efficient than applying general purpose security protocols to NTP. For example, one might consider simply applying TLS or DTLS to NTP packets to obtain authentication. Unfortunately, TLS and DTLS do not achieve full statelessness as is desirable for high throughput applications that need to resist denial of service attacks. TLS and DTLS both require that the server maintain state during the initial handshake (which requires 3 round trips) and during session resumption handshakes (which requires 2 round trips). While the server can offload state *between* the initial handshake and the session resumption using session tickets, there is no standardized mechanism to do so *during* the handshakes. DTLS servers also must maintain mappings between clients and sessions, as UDP does not provide this functionality. ANTP avoids these problems by having the server offload state at every step. ANTP is also much more efficient in terms of communication size, as TLS/DTLS have a variety of extensions that consume substantial bandwidth.

ANTP security. ANTP’s design is supported by a thorough analysis of its cryptographic security using the provable security paradigm. To do so, we extend existing frameworks for key exchange and secure channels [5, 11] to develop a novel framework that handles protocols where *time* plays a central role. The adversary in our security analysis is a network attacker capable of deleting, reordering, editing, and creating messages between parties. Since our model is about time synchronization, parties in our model have local clocks, and the adversary is given complete control over the initialization of all clocks, as well as the ability to increment the time of parties not involved in a protocol run. This allows us to model the ability of an adversary to delay packet transmission: this is particularly important in the case of NTP, where delaying packets asymmetrically can cause the client to synchronize to an inaccurate time. This differs from previous security frameworks that model time, such as ones introduced by Schwenk [27] (which uses a global time counter to model timestamps) and Basin et al. [4] (where the adversary cannot influence the offset or rate-of-change of the party clocks.)

We then show that ANTP achieves secure time synchronization as defined by our model, under standard assumptions on the security of the cryptographic primitives (key encapsulation mechanism, hash function, authenticated encryption, message authentication code, and key derivation function) used to construct the protocol.

2 Network Time Protocols

Here we review the two most commonly deployed time synchronization protocols, NTP and SNTP, as well as a recent proposal called Network Time Security [31].

2.1 The Network Time Protocol

The *Network Time Protocol (NTP)* was developed by Mills in 1985 [15], and revised in 1988, 1989, 1992 and 2010 (NTPv1 [9], NTPv2 [16], NTPv3 [17] and NTPv4 [18] respectively). NTP is designed to synchronize the clocks of machines directly connected to hardware clocks (known as *primary servers*) to machines without hardware clocks (known as *secondary servers*). NTP protects against Byzantine traitors by querying multiple servers, selecting a majority clique and updating the local clock with the majority offset. This assumes the attacker can only influence some minority of the queried servers.

2.2 The Simple Network Time Protocol

The *Simple Network time Protocol (SNTP)* is a variant of NTP that uses an identical message format [17] but only queries a single server when requesting time synchronization using a single time source (`time.windows.com` and `time.apple.com` respectively). Our construction lends itself well to SNTP, as it authenticates time samples from a single server. Security analysis is also easier as we can avoid the more complex sorting and filtering algorithms of NTP, and client and server behaviours are simpler. Note that SNTP and NTP client request messages are the same.

SNTP has three distinct stages: (1) the creation and transmission of `req` by the client; (2) the processing of `req` by the server, and transmission of `resp`; and (3) the processing of `resp` and clock update by the client. An abstraction of the protocol behaviour can be found in Figure 1, including the client’s clock update procedure. Though the format of NTP packets is identical for both client and server NTP messages, we use `req` to indicate a NTP packet in client mode, and `resp` to indicate a NTP packet in server mode, omitting packet content details.

1. The client creates an SNTP `req` packet, sets `transmit_timestamp` (t_1) to `Now()` and sends the message.¹
2. The server creates an SNTP `resp` packet with all fields identical to the received `req`, but signalling Server mode. The server sets `originate.timestamp` to the value `transmit_timestamp` from `req`. The server also sets `receive_timestamp` (t_2) to `Now()` immediately after receipt of `req`, and sets `transmit_timestamp` (t_3) to `Now()` immediately before sending the message to the client.
3. Upon receiving `resp`, the client notes the current time from `Now()` and saves it as t_4 . If `resp.originate_timestamp` is not equal to

¹`Now()` denotes a party reading its local clock’s current time.

