible attacks	Time window of attack	Vulnerable commit objects
Commit signing	all attacks	Anytime	Any object
RSL (full adoption)	no attacks	None	No object
RSL (partial adoption)	all attacks	After the latest RSL entry and before the next RSL entry	Objects added after the latest RSL entry

Table 2: Security guarantees offered by different adoption levels of the defense scheme

state. Since she does not control any of the developers’ keys, she can not forge a signature for a spurious RSL entry. As a result, a user who fetches from the main repository after the attack will notice the discrepancy between the RSL and the repository state that was presented to her. Each metadata manipulation attack would be detected as follows:

- *Branch Teleport and Deletion Attacks:* When this attack is performed, there is no mention of this branch pointing to such a commit, and the RSL validation procedure will fail.
- *Branch/Global Rollback and Tag Teleport Attacks:* These attacks can be detected because the latest entry in the RSL that corresponds to that branch points to the commit removed and the RSL validation procedure will fail.
- An attacker can attempt to remove the latest entries on the RSL so that the attacks remain undetected. However, after this moment, the server would need to consistently provide an incorrect view of the RSL to the target user, which would result in a fork attack. Finally, the attacker cannot remove RSL entries in between because these entries are chained using the previous hash field. Thus, the signature verification would fail if this field is modified.
- *Effort Duplication Attack:* This attack will result in a fork attack because the RSL created by the user requesting the commit will contain a proof about this request in the form of a nonce that has been incorporated into an RSL push entry or is still in the Nonce Bag. Any ensuing RSL push entry that was withheld from the user will not contain the user’s nonce.

6.3 Partial adoption of defense scheme

It is possible that not all developers in a Git repository use our solution. This can happen when, for example, a user has not configured the Git client to sign and update the RSL. When this is the case, the security properties of the RSL change.

To study the properties of using the RSL when not everyone is using the defense, we will define a commit object as a “*secure commit*” or an “*insecure commit*. The former will be commits made by users who employ our defense, while the latter are made by users who do not

use our defense (*i.e.*, they only use the Git commit signing mechanism). Consider that supporting partial adoption requires changing the validation during fetches to consider commits that are descendants of the latest secure commit, for users might push to branches without using the defense. For simplicity, we do not allow users to reset branches if they are not using the defense.

Compared to commit signing only, when our scheme is adopted by only some users, a user who writes an RSL entry might unwittingly attest to the insecure commits made by other users after the latest secure commit. However, this situation still provides a valuable advantage because the attacker’s window to execute Metadata Manipulation attacks is limited in time. That is, when our defense is not used at all, an attacker can execute Metadata Manipulation attacks on any commits in the repository, (e.g., the attacker can target a forgotten branch located early in the history). This is not possible with our scheme, where an attacker can only attack the commit objects added after the latest RSL entry for that branch. The differences between the three alternatives are summarized in Table 2.

6.4 Comparison with other defenses

In Table 3, we examine the protections offered by other defense schemes against metadata manipulation attacks. Specifically, we studied how Git commit signing, Git’s push certificate solution, and our solution (listed as RSL) fare against the attacks presented in this paper, as well as other usability aspects that may impact adoption.

Feature	Commit signing	Push certificate	RSL
Commit Tampering	✓	✓	✓
Branch Teleport	X	✓	✓
Branch Rollback	X	X	✓
Global Rollback	X	X	✓
Effort Duplication	X	X	✓
Tag Rollback	X	✓	✓
Minimum Git Version	1.7.9	2.2.0	1.7.9
Distribution Mechanism	in-band	(no default) or Additional server	in-band

Table 3: Comparison of defense schemes against Git metadata manipulation attacks. A ✓ indicates the attack is prevented.

As we can see, Git commit signing does not protect against the vast majority of attacks presented in

this paper. Also, Git’s push certificate solution provides a greater degree of protection, but still fails to protect against all rollback and effort duplication attacks. This is primarily because (1) a server could misbehave and not provide the certificates (there is no default distribution mechanism), and (2) a server can replay old push certificates along with an old history. Basically, this solution assumes a well-behaving server hosting push certificates.

In contrast, our solution protects against all attacks presented in Table 3. In addition to this, our solution presents an in-band distribution mechanism that does not rely on a trusted server in the same way that commit signing does. Lastly, we can see that our solution can be used today, because it does not require newer versions of Git on the client and requires no changes on the server, which allows for deployment in popular Git hosting platforms such as GitHub and Gitlab.

7 Implementation and evaluation

We have implemented a prototype for our defense scheme. This section provides implementation details and presents our experimental performance results.

7.1 Implementation

To implement our defense scheme, we leveraged *Git custom commands* to replace the push and fetch commands, and implemented the RSL as a separate branch inside the repository itself. To start using the defense, a user is only required to install two additional bash scripts and use them in lieu of the regular fetch and push commands. Our client scripts consist of less than a hundred (86) lines of code, and there is no need to install anything on the server.

RSL and Nonce Bag. We implemented the RSL in a detached branch of the repository, named “RSL.” Each RSL entry is stored as a Git commit object, with the entry’s information encoded in the commit message. We store each entry in a separate commit object to leverage Git’s pack protocol, which only sends objects if they are missing in the local client. Encoding the Git commit objects is also convenient because computing the previous hash field is done automatically.

We also represent the Nonce Bag as a Git commit object at the head of the RSL branch. When a nonce is added or updated, a new commit object with the nonces replaces the previous nonce bag, and its parent is set to the latest RSL entry. When a new RSL entry is added, the commit containing the nonce bag is garbage collected by Git because the RSL branch cannot reach it anymore.

When `securepush` is executed, the script first fetches and verifies the remote RSL branch. If verification is successful, it then creates an RSL entry by issuing a new commit object with a NULL tree (i.e., no local

Field	Description
Branch	Target branch name
HEAD	Branch location (target commit)
PREV_HASH	Hash over the previous RSL entry
Signature	Digital signature over RSL entry

Table 4: RSL push entry fields.

files), and a message consisting of the fields described in Table 4. After the new commit object with the RSL push entry is created, the RSL branch is pushed to the remote repository along with the target branch.

A `securefetch` invocation will fetch the RSL branch to update or add the random nonce in the Nonce Bag. If a nonce was already added to the commit object (with a NULL tree also), it will be amended with the replaced nonce. In order to keep track of the nonce and the commit object to which it belongs, two files are stored locally: `NONCE_HEAD`, which contains the reference of the Nonce Bag in the RSL branch, and `NONCE`, which contains the value of the nonce stored in it.

Atomicity of Git operations. The `securepush` and `securefetch` operations require fetching and/or pushing of the RSL branch in addition to the pushing/fetching to/from the target branch. Git does not support atomic fetch of multiple branches, and only supports atomic push of multiple branches after version 2.4.0¹.

In order to ensure backwards compatibility, we designed our solution without considering the existence of atomic operations. Unfortunately, the lack of atomic push opens the possibility of a DoS attack that exploits the ‘repeat’ loop in `Secure_fetch` (lines 3-12), that makes the algorithm loop endlessly. This could happen if a user executes `Secure_push` and is interrupted after pushing a new RSL entry, but before pushing the target branch (e.g., caused by a network failure). Also, a malicious user may provide an updated RSL, but an outdated history for that branch. However, this issue can be easily solved if the loop is set to be repeated only a finite number of times before notifying the user of a potential DoS attempt.

If atomic push for multiple branches is available, the `Secure_push` procedure can be simplified by replacing lines 17-22 with a single push. Availability of atomic push also eliminates the possibility of the endless loop mentioned above.

7.2 Experimental evaluation

Experimental Setup. We conducted experiments using a local Git client and the GitHub server that hosted the main repository. The client was running on an Intel Core i7 system with two CPUs and 8 GB RAM. The client software consisted of OS X 10.11.2, with Git 2.6.2 and

¹Note that **both Git client and server** must be at least version 2.4.0 in order to support atomic push.

the GnuPG 2.1.10 library for 1024-bit DSA signatures.

Our goal was to evaluate the overhead introduced by our defense scheme. Specifically, we want to determine the additional storage induced by the RSL, and the additional end-to-end delay induced by our `securefetch` and `secure push` operations. For this, we used the five most popular GitHub repositories²: `bootstrap`, `angular.js`, `d3`, `jQuery`, `oh-my-zsh`. We will refer to these as R1, R2, R3, R4, and R5, respectively. In the experiments, we only considered the commits in the master branch of the these repositories. Table 5 provides details about these repositories.

Repo.	Number of commits	Number of pushes	Repo. size	Repo. size with signed commits
R1	11,666	1,345	73.04	78.85
R2	7,521	26	66.96	69.79
R3	3,510	255	32.91	34.65
R4	6,031	194	15.79	19.98
R5	3,841	1,170	3.52	4.01

Table 5: The repositories used for evaluation (sizes are in MBs).

We used the repositories with signed commits as the baseline for the evaluation. We evaluated three defense schemes:

- Our defense: This is our proposed defense scheme.
- Our defense (light): A light version of our defense scheme, which does not use the nonce bag to keep track of user fetches. This scheme sacrifices protection against Effort Duplication attacks in favor of keeping the regular Git `fetch` operation unchanged.
- Push certificates: Push certificates used upon pushing.

For our defense and our defense (light), the repositories were hosted on GitHub. Given that GitHub does not support push certificates, we studied the network overhead using a self-hosted server on an AWS instance, and concluded that push certificates incur a negligible overhead compared to the baseline. Thus, we only compare our scheme with push certificates in regard to the storage overhead.

Storage overhead. Table 6 shows the additional storage induced by our defense, compared to push certificates. In our defense, the RSL determines the size of the additional storage. We can see that our defense requires between 0.009%-6.5% of the repository size, whereas push certificates require between 0.012%-10%. The reason behind this is that push certificates contain 7 fields in addition to the signature, whereas RSL push entries only have 3 additional fields.

²Popularity is based on the “star” ranking used by GitHub, which reflects users’ level of interest in a project (retrieved on Feb 14, 2016).

Repo.	Our defense	Push certificates
R1	301.93	461.27
R2	6.49	8.88
R3	58.91	86.05
R4	44.34	66.27
R5	261.3	402.19

Table 6: Repository storage overhead of defense schemes (in KBs).