Client	Server
$t_1 \leftarrow \text{Now}()$	
$\text{req} \leftarrow t_1$	$\xrightarrow{\text{req}}$
	$t_2 \leftarrow \text{Now}()$
	⋮
	$\xleftarrow{\text{resp}}$
$t_4 \leftarrow \text{Now}()$	$t_3 \leftarrow \text{Now}()$
$RTT \leftarrow (t_4 - t_1) - (t_3 - t_2)$	$\text{resp} \leftarrow t_2 \ t_3$
$\tilde{\theta}_3 \leftarrow RTT/2$	
$offset \leftarrow \frac{1}{2}(t_2 + t_3 - t_1 - t_4)$	
$time \leftarrow \text{Now}() + offset$	

Figure 1: Simple Network Time Protocol (SNTP). `Now()` denotes the procedure that outputs the local machine’s current time. RTT denotes the total round-trip delay the client observes and $\tilde{\theta}_3$ denotes the approximation of the propagation time from server to client. The time of the server receiving `req` is denoted t_2 and sending `resp` is t_3 . Note that $offset = t_3 + \tilde{\theta}_3 - t_4$, which we will use in our correctness analysis of ANTP.

`req.transmit_timestamp`, the client aborts the protocol run. The client calculates the total round-trip time RTT and the local clock offset $offset$ as in Figure 1.

(The rest of the fields in the NTP packets are irrelevant for calculating the local clock offset and correcting the local clock for a single-source time synchronization protocol. These extra fields in the NTP packet are used primarily for ranking multiple distinct time sources.)

From this, we can compute a bound of the amount of error that is introduced to the clock update procedure via asymmetric packet delay when the packets are unmodified. Asymmetric packet delay is the scenario where the propagation time from client to server is not equal to the propagation time from server to client. Let θ_1 be the propagation time from client to server, θ_2 the server processing time and θ_3 the propagation time from server to client. θ_3 is approximated in SNTP by $\tilde{\theta}_3 = \frac{RTT}{2}$, where $RTT = (t_4 - t_1) - (t_3 - t_2) = \theta_1 + \theta_3$.

The actual offset is $offset_{actual} = t_3 + \theta_3 - t_4$. The approximated offset is computed as $offset = \frac{1}{2}(t_2 + t_3 - t_1 - t_4)$. When $\theta_1 = \theta_3$, then $offset = t_3 + \theta_3 - t_4$ and $offset = offset_{actual}$. In the worst possible case, packet delivery is instantaneous, and the entire roundtrip time is asymmetric delay. The client approximates the offset as above, and thus the error introduced this way is $\frac{1}{2}|(\theta_1 - \theta_3)| \leq RTT$.

The error that a passive adversary with the ability to delay packets can introduce does not exceed the RTT : clients can abort the protocol run when RTT grows too large, giving them some control over the worst-case error.

2.3 NTP Security and Other Related Work

In terms of security, early versions of NTP (NTP to NTPv2) had no standardized authentication method.

NTPv3 symmetric key authentication. NTPv3 presented a method for authenticating time synchronization – using pre-shared key symmetric cryptography. NTPv3’s added additional extension fields to the NTP packet, consisting of a 32-bit key identifier, and a 64-bit cryptographic checksum. The specification of NTPv3 describes the checksum as the encryption of the NTP packet with DES, but notes that other algorithms could be negotiated. The distribution of keys and negotiation of algorithms was considered outside the scope of NTP.

NTPv4 Autokey public key authentication. NTPv4 introduced a method for using public key cryptography for authentication, known as the Autokey protocol. Autokey is designed to prevent inaccurate time synchronization by authenticating the server to the client, and verifying no modification of the packet has occurred in transit. Autokey is designed to work over the top of authenticated NTPv3. Autokey uses MD5 and a variety of Schnorr-like [26] identification schemes to prevent malicious attacks, but as an analysis of Autokey by Röttger shows [23], there are multiple weaknesses inherent in the Autokey protocol, including use of small seed values (32 bits) and allowing insecure identification schemes to be negotiated. The size of the seed allows a MITM adversary with sufficient computational power to generate all possible seed values and use the cookie to authenticate adversarial-chosen NTP packets. This weakness alone allows an attacker in control of the network to break authentication of time synchronization, thus NTP with the Autokey protocol is not a secure time synchronization protocol [30]. Mills describes his experiments on demonstrating reliability and accuracy of network time synchronization using NTPv2 implementations [19], but does not offer a formal security analysis of NTP. Mills does show that honest deployment of NTP in networks can offer time synchronization accuracy to within a few tens of milliseconds after only a few synchronizations. ANTP was originally intended as a means to addressing the vulnerabilities in the Autokey protocol, but with many changes to minimize public key and symmetric key operations, message bandwidth. While inspiration for ANTP is the Autokey protocol, the design diverged significantly enough to consider it a separate protocol design.

Network Time Security draft-12. The Network Time Security protocol (NTS) [31] is an IETF Internet-Draft that uses public key infrastructure in order to secure time synchronization protocols such as NTP and the Precision Time Protocol (PTP) [1]. However, NTS is costly in terms of server-side public key operations, is a four round-trip protocol, requires clients to manage public/private

key pairs and digital certificates, and does not have an equivalent to ANTP’s no-cryptographic-latency feature.

We note NTS is a work-in-progress and future revisions may be updated to address these issues. We discovered in draft-06 a flaw in the *Association Phase* that would allow MITM adversaries to perform downgrade attacks and communicated our findings to the authors. This has since been fixed and the following is an overview of draft-12.

NTS evolved as an attempt to fix the weaknesses in Autokey and has inherited many design choices from the Autokey protocol, in particular protocol flow and key derivation strategy using secret server seeds. Similarly to the Autokey protocol, NTS servers reuse the randomness *server_seed* used to generate a shared secret key (referred to as a *cookie*) for each client by $\text{cookie} = \text{HMAC}(\text{server_seed}, \text{Hash}(\text{client public key certificate}))$, encrypting this value and a client-chosen nonce with the client public key, authenticating the server by digitally signing the *cookie* with the server private key. Note that the client public key certificate in NTS serves to ensure the confidentiality and uniqueness of the *cookie* for each client using a different public key certificate. It does not serve to authenticate the client to the server. In ANTP clients do not need a certificate, only the server.

In the *Association Phase* NTS requires the server digitally sign the server *assoc* message, which (in draft-12) includes the client’s selection of hash and public key encryption algorithms in addition to a client nonce. The server must compute costly public key operations over these values for each association phase. As a result, a NTS server requires three public key operations per client to establish a shared secret *cookie*.

NTS draft-06 attack. Here we briefly describe our downgrade attack on NTS draft-06 and below. Figure 2 shows the NTS draft-06 *Association Phase*, which differs to the previously described draft-12. (This is analogous to the *Negotiation Phase* in ANTP.) In assoc_c , the client sends the highest version of NTS that it supports, in addition to lists of hash and public key encryption algorithms. The server responds with a signature over the server hostname, the negotiated version, and the negotiated hash and public key encryption algorithms. This does not contain the server’s received values of the client’s supported version and algorithms, so it is straightforward for a MITM attacker to strip assoc_c of strong hash and public key encryption algorithms. If the client supports weak algorithms, this can translate into a full break of time-synchronization security by recovery of the *cookie*, similarly to attacks on weak Diffie-Hellman groups in TLS [2].

tlodate. Another solution for synchronizing time is Appelbaum’s *tlodate* [3], which uses timestamps in the nonces of TLS handshakes to fetch the time. However, this requires stateful servers, is not as accurate as cur-

rent solutions and will no longer function when servers transition to TLS 1.3 (as the proposed protocol no longer includes timestamps in the nonces).

3 Authenticated NTP

In this section we present the *Authenticated Network Time Protocol (ANTP)*: a new variant of NTP designed to allow an SNTP client to authenticate a single NTP server and output a time counter within some accuracy margin of the server time counter. Our new protocol ANTP allows an ANTP server to authenticate itself to an ANTP client, as well as provide cryptographic assurances that no modification of the packets has occurred in transit. ANTP messages, much like Autokey and NTS, are included in the extension fields of NTP messages. We summarize the novel features of ANTP below:

- The client is capable of authenticating the server, and all messages from the server. Replay attacks are explicitly prevented for the client.
- The server does not need to keep state for each client.
- The server does only one public key operation per client in order to generate a shared secret key.
- The shared secret key can be used for multiple time synchronization attempts by the same client.
- The client has a “no-cryptographic-latency” option to avoid additional error in the approximation of $\tilde{\theta}_3$ due to cryptographic operations.