Communication overhead. To evaluate the additional network communication cost introduced by our `securepush` operation when compared to the regular push operation, we measured the cost of the last 10 pushes for the five considered repositories. To evaluate the cost of `securefetch`, we measured the cost of a fetch after each of the last 10 pushes.

Table 7 shows the cost incurred by push operations. We can see that our defense incurs, on average, between 25.24 and 26.21 KB more than a regular push, whereas our defense (light) only adds between 10.29 and 10.48 KB. This is because a `securepush` in our defense retrieves, updates and then stores the RSL in the remote repository. In contrast, our defense (light) only requires storing the RSL with the new push entry if there are no conflicts. Table 8 shows the cost incurred by fetch operations. A `securefetch` incurs on average between 25.1 and 25.55 KB more than a regular `fetch`, whereas our defense (light) only adds between 14.34 and 10.91 KB.

The observed overhead is a consequence of the fact that we implemented our defense scheme to respect design goal DG3, (*i.e.* no requirement to modify the Git server software). Since we implemented the RSL and the Nonce Bag as objects in a separate Git branch, `securepush` and `securefetch` require additional `push/fetch` commands to store/fetch these, and thus they incur additional TCP connections. Most of the communication overhead is caused by information that is automatically included by Git and is unrelated to our defense scheme. We found that Git adds to each `push` and `fetch` operation about 8-9 KBs of supported features and authentication parameters. If our defense is integrated into the Git software, the `securepush` and `securefetch` will only require one TCP session dramatically reducing the communication overhead. In fact, based on the size of an RSL entry (~325 bytes), which is the only additional information sent by a `securepush/securefetch` compared to a regular `push/fetch`, we estimate that the communication overhead of our defense will be less than 1KB per operation.

End-to-end delay. Table 9 shows the end-to-end delay incurred by push operations. We can see that our defense adds on average between 1.61 and 2.00 seconds more than a regular `push`, whereas our defense (light) only adds between 0.99 and 1.3 seconds. Table 10 shows

Scheme used	R1	R2	R3	R4	R5
Git w/ signed commits (baseline)	17.80	3,925.35	38.32	59.14	11.96
Our defense	44.01	3,950.87	63.56	84.71	37.65
Our defense (light)	28.28	3,935.71	48.61	69.52	22.28

Table 7: Average communication cost per push for the last 10 push operations, expressed in KBs.

Scheme used	R1	R2	R3	R4	R5
Git w/ signed commits (baseline)	20.68	3,896.98	40.93	65.85	13.67
Our defense	46.18	3,922.40	66.48	91.27	38.77
Our defense (light)	35.19	3,911.81	55.84	80.67	28.01

Table 8: Average communication cost per fetch for the last 10 fetch operations, expressed in KBs.

Scheme used	R1	R2	R3	R4	R5
Git w/ signed commits (baseline)	1.29	3.27	1.17	1.31	1.51
Our defense	3.11	5.27	2.78	2.95	3.51
Our defense (light)	2.44	4.49	2.16	2.40	2.81

Table 9: Average end-to-end delay per push for the last 10 push operations, expressed in seconds.

Scheme used	R1	R2	R3	R4	R5
Git w/ signed commits (baseline)	0.87	1.95	0.75	0.66	0.67
Our defense	2.93	3.86	2.52	2.40	2.75
Our defense (light)	1.60	2.75	1.52	1.31	1.30

Table 10: Average end-to-end delay per fetch for the last 10 fetch operations, expressed in seconds.

the end-to-end delay incurred by fetch operations. We can see that a `securefetch` incurs on average between 1.74 and 2.08 seconds more than a regular `fetch`, whereas our defense (light) only adds between 0.65 and 0.8 seconds.

The time Git uses to do a fetch or push is dominated by the network latency when talking with the remote repository. Since our defense is designed to be backwards compatible, it uses multiple Git commands per push or fetch. This explains the additional time incurred by our implementation. If our defense scheme is integrated into Git so that additional commands (and hence network connections) are not needed, we expect the additional delay to be negligible.

8 Conclusions

In this work, we present a new class of attacks against Git repositories. We show that, even when existing Git protection mechanisms such as Git commit signing, are used by developers, an attacker can still perform extremely impactful attacks, such as removing security patches, moving experimental features into production software, or causing a user to install a version of soft-

ware with known vulnerabilities.

To counter this new class of attacks, we devised a backwards compatible solution that prevents metadata manipulation attacks while not obstructing regular Git usage scenarios. Our evaluation shows that our solution incurs less than 1% storage overhead when applied to popular Git repositories, such as the five most popular repositories in GitHub.

We performed responsible disclosure of these issues to the Git community. We have been working with them to address these issues. Some of our patches have already been accepted into Git version 2.9. We are continuing to work with the Git community to fix these problems.

Acknowledgements

We would like to thank Junio C. Hamano, Jeff King, Eric Sunshine, and the rest of the Git community for their valuable feedback and insight regarding these attacks and their solutions as well as their guidance when exploring Git’s internals. Likewise, we thank Lois A. DeLong, Vladimir Diaz, and the anonymous reviewers for their feedback on the writing on this paper.

A Man In The Middle Example

This appendix contains a proof of concept of a Git metadata manipulation attack against a GitHub repository with the intention of showing how an attack could be carried out in practice.

To perform an attack of this nature, an attacker controls a server, compromises a server, or acts as a man-in-the-middle between a server and a developer. Having done this, the attacker is able to provide erroneous metadata to trick a developer into committing a tampered repository state.

We simulated a repeated line scenario, in which a Git merge accidentally results a repeated line. This can be devastating as it can completely alter the flow of a program — some researchers argue that the “goto fail;” [41] vulnerability that affected Apple devices [40] might have been caused by a VCS mistakenly repeating the line while merging.

A.1 Simulating the attack

To simulate the attack, we created a repository with a minimal working sample that resembles Figure 5(c). Also, we configured two Linux machines under the same network: one functioned as the malicious server providing tampered metadata information, while the other played the role of the victim’s client machine. The specific setup is described below.

Setup. To simulate the malicious server, we set up Git server on port 443 with no authentication enabled. Then, we created an SSL certificate and installed it in the victim machine. Finally, we a bare clone (using the `--bare` parameter) of the repository hosted on GitHub is created and placed on the pertinent path.

In order to redirect the user to the new branch, we modified the packed-refs file on the root of the repository so that the commit hash in the master branch matches the one for the experimental branch. Refer to Table 11 for an example.

On the client side, a clone of the repository is created before redirecting the traffic. After cloning, the attacker’s IP address is added to the victim’s `/etc/hosts` file as “github.com” to redirect the traffic.

As such, both the server and the developer are configured to instigate the attack the next time the developer pulls.

A.2 The attack

When the developer pulls, he or she is required to either merge or rebase the vulnerable changes into the working branch. These merged or rebased changes are not easy to identify as malicious activity, as they just resemble work performed by another developer on the

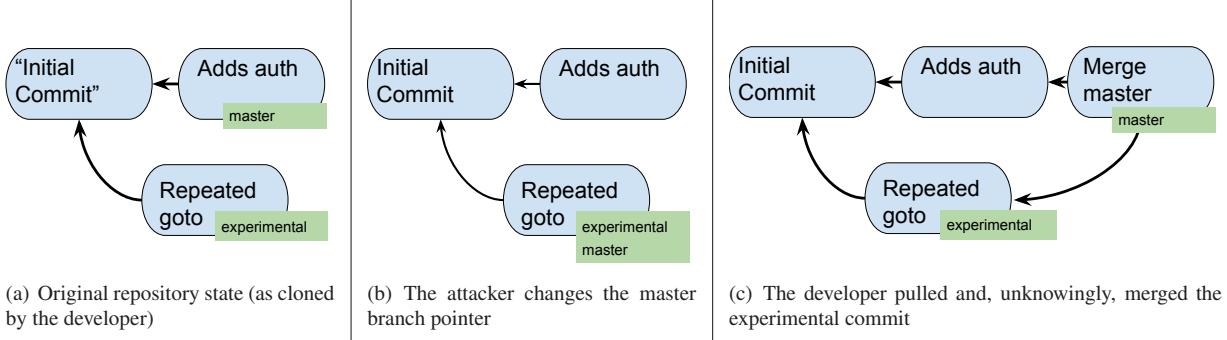

Figure 5: Maliciously merging vulnerable code

Table 11: The edited packed-refs file

same branch. Due to this, the user is likely to merge and sign the resulting merge commit.

Aftermath. Once the user successfully merges the vulnerable change, the attacker can stop re-routing the user’s traffic to the malicious server. With the malicious piece of code in the local repository, the developer is now expected to pollute the legitimate server the next time he or she pushes. In this case, the attacker **was able to merge a vulnerable piece of code into production**. Even worse, there is no trace of this happening, for the target developer willingly signed the merge commit object.

Setting up an environment for this attack is straightforward; the metadata modification is easy to perform with a text editor and requires no sophistication.

Defending against malicious peripherals with Cinch

Abstract

Malicious peripherals designed to attack their host computers are a growing problem. Inexpensive and powerful peripherals that attach to plug-and-play buses have made such attacks easy to mount. Making matters worse, commodity operating systems lack coherent defenses, and users are often unaware of the scope of the problem. We present Cinch, a pragmatic response to this threat. Cinch uses virtualization to attach peripheral devices to a logically separate, untrusted machine, and includes an interposition layer between the untrusted machine and the protected one. This layer regulates interaction with devices according to user-configured policies. Cinch integrates with existing OSes, enforces policies that thwart real-world attacks, and has low overhead.

1 Introduction

Peripheral devices are now powerful, portable, and plentiful. For example, the inexpensive “conference USB sticks” that we have all received include not only the stored conference proceedings but also a complete computer. Given this trend, it is easy to create *malicious* peripheral devices [43, 61, 88, 98]. And yet, it is difficult to defend against them: commodity machines and operating systems continue to be designed to trust connected peripherals.

Consider a user who is induced to insert a malicious USB stick into his or her laptop [91, 135, 148]. There are now many examples [16, 75, 89] of such devices injecting malware (most infamously, Stuxnet [94]), by exploiting vulnerabilities in the host’s drivers or system software.

Another alarming possibility is that, while following the USB specifications, the malicious device can masquerade as a keyboard. The device can then use its keystroke-producing ability to install a virus or exfiltrate files [43, 61, 125, 150]. As a last example, a USB device can eavesdrop on the communication between another device, such as the user’s true keyboard, and the host [12, 17, 25, 72, 124].