3.1 Protocol Description

ANTP is divided into four separate phases. A detailed protocol flow can be found in Figure 3, and exact message formatting can be found in the full version [6].

- *Setup:* The server chooses a long term key s for the authenticated encryption algorithm. This is used to encrypt and authenticate offloaded server state between phases.
- *Negotiation Phase:* The client and server communicate supported algorithms; the server sends its certificate and state C_1 , an authenticated encryption (using s) of the hash of the message flow. The value C_1 will be later used to authenticate negotiation.
- *Key Exchange Phase:* The client uses a key encapsulation mechanism (KEM) based on the server’s public key from its certificate to establish a shared key with the server. The client sends the KEM ciphertext and encrypted state C_1 to the server. The server derives the shared key k , then encrypts it (using s) to compute C_2 . The server replies with a MAC (for key confirmation) and offloaded state C_2 (for use in the next phase).

Figure 2: A description of the Network Time Security draft-06 Association Phase. vers is the NTS version indicator; name_c and name_s are the hostnames of the client and server respectively.

- *Time Synchronization Phase:* The client sends a time synchronization request and includes offloaded server state C_2 . The server recovers shared key k from C_2 and uses it to authenticate the response, which the client verifies. The client can also request “no-cryptographic-latency” time synchronization, where the server will immediately reply without authentication, and then send a second message with authentication.

3.2 Design Rationale and Discussion

Of the security properties discussed in RFC 7384 [20], ANTP achieves the following: *protection against manipulation, spoofing, replay and delay attacks; authentication of the server* (if ANTP is applied in a chain, implicit authentication of primary server); *key freshness; avoids degradation of time synchronization; minimizes computational load; minimizes per-client storage requirements of the server*. The following properties from [20] are only partly addressed by ANTP, which we explain in further detail below: resistance against the *rogue master, cryptographic DoS, and time-protocol DoS* attacks.

Stateless server. While storage costs are generally not an issue, synchronizing state between multiple servers implementing a high-volume network endpoint like `time.windows.com` is still expensive and complicated to deploy. For reliability and performance these servers are often in multiple data centres, spread across multiple geographic regions. In ANTP the server regenerates per-client state as needed. Our construction uses *authenticated encryption (AE)* in a similar manner to TLS Session Tickets [24] for session resumption, where the server authenticates and encrypts its per-client state using a long-term symmetric key, then sends the ciphertext to the client for storage. The client responds with the ciphertext in order for the server to decrypt and recover state. The server periodically refreshes the long-term secret key for the AE scheme (the intervals are dependent on the security requirements of the AE scheme).

No-cryptographic-latency mode. In SNTP, the accuracy is bounded by the total roundtrip time of the time

synchronization phase. If we build a secure authentication protocol over SNTP, then the total accuracy of the new authenticated protocol is also bound by the total round-trip time of the time synchronization phase.

Since cryptographic computations over the synchronization messages adds asymmetrically to propagation time, it introduces error in the approximation of propagation time $\tilde{\theta}_3$, so authentication operations degrade the accuracy of the `transmit_timestamp` in the `resp`. As noted above, ANTP includes a “no-cryptographic-latency” mode to reduce error due to authentication: during the Time Synchronization Phase, at the client’s option, the server will immediately process a `resp` as in Figure 1 and sends it to the client, without authentication. The server subsequently creates an ANTP `ServerResp` message, and sends the `resp` with `ServerResp` in the NTP extension fields of the saved `resp`. A client can then use the time when receiving the initial `resp` to set its clock, but only after verifying authentication with the ANTP `ServerResp`, aborting if authentication fails, if either message wasn’t received, or if messages were received in incorrect order. Here, cryptographic processing time does not introduce asymmetric propagation time. (The TESLA broadcast authentication protocol of Perrig et al. [22] delays authentication as well, to improve efficiency rather than accuracy as in ANTP.)