These problems will get worse: on next-generation laptops [5, 10], *all* ports, including the power port, are USB, which means that any of the attacks above could be carried out by a malicious charger. For that matter, your phone might be compromised right now, if you borrowed a USB charger from the wrong person.

On the one hand, the concepts needed to solve these problems have long been understood. For example, in

Rushby’s separation kernel [129] (see also its modern descendants [81, 122]), the operating system is architected to make different resources of the computer interact with each other as if they were members of a distributed system. More generally, the rich literature on high-assurance kernels offers isolation, confinement, access control, and many other relevant ideas. On the other hand, applying these works in full requires redesigning the operating system and possibly also the hardware.

Solutions that target device security for today’s commodity systems are not adequate for the task, often because they were designed under different models (§8). For example, work on device driver containment [80, 83, 93, 95, 96, 105, 112, 114, 127, 143–145, 152] and reliability [108, 130–132] trusts devices or assumes they are at worst buggy; the attacks mentioned earlier are largely out of scope. Hotplug control frameworks [13, 15, 18, 22, 33, 35, 37, 48, 50, 55], of which a notable example is udev on Linux [56, 110], enable users to express that certain devices should be denied access. However, access is all-or-nothing, decisions are based upon the device’s claimed identity rather than its ongoing behavior, and a malicious device can disarm the enforcement mechanism. Qubes [45] protects the OS and applications from malicious USB devices, but achieves its strong guarantees at the expense of functionality.

The fundamental issue is that the I/O subsystems in commodity operating systems do not have an organizing abstraction that could serve as a natural foundation for security features. This paper attempts to fill that void.

Our point of departure is a simple suggestion: rather than design a new framework, *why not arrange for attached peripheral devices on commodity operating systems to appear to the kernel as if they were untrusted network endpoints?* This would create an interposition point that would allow users and administrators to defend the rest of the computer, just as firewalls and other network middleboxes defend hosts from untrusted remote hosts. Our animating hope is that a system based on this picture would eliminate large classes of vulnerabilities, be easy to deploy, and enable new functionality. To explore that vision, this paper describes the design, implementation, and experimental evaluation of a system called *Cinch*. Cinch begins with the following requirements:

- *Cinch should make peripheral buses look “remote,” despite the physical coupling*, by preventing direct inter-

action with the rest of the computer (memory access, interrupts, etc.).

- *Under Cinch, traffic between the “remote” devices and the rest of the computer should travel through a narrow choke point.* This choke point then becomes a convenient location for deploying defenses that inspect and mediate interactions with untrusted devices.
- *Cinch should not require modifying bus standards, motherboards, OSes, or driver stacks.* Any of these would be massive undertakings, would have to be done for multiple platforms, and would jettison the immense effort behind today’s installed base.
- *Cinch should be portable,* in the sense that Cinch itself should not need to be re-designed or re-implemented for different operating systems.
- *Cinch should be flexible and extensible:* users, operators, and administrators should be able to quickly develop and deploy a wide range of defenses.
- *Cinch should impose reasonable overhead* in latency and throughput.

Cinch responds to these requirements with the following architecture, focused on USB as a target (§4). Under Cinch, USB devices attach to an isolated and untrusted module; this is enforced via hardware support for virtualizing I/O [70, 71]. The untrusted module tunnels USB traffic to the protected machine, and this tunnel serves as a choke point for enforcing policy.

To showcase the architecture, we build several example defenses (§5). These include detecting attacks by matching against a database of attack signatures (§5.1); sanitizing inputs by ensuring that messages and device state transitions comply with protocol and device specifications (§5.2); sandboxing device functions and enforcing hotplug policies (§5.3); device authentication and traffic encryption (§5.4); and logging and remote auditing (§5.5).

Our implementation of Cinch (§6) instantiates both the untrusted module and the protected machine as separate virtual machines. As a consequence, Cinch protects any OS that runs atop the underlying hypervisor. In principle, these virtualization layers can be reduced or eliminated, at the cost of development effort and portability (§4.2).

To study Cinch’s effectiveness, we developed exploits based on existing vulnerabilities [14], performed fuzzing, and conducted an exercise with a red team whose members were kept isolated from Cinch’s development (§7.1–§7.3). Our conclusion is that Cinch can prevent many attacks with relatively little operator intervention. We also find that developing new defenses on Cinch is convenient (§7.4). Finally, Cinch’s impact on performance is modest (§7.5): Cinch adds less than 3 milliseconds of latency and can handle USB 3 transfers of up to 2.1 Gbps, which is 38% less than the baseline of 3.4 Gbps.

Cinch is enabled—and inspired—by much prior work

in peripherals management, hardware-assisted virtualization, privilege separation, and network security. We delve into this work in Section 8. For now, we simply state that although Cinch’s individual elements are mostly borrowed, it is a novel synthesis. That is, its contributions are not mechanical but architectural. These contributions are: viewing peripherals as remote untrusted endpoints, and the architecture that results from this perspective; the instantiation of that architecture, which uses virtualization techniques to target a natural choke point in device driver stacks; a platform that allows defenses to existing attacks to be deployed naturally on commodity hardware, in contrast to the status quo; and the implementation and evaluation of Cinch.

Cinch is not perfect. First, it shrinks the attack surface that the protected machine exposes to devices, but introduces new trusted code elsewhere (§4.2). Second, although Cinch can reduce the universe of possible inputs to the drivers and OS on the protected machine (by ruling out noncompliant traffic), a malicious device might still exploit bugs in how the code handles *compliant* traffic. On the other hand, the user can decide which devices get this opportunity; further, addressing buggy drivers and system software is a complementary effort (§8). Third, Cinch does not unilaterally defend against higher-level threats (data exfiltration, malware, etc.); however, Cinch creates a platform by which one can borrow and deploy known responses from network security (§5). Finally, some of Cinch’s defenses require changes within the device ecosystem (§9). For example, defending against masquerading attacks requires device (but not bus) modifications. However, these changes are limited: in our implementation, one person prototyped them in less than two days (§6.3). Importantly, these changes can be used with unmodified legacy devices via an inexpensive adapter.

Despite its shortcomings, Cinch is a substantial improvement over the status quo when considering the misbehavior that it rules out and the functionality that it enables. Moreover, we hope that Cinch’s perspective on device security will be useful in its own right.

2 Background: Universal Serial Bus (USB)

Commodity computing devices (phones, tablets, laptops, workstations, etc.) have several peripheral buses for pluggable devices. These include USB [57, 58], Firewire [1], and Thunderbolt [54]. Cinch focuses on USB as an initial target; we make this choice because USB is ubiquitous and complex, and because it has become a popular locus of hardware-based attacks. However, our approach applies to other buses.

Figure 1 depicts the hardware and software architecture of USB. USB is a family of specifications for connecting and powering peripheral devices. Bandwidth ranges from 1.5 Mb/s (USB 1.0) to 10 Gb/s (USB 3.1). Example

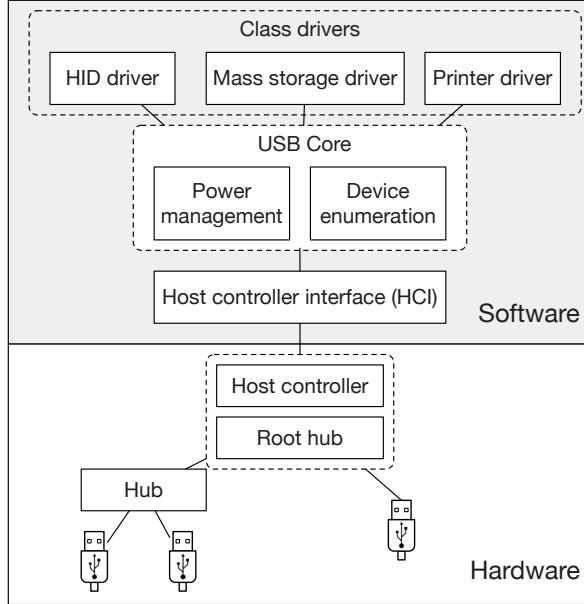

FIGURE 1—The hardware and software of a USB stack (§2). Both physical devices and drivers are arranged hierarchically; devices are rooted at the host controller, and drivers are rooted at the host controller interface. Components in dashed boxes are logically in the same layer of the USB stack.

devices include storage (e.g., memory sticks), keyboards, sound cards, video cameras, Ethernet adapters, and smart card readers. These devices connect to a host (for example, a laptop or desktop). Some computers can act as either a device or a host; for example, a smart phone or laptop can appear as a storage device or power consumer to a desktop, but as a host to a keyboard.

USB hardware. USB has a tree topology. Each device has an *upstream* connection to a *hub*. Hubs multiplex communication from one or more *downstream* devices, and are themselves devices with an upstream connection to another hub or to the root of the tree. The root is a *host controller*, which connects to the host by, for example, PCIe. The host controller acts as the bus master: it initiates all transfers to and from devices, and devices are not permitted to transmit except when polled by the host controller. Also, the host controller issues interrupts to the host and has direct access to host memory via DMA.

USB protocol. The USB specifications [57, 58] define a protocol stack comprising three layers. The bottom layer includes electrical specifications and a low-level packet protocol. The middle layer of the stack includes addressing, power management primitives, and high-level communication abstractions. USB devices, comprising one or more *functions*, sit at the top of the stack. Functions act as logically separate peripherals that are exposed by a single physical device. For example, a phone might ex-

pose a camera function, a network adapter function, and a storage function. Each of these functions is associated with its own high-level driver software.

USB driver architecture. The USB specification describes three layers of software abstraction on the host. The lowest level, the *host controller interface* or *HCI*, configures and interacts with the host controller hardware via a local bus (e.g., PCIe). An HCI driver is particular to a host controller’s hardware interface but exposes a hardware-independent abstraction to the next software layer, called *core*. Core manages device addressing and power management, and exposes an interface for high-level drivers to communicate with devices. Core also *enumerates* devices when they are attached, which entails identifying the device and activating its driver.

The uppermost layer, *class drivers*, are high-level drivers that interact with functions (as described above). These drivers provide an interface between USB devices and the rest of the OS. For example, a keyboard’s class driver interacts with the kernel’s input subsystem. Another example is the mass storage class driver, which talks to the kernel’s storage subsystem. The USB specification defines a set of generic classes for a broad range of devices, e.g., keyboards, mice, network interfaces, storage, cameras, audio, and more. Operating systems generally include support for a large subset of the generic classes, allowing devices to leverage preexisting drivers.

3 Causes, threat model, and taxonomy

3.1 Why is USB so vulnerable?

The root of the problem is the implicit assumption that hardware is inherently trustworthy, or at worst buggy but non-malicious. As a consequence, neither USB nor mainstream OSes are designed to be robust in the face of malicious devices. One manifestation of this is the lack of authentication or confidentiality guarantees at any layer of the USB standard. As examples, devices self-report their identity and capabilities without authentication; the communication primitives at all layers of the protocol stack (§2) are cleartext; and, prior to USB 3, host-to-device messages are broadcast across the entire bus [124].

A related issue is that the USB protocol and common driver stacks emphasize convenience above correctness and security. For example, hotplugged devices are often activated without user confirmation. Coupled with the lack of device authentication, this means that the OS cannot determine what device the user intended to connect, or even that a hotplug event was generated by the *user* rather than a malicious device [24, 75]. Moreover, malicious device makers can rely on the near universal availability of generic class drivers (e.g., for keyboards), since users expect these devices to “just work.”

The range and sophistication of USB-based threats has escalated substantially in recent years. Whereas hardware design costs were once a barrier to entry, creating custom USB devices is now cheap, both in dollars and development time [43, 52, 61, 98, 100]; in fact, today’s commodity USB devices are essentially software defined [43, 75, 98].

The press plays a role too: demonstrating USB attacks has become fashionable (e.g., recent media hype [6–8, 39, 53, 118] surrounding USB devices with reprogrammable firmware [43, 84, 125]). A third factor is ease of transmission: malicious USB devices can easily find their way into the hands of victims [148]. This is partly due to vulnerabilities in the supply chain [38, 74, 101, 141], such as adversarial manufacturers [102]. Intelligence agencies have also been known to use their resources to intercept and “enhance” shipments [27, 97], including conference giveaways [20, 21].

3.2 Threat model

We assume that devices can deviate from the USB specification arbitrarily. They may also violate the user’s expectations, for example by masquerading as other devices or passively intercepting bus traffic. Alternatively, devices can present a higher-level threat; for example, a storage device can contain an invalid filesystem that triggers a bug in a filesystem driver. However, devices that cause physical damage to the host, with high voltage [86] for example, are out of scope.

We assume that the host’s OS and drivers can be buggy but not malicious. We assume the same for the host’s hardware besides the USB controller and USB devices.

3.3 A taxonomy of USB attacks

Attacks on USB drivers. USB drivers present an attack surface to devices. For example, a driver with an unchecked buffer access might allow a malicious device to overwrite kernel memory via an overflow. The space of possible misbehavior here is vast. For instance, devices might try to deliver more data to the driver than indicated by the device’s configuration [31]; claim impossible configurations [28, 30]; exceed limits prescribed by USB class specifications [4, 32, 42]; or produce otherwise invalid or nonsensical reports [75, 87–89, 92, 137].

The prevalence of these attacks reflects a difficult software engineering situation. Since a driver writer needs to be prepared for an enormous range of undocumented behavior, drivers need lots of error checking code; such code is often ill-exercised and creates complexity, leading to more vulnerabilities. Indeed, more than half of the vulnerabilities related to USB drivers in the CVE database [14] are the result of improper handling of noncompliant USB transfers; many more such vulnerabilities likely remain undisclosed [87, 137].

Other attacks on the host via USB. USB can also expose the rest of the host system’s kernel or user software to attacks by malicious devices. Recall that USB class drivers provide an interface between devices and other kernel subsystems (§2). Leveraging this interface, a USB flash drive might be used to attack the kernel’s storage or filesystem drivers [19, 44, 63, 64]. Or the drive might carry a virus [94] or covertly steal data [140].

Of particular concern is the possibility of attacks in which the USB host controller uses DMA (direct memory access) to bypass the CPU and read or write arbitrarily to RAM [26, 116, 139, 142]. A successful DMA attack neutralizes essentially all software security measures, allowing the attacker to steal sensitive data, modify running software (including the kernel itself), and execute arbitrary code [128]. And the host controller does not need to be malicious: misconfigured DMA-capable hardware is a proven vector for such attacks [153, 154].

Privacy and authentication threats.

Device masquerading. When a device is plugged in, the host asks the device for information about its capabilities. The device can respond, disguised as another device or even another class [29, 41, 43, 65, 85, 120, 125, 150]. For example, Psychson [43] enables rewriting the firmware on a cheap USB storage device so that it will act like a keyboard; similarly, the commercially available “USB Rubber Ducky” [61] is a programmable keystroke injector in the guise of a flash drive. Likewise, a malicious hub can masquerade as other devices [25]. These examples are more than idle threats: penetration testers regularly use such tools to breach security systems [3, 24].

Bus eavesdropping. In USB 2 and earlier versions, hubs broadcast traffic from their upstream port to all downstream ports (§2), so any device on the bus can eavesdrop on traffic from the host to any other device [124]. In all protocol versions, malicious hubs can eavesdrop on upstream and downstream traffic [17, 72]. Furthermore, a hub need not be malicious: if its firmware is buggy, it can be exploited by a malicious device [25].

4 Architecture and rationale

The top-level goal of Cinch is to enforce security policies that enable safe interactions between devices and the host machine. This enforcement must be done in a way that respects the requirements outlined in Section 1. In particular, we must answer two questions in the context of USB: (1) Where and how can one create a logical separation between the bus and the host, while arranging for an explicit communication channel that a policy enforcement mechanism can interpose on? (2) How can one instantiate this separation and channel with no modifications to bus standards, OSes, or driver stacks?

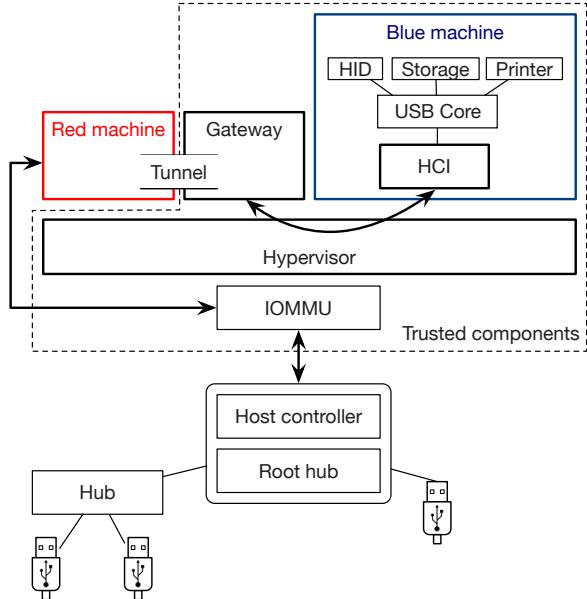

FIGURE 2—The architecture of Cinch. The trusted components are surrounded by the dashed line. I/O virtualization separates the USB host controller from the blue machine’s HCI, redirecting DMA and interrupts to the red machine. The red machine encapsulates and sends USB transfers through the Tunnel to the Gateway. Once the Gateway has applied all security policies, it redirects those transfers to the blue machine’s HCI.

We begin with the logical separation, which Cinch enforces at the boundary between the host controller and its driver (HCI), depicted in Figure 1. We choose this separation point for two reasons: first, it results in a narrow choke point where software can interpose. Second, the host controller is “dangerous”—it issues interrupts and accesses memory via DMA (§2, §3.3)—so there should be a barrier between it and the rest of the system, including the modules that administer policy decisions.

The architecture is depicted in Figure 2. After logically separating the host controller, Cinch attaches it to a new module, the *red machine*. The red machine is an endpoint to a communication channel, the *Tunnel*. The other endpoint, the *Gateway*, is positioned at the entrance to the host that Cinch protects, the *blue machine*. (These names are inspired by Lampson’s red/green machine partitioning [111].) The Gateway mediates all transfers through the Tunnel and enforces security policies (for example, dropping or rewriting USB traffic, as described in §5) before those transfers reach the blue machine’s USB stack.

To connect the host controller to the red machine, Cinch uses I/O virtualization hardware, which is widely available in modern CPUs [70, 71]. Specifically, an IOMMU provides address translation and protection, which restricts a physical device’s DMA transfers to a designated memory region (in this case, that of the red machine); and interrupt remapping provides analogous translation and protection for interrupts.

4.1 Instantiation

In our current implementation, the lowest layer of software—the one that manages the hardware resources and configures the I/O virtualization hardware—is a combination of hypervisor and OS, and is trusted. The red machine runs on top of this hypervisor and is a full-fledged virtual machine, with a normal OS that has a stripped-down USB stack (§6.1). The blue machine is also a full-fledged virtual machine atop the hypervisor, and the Gateway is a separate process.

4.2 Discussion

With the instantiation described immediately above, Cinch meets the requirements described in Section 1. It isolates devices in the red machine, and its Gateway is a narrow choke point. It limits overhead to reasonable factors (§7.5), in part by leveraging hardware-assisted processor and memory virtualization [68, 123] (as distinct from I/O virtualization). It works with existing USB stacks; the main component needed is a driver in the hypervisor, to receive transfers from the Gateway. It works with a range of OSes because the blue machine runs unmodified. For the remaining requirements, flexibility is demonstrated in the next section (§5), and extensibility arises from Cinch’s software structure (§6.2).

But a disadvantage is the size of the trusted computing base (TCB) and attack surfaces. Specifically, the TCB includes a full-featured hypervisor. The attack surface includes the red machine, which is running a full OS and which, if compromised, can attack the hypervisor and the blue machine via the virtualization interface (by attempting VM escapes, side channel inference, etc.).

There are a number of alternatives that, by tailoring the hypervisor and red machine, reduce the TCB at the cost of portability and additional development effort. As an extreme example, the blue machine could run directly on the host’s hardware (“bare metal”), with the red machine running in an untrusted user-level process; the Gateway would also run in user space. In this setup, there would be no separate hypervisor; the blue machine would perform the few required hypervisor-like functions, such as configuring the I/O virtualization hardware to connect the host controller to the red machine process (see [77, 78, 126]). Compared to Cinch’s instantiation, this one has a smaller TCB; it also has lower overhead, owing to the absence of virtual machines. However, it is less portable: each new blue machine OS needs corresponding “hypervisor” module and red machine implementations.