Efficient cryptography. Public key operations are computationally expensive, especially in the case of a server servicing a large pool of NTP clients. ANTP only requires a single public key operation per-client to ensure authentication and confidentiality of the premaster secret key material. The client can reuse the shared secret key on multiple subsequent time synchronization requests with that server. ANTP uses a *key encapsulation mechanism* for establishing the shared secret key. We allow either static-ephemeral elliptic curve Diffie-Hellman key exchange or key transport using RSA public key encryption. While one might ordinarily avoid use of RSA or static-ephemeral DH for key exchange since they do not provide forward secrecy, this is not a concern for ANTP since we do not need confidentiality as the contents of the messages (time synchronization data) are public.

Figure 3: Authenticated NTP (ANTP_E), where E is a fixed upper bound on the desired accuracy. The pre-determined negotiation function negotiate takes as input two ordered lists of algorithms and returns a single algorithm. n denotes the maximum number of synchronization phases, and p denotes the current synchronization phase. $[m_6^*]$ indicates an optional message sent based on a “no-cryptographic-latency” flag present in m_5 , omitted in this figure. Note that if KEM.Decap or AuthDec fails for any ANTP server, the server simply stops processing the message, aborts, and allows the client to time-out. If certificate validation fails, the client aborts the protocol run. Each of the messages contains an identifier flag to prevent confusion between MACs. The protocol in the figure is an abstraction: messages $m_1 \dots m_4$ and the cryptographic components of m_5 and m_6 are sent as extensions of NTP messages, and detailed message structure can be found in the full version [6]. Authenticated Encryption schemes are not negotiated as they are entirely opaque to the client.

Key freshness and reuse. ANTP allows multiple time synchronization phases for each session using the same shared secret key k but with a new nonce in each Time Synchronization Phase to prevent replay attacks and ensure uniqueness of the protocol flow. This reuse can continue until either the client restarts the negotiation phase or the server rotates public keys or authenticated encryption keys.

Denial of service attacks. Against a man-in-the-middle, some types of denial-of-service (DoS) attacks are unavoidable, as the adversary may always drop messages.

Amplification attacks can be of concern. Unauthenticated SNTP has a roughly 1:1 ratio of attacker work to server work, in that one attack packet causes one packet in response, and a small computational effort is required by the server. In ANTP, the cryptographic operations do allow some amplification of work. Based on the experimental results in Table 1, the negotiation and time synchronization phases have less than a 1:2 ratio of attacker work to server work. As for the key exchange phase, the server performs a public key operation while a malicious client may not. However, a server under attack can temporarily stop responding to key exchange requests while still responding to time synchronization requests, and since most honest clients will perform key exchange infrequently, their service will not be denied.

Another amplification can be caused by the no-cryptographic-latency feature, since two response packets are sent for each request. This mode can be turned off during attack, the server indicating with a flag that it does not (currently) support this feature.

Finally, in the negotiation phase the server’s response is also considerably larger than the client request (because it includes a certificate), but, like the key exchange phase, the negotiation phase may be temporarily disabled without denying service to clients who already have established a premaster secret. Another option is to replace the server certificate chain with a URL where the client can download it. Depending on the size of the certificate(s) this could reduce the bandwidth amplification considerably. This last mitigation requires detailed analysis, which we leave to future work.

Certificate validation. When using digital certificates to authenticate public keys, the synchronization of the issuer and the relying party is an underlying assumption. This serves to highlight a significant problem – *how do you securely authenticate time using public key infrastructure without previously having time synchronization with the issuer?* For our construction this must be done once, and we assume that the client has some out-of-band method for establishing the trustworthiness of public keys, perhaps using OCSP [25] with nonces to ensure freshness of responses, by the user manually setting the time for first certificate validation, or shipping a trusted certificate with

the operating system. Since certificate validity periods typically range from months to years, if the user is assured of time synchronization with the issuer to be within range of hours or days and that range sits comfortably within the certificate validation period, this is a viable solution.