One can go further: the Gateway could entirely bypass the blue machine’s USB stack, sending device traffic directly to the corresponding kernel subsystem (for example, sending USB keyboard events to the input subsystem). This would further reduce the TCB, at the cost of even more development work and less portability.

Another design point is a hardware-only solution: the red machine and Gateway would run on a device placed between USB devices and the blue machine, which would run as a normal, unmodified host. Compared to Cinch, this solution is potentially more portable, in that no software modifications or reconfiguration are needed. Further, this solution does not rely on I/O virtualization (which is widespread but not universal), and it leaves the host’s virtualization hardware available for other uses. The disadvantages are that a hardware solution is likely to be less flexible, and that building hardware may be substantially more effort than building Cinch.

A non-solution, in our view, is to implement the Gateway in the host’s USB stack, without a separate red machine. This setup does not have the separation discussed earlier; it would leave the host and Gateway vulnerable to DMA attacks by a compromised host controller.

5 Building defenses with Cinch

This section describes some of the defenses (which we call *Policies*) that Cinch supports, and the threats (§3) against which they defend. These Policies are not new; we discuss previous implementations in Section 8. The novelty is in providing a platform that makes a range of Policies straightforward to develop and deploy.

5.1 Detecting attacks by signature

The first strategy is signature matching: dropping messages that match a known pattern. Defenses in this class protect against attacks on drivers and user software (§3.3). The same strategy is used in network security (intrusion detection [47]) and desktop security (antivirus [11]) and has been effective in practice, as a first-line defense. The advantages and disadvantages hold in our context; we review them briefly.

To begin with, signature generation is flexible and can be done by victimized companies, individual users, and designated experts, based on observations of past attacks and reverse engineering of malicious devices. Further, shared databases of observed attack signatures can immunize others. This strategy also enables rapid responses to emerging threats: a signature of an attack is typically available long before the vulnerability is patched.

The principal disadvantage, of course, is that signatures generally provide protection only against previously observed attacks. Furthermore, they suffer from both false positives and false negatives: signatures that are too general may disable benign devices, while signatures that are too specialized can fail to catch all variants of an attack.

Cinch’s signature Policy. We implement a signature matching module in Cinch that compares all USB traffic from the red machine to a database of malicious payload signatures. When a match occurs, Cinch disallows further traffic between the offending device and the blue machine.

5.2 Sanitizing inputs

Another class of defensive strategies detects when devices deviate from their specification; this is useful for defending against attacks on USB drivers (§3.3). Given a specification (say, provided by the manufacturer or converted from a standards document), Cinch checks that messages are properly formatted and that devices respond correctly to commands. While drivers can (and in some cases, do) implement such checks, moving enforcement to a dedicated module can eliminate redundant code and reduce driver complexity (§3.3, “Attacks on USB drivers”).

A related strategy in Cinch modifies apparent device behavior, either forcing adherence to a *strict subset* of the USB spec in order to match driver expectations, or else *relaxing* the USB spec by recognizing and fixing device “quirks”—behavior that is noncompliant but known to be benign—so that drivers need not do so.¹ This is closely related to traffic normalization [103], in which a firewall converts traffic to a canonical representation to aid analysis and ensure that decisions are consistent with end-host protocol implementations.

Cinch’s compliance Policy. This Policy enforces device compliance with USB specifications. To build it, we manually processed the USB 2 and 3 specifications [57, 58], along with the specifications of five device classes (mass storage, HID, printer, power, and debug) [59]. The result is a module that monitors device states and transitions, and enforces invariants on individual messages and entire transactions. As a simple example, the compliance Policy checks that device-supplied identification strings are well formed—that is, that they comprise a valid UTF-16 string of acceptable length—and rewrites noncompliant strings. More complex state and transition checking is effected by keeping persistent information about each device for the duration of its connection.

Cinch’s compliance Policy is conservative in handling noncompliance: if it cannot easily fix a device’s behavior (for example, by rewriting identification strings as described above), it assumes the device is malicious and disables it.

Cinch’s assertion Policy. This Policy implements the aforementioned relaxations and restrictions, by modifying how Cinch’s compliance Policy regulates specific devices. As examples, a user might specify that a particular device’s requests should be rewritten to work around buggy firmware. Or Cinch can require that devices handled by a certain driver must expose an interface that matches a specified template, obviating bug-prone compatibility checks in the driver’s code (§3.3).

¹In practice, many non-malicious devices fail to comply with the specification: the word “quirk” appears about once every 300 lines throughout the 300 kLoC Linux USB stack (!), and nearly all the devices we tested deviated from prescribed behavior in at least a small way.

5.3 Containing devices

This category includes querying a user for information about a newly connected device, restricting a device to a subset of its functionality, and isolating devices in private protection domains. Such defenses, which are useful against attacks on driver and user software and can foil masquerading attacks (§3.3), are forms of *hotplug control*. They decide—say, by asking the user—whether a newly connected device should be allowed to communicate with the blue machine, and if so, what functionality should be allowed. For example, Cinch might ask the user, “I see you just connected a keyboard. Is this right?”

In practice, such decisions can be much more complex. Recall from Section 2 that devices can define multiple functions, each of which is a logically separate peripheral. A careful user wishing to tether his or her laptop to a friend’s phone could be informed of available functionality upon device connection, and choose to disallow the phone’s storage function as a precaution against viruses.

Alternatively, the user might choose to connect the phone’s file storage function to a separate protection domain—a sandbox—with limited capabilities and a narrow interface to the blue machine. In this case, the sandbox could scan files for viruses, and could expose a high-level interface (e.g., an HTTP or NFS server) to the blue machine. This approach leverages existing software designed for interacting with untrusted machines (in this case, a web or file browser), and can bypass many layers of software in the blue machine; on the other hand, it changes the interface to the device.

Cinch’s containment Policy. We implement a “surgical” hotplug Policy: individual device functions can be allowed or disallowed, and the blue machine never interacts with disallowed devices. Cinch’s Gateway can also sandbox whole devices or individual functions by redirecting selected USB traffic to separate protection domains that expose functionality to the blue machine through narrow interfaces, as described above.

5.4 Encryption and authentication

To handle devices that eavesdrop on the bus or masquerade as other devices, Cinch adapts well-known responses—authentication and encryption—to USB. For example, a user can disallow all keyboards except those having a certificate signed by a particular manufacturer. This prevents a malicious device without such a certificate from acting as a keyboard.

In more detail, a device authenticates to the Gateway by leveraging a trust relationship. As examples, manufacturers sign certificates and install them on devices, and users are required to use devices whose certificates are signed by a trusted manufacturer; or users follow a pairing procedure as in Bluetooth [67] or GoodUSB [146], obvi-

ating a trusted manufacturer but adding a setup step. After completing a key exchange, the device and host share an encryption key. The user can then prevent masquerading and eavesdropping by installing a policy that disallows unauthenticated, untrusted, or unencrypted devices.

This arrangement raises several potential concerns: development overhead to build new devices, computational overhead for cryptography, and deployment on legacy devices. Below, we describe a proof-of-concept design that addresses these concerns. At a high level, the concerns are addressed by, respectively, abundant support for rapid development of embedded cryptographic applications [34, 36, 66], the speed of modern embedded processors, and a physical *adapter* that adds cryptographic functionality to legacy devices.

Proof-of-concept USB crypto support. To support authentication and encryption, we designed a *cryptographic overlay protocol*. This mechanism allows compatible devices to communicate with the Gateway via a TLS session that encapsulates all of their USB transfers.

To evaluate the crypto overlay, we built a *crypto adapter*, a physical device that sits between unmodified legacy devices and a host system running Cinch. The crypto adapter acts as a USB host for the legacy device, encapsulating and decapsulating the device’s USB traffic inside a TLS session. To communicate this TLS-encrypted traffic to the host system, the crypto adapter also acts as a USB device attached to the host system, as we detail below. We refer to the crypto adapter’s USB connection to the legacy device as the “inner” connection, and its connection to the host as the “outer” connection.

Two issues arise in designing the crypto overlay and adapter. First, a TLS session requires a full duplex stream transport, while USB’s communication primitives are based on host-initiated polling (§2). This means that the outer USB connection cannot directly encapsulate a TLS session. Second, the Gateway does not implement a USB stack, meaning that, on its own, it cannot communicate with the crypto adapter via the outer USB connection.

To solve the first issue, Cinch uses an existing USB class that exposes a full-duplex Ethernet interface [59]; this Ethernet-over-USB traffic is carried by the outer USB connection. Then Cinch uses TCP over this Ethernet connection as the stream abstraction for TLS, yielding an indirect encapsulation of TLS in the outer USB connection.² To solve the second issue, we observe that, with the foregoing encapsulation, the Gateway need not handle the outer USB connection. Instead, the red machine treats the outer USB connection as an Ethernet device (thereby terminating the outer USB connection), and it forwards all packets it receives from that device to the Gateway via

²An alternate approach with less overhead than TCP-over-IP-over-Ethernet-over-USB is to create a custom USB class providing a full-duplex stream abstraction with less generality than Ethernet.

the Tunnel. Meanwhile, these packets are just the TCP stream carrying the TLS session, and thus the Gateway can talk TLS to the crypto adapter without a USB stack.

Note that this arrangement differs from the way that Cinch handles other USB devices. For unencrypted devices, the Gateway receives USB transfers captured by the red machine; it inspects these transfers and then forwards them to the blue machine’s HCI. But here, the Gateway receives packets (which the red machine decapsulated) that contain a TLS session. The Gateway decrypts to recover USB transfers, which it inspects and forwards.

Cinch’s crypto Policy. Given devices implementing the crypto overlay, Cinch can enforce policies that rule out eavesdropping and masquerading by requiring authenticated and encrypted devices, as described at the outset of this section.

5.5 Logging and auditing

Logging is part of many defensive strategies: auditing logs can reveal anomalous behavior that might indicate a new attack. Moreover, logs can be used to develop new signature-based defenses (§5.1).

Cinch’s logging Policy. Cinch’s Gateway can be configured to log some or all traffic to and from the blue machine. Cinch can also replay logged data; we used this functionality to help develop attack signatures for our security evaluation (§7.3). Furthermore, Cinch can be configured to log to a remote server. This feature could allow real-time analysis of data from many different blue machines, for example in a corporate environment.

5.6 Extensions

Cinch enables usage scenarios beyond the ones described above. One example is data exfiltration prevention, which is often employed at the network level to address the threat of data theft [104, 115, 117, 133, 134], but is generally considered a more difficult problem in the context of USB [140]. By combining real-time remote auditing (§5.5) with signature detection (§5.1), Cinch allows administrators to apply exfiltration prevention policies to USB devices.

6 Implementation

We describe the components and the communication paths in our implementation of Cinch (§6.1). We also discuss the Policies implemented in Cinch, utilities that we use to create and test new exploits, and our method for deriving payload signatures (§6.2). Finally, we describe the proof-of-concept crypto adapter (§5.4) that we use to transparently provide encryption and authentication for existing USB devices (§6.3).

6.1 Components and communication paths

The hypervisor (§4.1) is Linux with KVM, meaning that virtual machines run in QEMU processes that are accelerated with virtualization hardware [68, 123]. In particular, Cinch requires hardware support for I/O virtualization [70, 71]. We tested with Intel hardware, but KVM also supports equivalent functionality from AMD.

The red machine runs Linux. It is configured to load only the HCI and core drivers (§2); higher-level USB drivers are not needed to capture USB transfers from devices. (An exception is the case of the crypto overlay, which requires a USB network driver; §5.4). The blue machine is another VM and, as stated in Section 4.2, can be any OS supported by QEMU. The Gateway runs as a user-level process on the Linux-KVM hypervisor.

The Tunnel between the red machine and the Gateway appears to both entities as a network device. The appeal of this approach is that the Tunnel connects to the untrusted part of the system (Figure 2, §4), and meanwhile IP stacks have been hardened over decades. Furthermore, this lets us leverage existing software for remotely accessing USB devices over a network [60, 73, 106]. Our implementation uses usbredir [73], which (on the red machine), captures USB transfers, listens on a network socket, and uses a custom protocol to encapsulate USB transfers inside a TCP stream.

As a usbredir client, the Gateway receives usbredir packets, filters or modifies them, and then, playing the role of a usbredir server, delivers them to the QEMU process running the blue machine. A module in QEMU is the corresponding client; it decapsulates the USB transfers (using usbredir) and injects them into a virtual host controller created by QEMU and exposed to the blue machine. From the virtual host controller, the USB transfers travel into the blue machine’s HCI, with no software modifications on the blue machine.

Our implementation of Cinch supports USB versions through USB 3.

6.2 Gateway details

The Gateway is implemented in Rust [46]; it comprises about 8 kSLoC. Its major modules are parsers for usbredir packets and USB transfers, and a library that provides abstractions for creating new Policies. This library is inspired by the Click modular router [109] and provides domain-specific abstractions for USB (as examples, de-multiplexing usbredir packets into USB transfers and filtering those transfers). As in Click, the user organizes modules into chains where one module’s output is the next module’s input. Several such chains can be configured to operate in parallel. Users configure module chains with files in JSON format.

OS	exploit identifier	exploit description	prevention mechanism
Windows 8.1	01:01:00:C:4	Audio device with non-existent streaming interface	Signature Policy*

	CVE-2016-3140	Serial converter device with invalid USB descriptor	Assertion Policy
	CVE-2016-3951	Communication device with invalid descriptor and payload	Compliance Policy

*Exploit can be prevented with the compliance Policy, but we have not yet incorporated the necessary class specification (Audio) into Cinch.

FIGURE 3—Exploits for known-signature exercise (§7.1). Windows exploits were found by Boteanu and Fowler [79] with *umap* [88]; the reported identifier can be passed to *umap* using the “-s” flag to reproduce the exploit. We implemented the Linux exploits to target all USB-related CVEs from January–June 2016. The last column describes which Policy (§5) of Cinch prevents the exploit.

6.3 Proof-of-concept USB crypto adapter

We implement the crypto adapter (§5.4) using a Beagle-Bone Black [9] single-board computer that has a 1 GHz ARM Cortex-A8 processor and 512 MB RAM. For authentication, we generate a CA certificate and install it on the Gateway and crypto adapter. We use that CA certificate to sign certificates for the Gateway and crypto adapter, which mutually authenticate during the TLS handshake. The crypto adapter runs a version of *usbredir* that we augmented with support for TLS 1.2 [90] using OpenSSL [40]; these changes comprise less than 200 lines of code. The Gateway’s crypto module uses *stunnel* [49] to listen for TLS connections.

7 Evaluation

Our evaluation of Cinch answers the following questions:

- *How effectively does Cinch defend against attacks?* We subject Cinch to known exploits (§7.1), fuzzing (§7.2), and a red team exercise (§7.3).
- *Can new functionality be developed and deployed on Cinch with ease?* We answer this question qualitatively, by relating our experiences (§7.4).
- *What is Cinch’s performance overhead?* We examine latency and throughput (§7.5).

Experimental hardware and OSes. All of our experiments run on a single machine with a 3.3 GHz Intel i5-4590 and 16 GB of RAM. The hypervisor is Debian Jessie running Linux 4.2.0 with KVM enabled. The red machine’s OS is also Debian Jessie running Linux 4.2.0. The blue machine’s OS depends on the experiment and is either Windows 7 Ultimate SP1 (build 7601), Windows

8.1 Professional (build 9600), Debian Jessie with Linux 4.2.0, or Ubuntu 14.04 with a modified 4.2.0 kernel.

7.1 Known-signature attacks

We begin our evaluation of Cinch by subjecting it to synthetic attacks, based on documented vulnerabilities. For the attacks that succeed, we specify a “rematch” protocol, in which the operator can install a signature (§5.1) and then retry. This exercise is intended to address a counterfactual hypothetical: if Cinch had been deployed at the time of these vulnerabilities, would it have protected against their exploitation? And, if not, would a subsequent defensive reaction have been effective?

Method and experiment. We filter the CVE database [14] to select all the USB-related vulnerabilities reported from January to June of 2016. The resulting 13 CVEs apply to Linux 4.5 and earlier. For each CVE, we construct a payload that exploits it. We also include five exploits, disclosed by Boteanu and Fowler [79], that affect the most recent version of Windows 8.1; the targeted vulnerabilities are not in the CVE database.

Figure 3 summarizes the exploits. We confirm that each exploit successfully compromises the blue machine (Debian Jessie with Linux 4.2.0 or Windows 8.1) in the absence of Cinch. Once Cinch is enabled, we consider an attack successful if it compromises either the blue machine’s kernel or the Gateway.

On the offensive side, we mount the attacks using a Facedancer [98]—a custom USB microcontroller that can masquerade as any USB device and issue arbitrary payloads when connected to the target machine. We program

	exploits prevented	
	match phase	rematch phase
Known exploits (§7.1)		
Windows 8.1	3 / 5	5 / 5
Linux 4.2.0	13 / 13	13 / 13
vUSBf [136, 137] payloads (§7.2)		
randomized devices	10,000 / 10,000	N/A
sample exploits	13 / 13	N/A
red team round 1 (§7.3)		
Windows 7	2 / 2	2 / 2
Linux 4.2.0	3 / 5	5 / 5
red team round 2 (§7.3)		
Windows 7	3 / 3	3 / 3
Linux 4.2.0	11 / 16	13 / 16
red team round 3 (§7.3)		
Windows 7	3 / 3	3 / 3
Linux 4.2.0	15 / 20	16 / 20

FIGURE 4—Summary of Cinch’s security evaluation.

and control the Facedancer through a Python interface, using the GoodFET [99] and umap [88] tools.

On the defensive side, we configure Cinch with the signature, assertion, compliance, and logging Policies (§5). For the assertion Policy, we install 12 driver-specific configuration restrictions; these fix buggy or nonexistent checks, identified by the CVEs. For the signature Policy, we start with an empty signature database and check whether each attack succeeds; if it does, we craft a signature based on the payload and associated metadata, then conduct a rematch.

Results are summarized in Figure 4 (“Known exploits”); for each exploit, the mechanism that prevented it is listed in Figure 3. Cinch successfully detects and drops 16 offending payloads with no additional configuration. Two of the payloads were successful on their first try, but were blocked in the rematch phase; these payloads targeted vulnerabilities in the USB Audio class, which we have not yet included in Cinch’s compliance Policy.

7.2 Fuzzing

Next, we assess the robustness of Cinch’s compliance Policy (§5.2), via fuzz testing. We limit this exercise to attacks that target device enumeration, as implemented in the core and class drivers (§2). On the one hand, this is not a comprehensive exercise. At the same time, device enumeration is a common and well-studied source of vulnerabilities [137], accounting for about half of all USB-related entries in the CVE database.

In enumerating devices, USB core processes each device’s USB *descriptors*: records, generated by the device, that identify its manufacturer, function, USB version, capabilities, etc. This process is complex because of the

wide range of possible device configurations. Furthermore, the attack surface includes class driver initialization functions, since USB core passes descriptors to those functions; Schumilo et al. [137] demonstrate that many OSes and drivers do not handle device enumeration properly, especially when the device information is inconsistent or maliciously crafted.

Method and experiment. On the offensive side, we use vUSBf [136], a fuzzing tool that generates a random set of device descriptors and then emulates a device attach event. We update vUSBf to work with the most recent version of usbredir (v0.7.1), and we replace the red machine with an instance of vUSBf (that is, vUSBf communicates directly with the Gateway). In this setup, vUSBf can emulate hundreds of randomized devices per minute.

We run two experiments. In the first, we use vUSBf to emulate 10,000 randomly-generated devices. In the second, we use vUSBf to emulate 13 specific configurations identified by the vUSBf authors (after millions of trials) that crash some (older) systems.

On the defensive side, we run Cinch, configured with compliance (§5.2) and logging (§5.5) Policies. If Cinch allows the emulated device to communicate with the blue machine, we account this a failure.

We expect that the overwhelming majority of test cases will not obey the USB specification, and that Cinch’s compliance Policy will detect and prevent these cases. As a baseline, we also present the same 10,000 inputs to a system that is not running Cinch.

Results are summarized in Figure 4 (“vUSBf”). Cinch’s compliance module prevents all emulated devices from connecting to the blue machine. The three most commonly detected violations are: (1) improperly formatted strings, (2) invalid device classes, and (3) invalid or inconsistent number of functions. On the one hand, these results could be argued to be inconclusive because none of these inputs were successful against the baseline setup *without* Cinch. On the other hand, Cinch detected and blocked even the 13 configurations known to crash older systems.