ANTP to NTP downgrade. ANTP servers are also NTP servers, since ANTP is implemented as an NTP extension. This eases deployment; older clients can continue using NTP, while newer clients can use ANTP. However, a network adversary can drop the ANTP extension from the request, and the server will respond with NTP (having interpreted the request as NTP). For this reason, clients that send an ANTP request must only update their clock based on a valid ANTP response, and ignore NTP responses. For similar reasons, clients are not recommended to implement a fall back from ANTP to NTP.

4 Implementation and Performance

Here we describe our instantiation of ANTP in terms of cryptographic primitives used as well as its implementation and results on its performance.²

4.1 Instantiation and Implementation

We instantiate ANTP using the following cryptographic algorithms. We use AES128-GCM as the symmetric encryption algorithm for the server to encrypt and decrypt state, SHA-256 as the hash algorithm, and HMAC-SHA256 as the MAC and key derivation function. We support two key encapsulation mechanisms, RSA key transport and static-ephemeral elliptic curve Diffie-Hellman:

- RSA key transport: In KeyGen, the public key and secret key are a 2048-bit RSA key pair. Encap is defined by selecting a key $pms \leftarrow \{0, 1\}^{128}$ and encrypting pms using the RSA public key with RSA-PKCS#1.5 encryption; Decap performs decryption with the corresponding RSA secret key. The shared secret is $k \leftarrow KDF(pms, \perp, "ANTP", len)$.
- Static-ephemeral elliptic curve Diffie–Hellman: Let P be the generator (base point) of the NIST-P256 elliptic curve group of prime order q . In KeyGen, the secret key is $sk \leftarrow \mathbb{Z}_q$ and the public key is $pk = sk \cdot P$, where \cdot denotes scalar-point multiplication. In Encap, select $r \leftarrow \mathbb{Z}_q$ and compute $c \leftarrow r \cdot P$ and $pms \leftarrow X(r \cdot pk)$, where $X(Q)$ gives the x-coordinate of elliptic curve point Q . In Decap, compute $pms \leftarrow X(sk \cdot c)$. The shared secret is $k \leftarrow KDF(pms, \perp, "ANTP" \| c, len)$. This is the ECIES-KEM [29] which is IND-CCA secure under the el-

²Our implementation code and benchmarking tools can be found at <https://github.com/DowlingBJ/AuthenticatedNTP>.

liptic curve discrete logarithm assumption in the random oracle model [8].

We implemented ANTP by extending OpenNTPD version 1.92 [34]. Our implementation relies on OpenSSL version 1.0.2f [35] for its cryptographic components; notably, this version includes a high-speed assembly implementation of the NIST P-256 curve; AES-GCM encryption/decryption uses the AES-NI instruction.

4.2 Performance

Methodology. We collected performance measurements for each of the negotiation, key exchange, and time synchronization phases. We wanted to know the maximum number of connections per second that could be supported in each phase, as well as the latency a client would experience for a typical server. For comparison we also collected performance measurements for unauthenticated NTP time synchronization phases.

Our throughput and LAN latency experiments were carried out in the following environment on our local area network. We had two machines acting as clients, and a single server machine running ANTP. The server had an Intel Core i7-4770 (Haswell) processor with 4 cores running at 3.4 GHz with 15.6 GiB of RAM; we used two similar client machines, which in our experiments were always sufficient to saturate the server. The clients and server were connected over an isolated 1 gigabit LAN. The server was running Linux Mint 17.2 with no other software installed.

Our latency experiments across the US were carried out between two Amazon AWS m4.2xlarge instances, the server in the US East (N. Virginia) region and the client in the US West 1 (N. California) region. These instances each had eight virtual CPUs, each of which was an Intel Xeon E5-2676 v3 (Haswell) core running at 2.4 GHz, with 32 GiB of RAM, and 1 Gbps of dedicated bandwidth; the instances were running Ubuntu 14.04 with no other software installed.

It is important to note that OpenNTPD is not multi-threaded, so the OpenNTPD server process runs on a single core, regardless of the number of cores on the machine. As the key exchange phase is CPU bound, in a threaded server implementation we expect key exchange phase throughput to increase linearly with the number of CPU cores until bandwidth is saturated.