7.3 Red team exercise

Our next set of exercises evaluates Cinch against attacks that were not known to us a priori. This is intended to assess Cinch’s effectiveness and to avoid some of the bias that may arise when developers choose the attack experiments (as above).

Specifically, we set up a red team that was charged with developing new USB exploits to compromise blue machines; this activity included crafting new vulnerabilities in the blue machine’s OS, which was meant to emulate the ongoing process of discovering and patching bugs. In our case, the red team comprised a subset of the authors who were kept separate from the developers of Cinch and

Protocol	There are three rounds, each of which has a <i>setup</i> , <i>match</i> and <i>rematch</i> phase. Setup: Red team chooses an OS (which they can modify arbitrarily) and develops exploits that crash the OS. Match: Cinch developers configure Cinch to run the OS provided by the red team as the blue machine; both teams confirm that the exploits crash the OS when Cinch is not present. The Cinch developers deploy Cinch, and the red team mounts its exploits. The Cinch developers collect traces, and both teams document the outcome of the exercise. Rematch: Cinch developers get the traces, and are given the opportunity to analyze and react to them. Then the match phase is rerun.
Attacker knowledge	Round 1: The red team is given access to a technical report that documents an earlier version of Cinch. This models an attacker with limited knowledge of Cinch. Round 2: The red team is given access to a machine that is running Cinch. This models an attacker with black-box access to Cinch, or an attacker that possesses Cinch’s binaries. Round 3: The red team is given access to Cinch’s source code. This models an attacker with full knowledge of Cinch’s logic (but not its configuration).
Developer ability	Cinch developers freeze Cinch’s code prior to the match phase of round 1. After that, Cinch developers may apply configuration-only changes: new signatures, etc.

FIGURE 5—Summary of the protocol for the red team exercise. This protocol was codified before the exercise began.

worked independently. Interactions between the red team and the developers were tightly controlled, following an evaluation protocol that was documented in advance. Figure 5 summarizes the protocol.

Summary of red team exploits. The red team developed 3 exploits for Windows and 20 exploits for Linux across the three rounds of the protocol. Some exploits shared the same attack vector but used different payloads.

The Windows exploits attacked a fresh copy of Windows 7; the red team did not install updates because the vulnerabilities their exploits targeted have been patched. Since red team members did not have access or visibility into the Windows USB stack, these exploits were found primarily through fuzzing, guided by past CVEs.

For Linux, the red team installed a modified version of kernel 4.2.0 on a fresh copy of Ubuntu 14.04. In particular, the red team modified a function within HCI that processes USB request blocks (the data structure representing a message in the USB subsystem) to trigger a kernel crash on certain device payloads; introduced a bug in USB core that causes the kernel to crash whenever a device with a certain configuration is connected; inserted a bug in Linux’s HID input subsystem (`drivers/input/input.c`) that leads to a null pointer dereference when it receives a specific sequence of input events; and introduced buggy drivers for a USB printer, camera, audio, and HID device.

Finally, the red team noticed that the VFAT filesystem driver in Linux 4.2 does not correctly validate the BIOS Parameter Block (BPB). While they were unable to exploit this bug directly, it can result in an invalid filesystem being mounted. To “enhance” this bug, the red team introduced a null pointer dereference in the BPB handling routine (`fs/fat/inode.c`), triggered by a filesystem with an invalid BPB.

Results are summarized in the last 3 sections of Figure 4.

First round. The red team developed 7 exploits for this round (2 for Windows and 5 for Linux). In the match phase, Cinch prevented both Windows exploits and 3 out of the 5 Linux exploits. The Windows exploits were prevented by Cinch’s architecture rather than by any of its Policies. Specifically, the red machine runs a Linux kernel; that kernel is not vulnerable to either of the Windows exploits and recognizes both connected devices as invalid. As a result, Cinch does not export these devices in the first place, protecting the Windows blue machine.

The two Linux exploits that Cinch was unable to prevent occurred at layers that were outside of its semantic knowledge (VFAT and the input subsystem). Using the traces—collected with Cinch’s logging module (§5.5)—the Cinch developers derived signatures. In the rematch phase, these signatures prevented the exploits.

Second round. In the match phase, Cinch prevented 14 out of 19 attacks, including attacks from the first round. The rematch phase again relied on signatures; of the remaining five exploits, signatures blocked two. The remaining three succeeded because they are polymorphic: they alter their payload to evade detection.

Third round. In the match phase, Cinch prevented 18 out of 23 attacks, including attacks from prior rounds for which signatures were available. In the rematch phase, Cinch was able to defend against an additional exploit using a signature that prevents a particular sequence of key presses from triggering a bug in the modified USB HID driver. The remaining four exploits are polymorphic and escaped evasion by signature and compliance checks.

These results, while preliminary, suggest that Cinch is able to prevent several exploits—primarily those that act as invalid USB devices—with prior configuration; several more can be prevented after deriving signatures. The remaining exploits might be prevented with more intrusive approaches (e.g., sandboxing; §5.3)

Tradeoff between security and availability. It is possible to develop more aggressive signatures to prevent polymorphic attacks (for example, using regular expressions); however, this risks disabling benign devices. To ensure that our signatures did not cause such false positives, we established a representative set of benign devices: a USB flash drive, printer, phone, SSD, keyboard, and mouse. After each phase of the experiment, we checked that our signatures did not keep these devices from working.

We found one failure: the signatures for the VFAT exploit prevented the blue machine from communicating with *any* storage device with a VFAT filesystem. We removed the offending signature and accounted that test a failure (i.e., Cinch did not prevent the exploit), since such a signature would not be deployable for most users.

7.4 Cinch’s flexibility and extensibility

There are two ways that Cinch can currently be extended: through new signatures and configurations to enhance existing Policies (§5), and through new Policies that add new functionality. We discuss our experience in both cases.

Deriving new signatures. We take a straightforward approach to deriving signatures for a given attack: we first log malicious traces, and then replay them in a controlled debugging environment. This allows us to analyze the configuration and the attack. We use this information to derive candidate signatures that are on the order of 10–15 lines of JSON; deriving a signature for the exploits in Section 7.3 took roughly 5 to 30 minutes, depending on: (1) the amount of data the exploit sent, and (2) the complexity of the subsystem the exploit targeted.

Creating new Policies. Adding a new Policy for Cinch requires implementing an instance of a Rust *trait* [2] (roughly analogous to a Java interface or a C++ abstract class; this trait is defined in the Gateway library, §6.2) that processes USB transfers, and adding the new Policy to Cinch’s configuration file. Based on this configuration, Cinch’s module subsystem automatically dispatches USB transfers to configured chains (§6.2). To give an idea of Policies’ complexity, Cinch’s largest—compliance—is 2500 SLoC while the rest average just 180 SLoC.

7.5 What are the costs of Cinch?

To understand the performance cost associated with using Cinch, we investigate two microbenchmarks, one for latency and one for throughput. We use Debian Jessie (Linux 4.2.0) as the blue machine’s OS.

Is Cinch’s added latency acceptable? To quantify the delay introduced by the components of Cinch, we connect the blue machine and another machine on a local network, using an Ethernet-over-USB adapter. We record the round-trip time between the two machines (using ping) as we

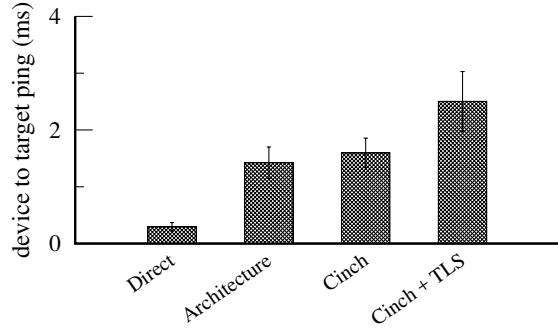

FIGURE 6—Round-trip time between the blue machine and USB device as components of Cinch are progressively added. Results are averaged over 1000 pings and error bars represent one standard deviation of the mean.

	direct	Cinch
USB 2 device (flash drive)		
% of CPU cycles	1.8 %	8.1%
memory	9 MB	205 MB
I/O throughput	181.6 Mbps	145.6 Mbps
Encrypted I/O throughput	–	35.4 Mbps
USB 3 device (SSD)		
% of CPU cycles	5.6%	38.2%
memory	9 MB	207 MB
I/O throughput	3.4 Gbps	2.1 Gbps

FIGURE 7—Resource consumption of Cinch when transferring a 1 GB file from storage devices to the blue machine. The “direct” baseline is a setup where devices are connected directly to the blue machine. Entries are the mean over 20 trials; standard deviation is less than 5%. We do not report encrypted throughput for the SSD because the crypto adapter does not support USB 3.

add components of Cinch. Figure 6 shows the results.

For our baseline, we connect the Ethernet-over-USB adapter directly to a USB port on the host (Fig. 6, “Direct”). We next attach the device to the red machine and export it to the blue machine through the Tunnel without the Gateway (i.e., the Tunnel runs directly to the blue machine); this arrangement demonstrates the latency cost of Cinch’s use of virtualization (Fig. 6, “Architecture”). Next, we add the Gateway to the above configuration, enabling all of Cinch’s Policies (§5), demonstrating the overhead when the Gateway interposes on all USB transfers (Fig. 6, “Cinch”). Finally, we place the crypto adapter (§5.4) in between the Ethernet-over-USB device and the Gateway (Fig. 6, “Cinch + TLS”).

Each component of Cinch adds moderate delay, with the full setup (including the crypto adapter) resulting in a round-trip time of less than 2.5 ms. We believe that this delay is acceptable for latency-sensitive input devices; as a comparison, high-performance mechanical keyboards introduce delays on the order of 5 ms between successive keystrokes (for debouncing [69, 107]).

What is Cinch’s impact on throughput and other resources? We read 1 GB of data from a USB storage device to the blue machine and measure the throughput, memory consumption, and CPU load with and without Cinch; we repeat these experiments 20 times. Storage devices range in performance, so we experiment with two: a USB 2 flash drive and a USB 3 SSD.