For testing throughput (connections/second), we used our own multi-threaded UDP flooding benchmarking tool that sends static packets and collects the number of responses, the average latency of those responses, and the number of dropped packets. We tuned the number of queries per second to ensure that the server’s (single) core had around 95% utilization, and that more client packets were sent than being processed, but not so many more that

performance became degraded (i.e., the server dropped less than 1% of packets being received per second).

For testing individual phase latency, we again used our UDP benchmarking tool, this time measuring latency of a subset of connections while maintaining a particular background ANTP load at the server (either 50% or 90% of supported throughput), to measure the latency a client would experience at an unloaded or loaded server.

For testing total protocol runtime, we instrumented the OpenNTPD client to report the runtime of a single complete (all three phases) ANTP synchronization, again with background ANTP load as above.

Results – individual phases.

Table 1 shows the results of each phase. Results reported are the average of 5 trials to prevent outlier results. For throughput and individual phase latency, each trial was run for 100 seconds. For throughput, Table 1 reports the number of response packets received at the client machine.

Negotiation phases. The lower throughput of RSA and ECDH negotiation messages (compared to NTP) is due to larger message size of ANTP messages, as network bandwidth was saturated for this measurement. Latency for ECDH negotiation at 90% load is higher compared to RSA negotiation at 90% load; at that load level, a much larger number of ECDH packets are being sent than RSA packets, so CPU load in the ECDH is higher even though they have the same bandwidth consumption, leading to higher latency for ECDH negotiation.

Key exchange phases. As expected, server key exchange throughput is higher when ECC is used for public key operations compared to RSA. This difference is explained by the relative costs of the underlying cryptographic operations: using OpenSSL’s speed command for benchmarking individual crypto operations, the runtime of ECC NIST P-256 point multiplication is $8.62 \times$ faster than RSA 2048 private key operations, whereas we observe a $7.54 \times$ improvement in throughput for ANTP’s ECDH key exchange over ANTP’s RSA key exchange. Latency on the local network for RSA key exchange is approximately $2.9 \times$ that of ECDH key exchange at 90% load.

Time synchronization phases. While ANTP time synchronization phases are more computationally intensive than unauthenticated NTP, throughput is reduced by only a factor of approximately 1.6. Since this phase is CPU bound, we expect a multi-threaded server implementation to increase ANTP throughput. Latency increase on the local network for ANTP at 50% load is only about 14% and at 90% load is about 27%.

Results and extrapolation – all 3 phases. Since each client makes a full 3-phase time synchronization (negotiation, followed by key exchange, followed by time synchronization) relatively infrequently, it does not make

sense to measure server throughput for complete 3-phase time synchronizations. We did measure latency of a 3-phase time synchronization to note the performance that a client would perceive on its initial synchronization. As expected, the total runtime of a client exceeds the sum of the latencies from each individual phase due to the client performing its own cryptographic operations.

It is interesting to note that latency slows as the server approaches load capacity. Future work on OpenNTPD and other NTP servers could include optimizations to reduce latency and improve time synchronization accuracy under increasing load.

We can extrapolate from the individual phase results the client pool that ANTP could feasibly support running on the same hardware. For example, Windows by default polls time servers every 9 hours [13]. Assuming this is true for all clients (and that the clients synchronize uniformly across the period) 175,644 time synchronization requests per second would correspond to a pool of 5,755,502,592 clients.

ANTP clients would choose how often to restart the negotiation phase and we recommend doing so periodically to ensure the attack window from exposure of the symmetric key is limited. If keys are re-exchanged monthly, this is a ratio of 1:1:1440 for expected negotiation, key exchange, and time synchronization messages, which increases to 1:1:8640 if clients re-exchanged every 6 months. From these or other expected ratios, one could extrapolate the expected performance impact of using ANTP over NTP.

5 Security Framework

In this section we introduce our new time synchronization provable security framework for analyzing time synchronization protocols such as ANTP, NTP, and the Precision Time Protocol. It builds on both the Bellare–Rogaway model [5] for *authenticated key exchange* and the Jager et al. framework for *authenticated and confidential channel establishment* [11]. Neither of those models however includes time.

Our framework models time as a counter that each party separately maintains, as the goal of the protocol is to synchronize these disparate counters. Additionally, the adversary in our execution environment has the ability to initialize each protocol run with a new time counter independent of the party’s own counter, and controls when protocol runs can increment their counter, effectively giving the adversary complete control of both the latency of the network and the computation time of the parties.