Figure 7 tabulates the results. For the flash drive, Cinch achieves $0.8\times$ the baseline’s throughput. There are two main reasons for this: (1) Cinch copies USB transfers at several stages in its architecture; and (2) USB 2 flash drives use exclusively synchronous transfers, meaning that Cinch’s added latency translates to lower throughput. For the USB 3 SSD, Cinch achieves $0.6\times$ the baseline’s throughput. Unlike in USB 2, USB 3 storage devices use asynchronous transfers and allow multiple in-flight requests. The primary overhead is thus memory copies.

With regard to CPU and memory use, Cinch has modest overhead. The memory Cinch consumes, which is primarily allocated to running the red machine, is in line with the cost of other security applications (e.g., antivirus).

7.6 Summary and critique

Our evaluation shows that Cinch can prevent previously documented vulnerabilities, fuzzing attempts, and crafted attacks, even without attack-specific configuration. Augmented with a signature database, its success is even higher, though none of its Policies are well suited to defeating polymorphic attacks. In this respect, Cinch is comparable to related tools in network security: it rules out certain classes of vulnerabilities and can be adapted to address specific issues, but it is not perfect. Cinch’s extensibility also seems reasonable, though our metrics here are subjective; and the performance impact, while not negligible, may be a good trade-off.

While this evaluation suggests that Cinch is a step in the right direction, it is far from definitive. First, we have likely not explored the full attack space, especially with regard to attacks on the non-USB portions of the kernel and on user software. Second, the red team comprised authors rather than disinterested parties, which may bias the security evaluation. Third, most systems are considered usable by their implementers; a neutral, non-expert operator may have a different perspective. Finally, Cinch’s performance impact may be acceptable for a wide range of devices, but others (e.g., audio and video devices) have more stringent latency requirements that Cinch might not meet, especially when using the crypto adapter.

8 Related work

Cinch’s contribution is architectural: most of its mechanisms are adapted from prior works and existing areas of research. Nevertheless, we are not aware of any other

system that addresses the full space of attacks described in Section 3.

USB security mechanisms (similar problem, different mechanisms). One can purchase an adapter that prevents data interchange on the USB bus, converting the bus into power lines only [51]. A software version of this protection is a set of Linux kernel patches known as grsecurity [23], which essentially disable hotplug. This “air gap ethos”—provide defense by eliminating connectivity—conflicts with Cinch’s aim of controlled interaction.

Qubes [45] is a distribution of Linux that makes extensive use of virtualization to create isolated privilege domains for *applications*. Qubes can place USB devices in their own virtual machines (USB VMs). A device’s transfers are delivered to its USB VM, and hence applications accessing that device need to live on that VM, wherein the threats enumerated in Section 3 are reprise. An exception is that Qubes allows a user to safely share USB storage devices from a USB VM with other VMs on the system by exporting them as block devices. Qubes also supports exporting keyboards and mice from a USB VM, but its developers warn that doing so risks exposing the system to attacks [62].

The udev user space daemon on Linux [56, 110] implements finer-grained policies than Qubes, akin to Cinch’s containment Policy (§5.3). However, udev can itself be attacked: udev requires the kernel to interact with every device that connects, so the device has an opportunity to attack the host machine before udev makes a policy decision. There are many commercial offerings that enable access control for USB devices [13, 15, 18, 22, 33, 35, 37, 48, 50, 55]; the issues with these are similar to udev.

USBFILTER [147] enables more precise and expressive access control policies than udev. Furthermore, these policies are enforced throughout the lifetime of the interaction rather than only at connection time. In particular, a user can define rules to dictate which entities (processes and drivers) can interact with a device (and vice versa). This is similar to Cinch’s containment Policy (§5.3), but USBFILTER’s rules support finer-grained statements, for example, restricting interaction to particular processes. The tradeoff is that it requires instrumenting the host’s OS to trace USB transfers all the way to the requesting processes and drivers. USBSec [149] brings a similar tradeoff: it extends the USB protocol with mutual authentication between the host and a compatible device (providing a subset of Cinch’s crypto Policy functionality; §5.4) but requires changes to the host’s USB stack.

GoodUSB [146] loads devices in a sandboxed environment and prompts the user to enable functions based on a device’s claimed identity. This is similar to (but richer than) Cinch’s containment Policy (§5.3), which could be enhanced accordingly. GoodUSB’s mechanisms might

also be used to bootstrap Cinch’s crypto overlay, as mentioned in Section 5.4.

Under UScramBle [124], devices provide a key to the host that can be used to encrypt further messages; the message goes upstream and thus is not broadcast across the bus (§3.3). This prevents eavesdropping for USB 2 and earlier, but unlike Cinch’s crypto overlay (§5.4), it cannot protect against malicious or compromised hubs that see the key.

Of the foregoing, only USBFILTER, USBSec, and GoodUSB address masquerading attacks (with the help of the user; §5.3); eavesdropping (§3.3) is out of scope for these systems. In contrast, UScramBle addresses eavesdropping but not masquerading.

Device driver isolation and reliability (complementary problem, overlapping mechanisms). There is a vast literature on device driver containment and reliability. We will go over some of it, but we can only scratch the surface (a helpful survey appears in SUD [80]). We note at the outset that Cinch borrows mechanisms from many of these works: placing drivers in a separate virtual machine [93, 95, 114], isolating a device with the IOMMU [105], and leveraging hardware-assisted I/O virtualization [105, 114, 145]. However, the threat and the resulting architecture are different.

Specifically, work that isolates faulty device drivers [80, 83, 93, 95, 96, 105, 112, 114, 127, 143–145, 152] assumes that hardware obeys its specification (and, with the exception of SUD [80], that drivers may be buggy, but not malicious). The same assumption about hardware is made by work that validates the commands passed to devices [152], eliminates bugs from drivers [130], and synthesizes drivers that are correct by construction [131, 132]. There is work that aims at tolerating hardware faults [108], but these faults are non-malicious and constrained (for example, flipped bits) compared to the types of attacks outlined in Section 3.

As a result of the assumption about faithful hardware, masquerading and eavesdropping are out of scope; often, devices that deviate from specification (§3.3) are, too. On the other hand, Cinch does not provide comprehensive protection against compromised drivers (though it can sanitize drivers’ inputs, as outlined in §5.2). For this reason, the works covered above are complementary to—and in many cases composable with—Cinch.

Secure peripheral interaction (different problem, overlapping mechanisms). Kells [82], USB Fingerprinting [76, 113], and work by Wang and Stavrou [150] allow a USB device to establish the identity of a host. The first two works are defense mechanisms *against* the host: they prevent compromised OSes from corrupting devices or propagating malware; the latter is an attack primitive and

allows a malicious device to compromise hosts selectively. Cinch’s crypto overlay (§5.4) also allows a device to identify a host (since connections can be mutually authenticated; §6.3), but the goal is to prevent eavesdropping and device masquerading.

SeRPEnT [151] and Bumpy [121] provide a safe pathway from devices, through an untrusted host machine, to a trusted, remote machine. SeRPEnT provides a similar abstraction to Cinch’s crypto overlay (§5.4), and its mechanism is comparable to Cinch’s crypto adapter. Bumpy’s goal, however, is remote attestation of user input rather than prevention of masquerading attacks; its mechanisms are based on trusted hardware. Both of these works target wide area networking, while Cinch focuses on intra-host communication.

Zhou et al. [155] allow trusted applications running on top of untrusted OSes to securely communicate with I/O devices. This is done via a trusted hypervisor that mediates access to hardware by both the trusted and untrusted components. Cinch also interacts with peripheral devices via an untrusted intermediary, but the architecture, mechanisms, goals, and threat model are all different.

Separation kernels and network security (related problems, related mechanisms). Two other research areas deserve special mention. The first is Rushby’s separation kernel [129], in which the operating system is architected to make a computer’s components interact as if they were part of a distributed system (see [81] and [122] for modern implementations). The foundational observation of this work—that networks are a useful abstraction for interposition—is one that we share. However, our goals and scenario are different. The separation kernel was intended to be a small kernel, with compartmentalized units that could be formally verified, and it provided separation through information flow control. In contrast, our scenario is commodity operating systems, and we are seeking to apply the conceptual framework of network security.

This brings us to network security itself. Cinch owes a substantial debt to this field, borrowing as it does concepts like firewalls, deep packet inspection, and virtual private networks. Moreover, the recent trend toward Network Function Virtualization (NFV) [119, 138] applies I/O virtualization (as do Cinch and some of the works cited earlier), but the point in NFV is to make middleboxes virtual, for reasons of configurability and cost.

9 Summary and conclusion

Cinch was motivated in large part by the observation that hardware security is recapitulating the history of network security. Originally, the Internet was a comparatively small number of mutually trusting organizations and users. As a consequence, there was relatively little focus on support for security within the network infras-

ture. With the explosion of Internet users, spurred by changing economics, security suddenly became a serious problem. Similarly, commodity operating systems have relatively few safeguards against misbehaving hardware, reflecting a time when peripheral devices could be trusted. But, with the rapid decline in the barriers to producing plug and play peripherals, those days have come to an end—and Cinch aims to be useful in the world ahead.

Although Cinch’s individual mechanisms have ample precedent in the literature, the architecture and the synthesis is novel, to the best of our knowledge. Moreover, as the evaluation results make clear, the implementation is pragmatic and surprisingly powerful. Looking at this fact, we feel comfortable stating that we have identified a good abstraction for the problem at hand.

To be clear, we are not saying that Cinch uniquely enables any one piece of its functionality (§5); rather, the abstraction makes it natural to develop and deploy what would require far more work under alternative solutions (§8).

We are also not saying that Cinch is comprehensive. Indeed, besides the limitations covered earlier (§1, §4.2, §7.6), some of Cinch’s solutions are effective only with additional mechanisms. As a key example, providing authentication and privacy with Cinch requires certificates or pairing, and device modifications. However, certificates are compatible with the chain of trust inherent in purchasing hardware, pairing is similar to the permissions model on mobile devices, and the required modifications are not onerous, as our implementation of the adapter (§6.3) indicates. As another example, Cinch’s compliance Policy (§5.2) would be strengthened by formal verification.

Despite the issues, Cinch appears to improve on the status quo. Of course, it is possible that, if Cinch were widely deployed, it would only escalate an arms race, and drive attackers to find ever more esoteric vulnerabilities. On the other hand, security is always about building higher fences, and the considerations at the heart of our work could guide the future design of peripheral buses and drivers.