5.1 Execution Environment

There are n_p parties P_1, \dots, P_{n_p} , each of whom is a protocol participant. Each party generates a long-term key-pair

(sk_i, pk_i) , and can run up to n_s instances of the protocol which are referred to as sessions. We denote the s th session of a party P_i as π_i^s . Note that each session π_i^s has access to the long-term key pair of the party P_i . In addition, we denote with T and T_c the full transcript and server-session maintained client transcript T_c .

Per-Session Variables. The following variables are maintained by each session:

- $\rho \in \{\text{client}, \text{server}\}$: the role of the party.
- $id \in \{1, \dots, n_p\}$: the identity of the party.
- $pid \in \{1, \dots, n_p\}$: the believed identity of the partner.
- $\alpha \in \{\text{accept}, \text{reject}, \text{in-progress}\}$: the session status.
- $k \in \{0, 1\}^{128}$: the session key.
- $T_c \in \{\{0, 1\}^*, \emptyset\}$: if $\rho = \text{server}$, the transcript of client messages, otherwise $T_c = \emptyset$.
- $T \in \{0, 1\}^*$: the transcript of messages sent and received.
- $time \in \mathbb{N}$: a counter maintained by the session.

Adversary Interaction. The adversary schedules and controls all interactions between protocol participants. The adversary has control of all communication, able to create, delete, reorder or modify messages at will. The adversary can compromise long-term and session keys. Additionally, the adversary is able to set the clock of a party to an arbitrary time when a session begins and control the rate at which time progresses during the execution of a session. The following queries model normal execution with adversary control of time:

- $\text{Create}(i, r, t)$: The adversary activates a new session with party P_i , initializing $\pi_i^s.\rho = r$ and $\pi_i^s.time = t$. Note that if $\pi_i^s.\rho = \text{client}$, then π_i^s responds with the first message of the protocol run.
- $\text{Send}(i, s, m, \vec{\Delta})$: The adversary sends a message m to a session π_i^s . Party P_i processes the message m and responds according to protocol specification, updating per-session variables and outputting some message m^* if necessary. During message processing, the party may execute multiple calls to a distinguished $\text{Now}()$ procedure, modelling the party reading its current time from memory; immediately before the ℓ th such call to the $\text{Now}()$ procedure, the session’s $\pi_i^s.time$ variable is incremented by Δ_ℓ .

These queries model compromise of secret data:

- $\text{Reveal}(i, s)$: The adversary receives the session key k of the session π_i^s .
- $\text{Corrupt}(i)$: The adversary receives the long-term secret-key sk_i of the party P_i .

The following query allows additional adversary control of the clock:

- $\text{Tick}(i, s, \Delta)$: The adversary increments the counter $\pi_i^s.\text{time}$ by Δ .

The vector $\vec{\Delta}$ in Send is necessary due to subtleties in the security framework: An adversary cannot issue Tick queries to a session during the processing of a Send query, but a party may read its clock multiple times while processing a message and thus expect to receive different clock times. The vector $\vec{\Delta}$ in the Send query allows adversary control of this clock rate.

Note that our model assumes that during execution of a session, the clocks between two parties advance at the same rate, otherwise it does not make sense for two parties to try to synchronize their clocks at all. This implicitly assumes that the parties are in the same reference frame. Additionally, while computer clocks may progress at different rates, we are assuming that, over a relatively short period of time, like the few seconds for an execution of the protocol, the difference in clock rate will be negligible. This will be formalized in Definitions 3 and 4 with the condition that the adversary advances the *time* of matching sessions symmetrically: a $\text{Tick}(j, t, \sum_{l=1}^{\ell} \Delta_l)$ must be issued if session π_j^t matching π_i^s exists when $\text{Send}(i, s, m, \vec{\Delta})$ is issued.

Security Experiment. The *time synchronization security experiment* is played between a challenger \mathcal{C} who implements all n_p parties according to the execution environment and protocol specification, and an adversary \mathcal{A} . After the challenger generates the long-term key pairs, the adversary receives the list of public keys and interacts with the challenger using the queries described above. Eventually the adversary terminates.

5.2 Security Definitions

The goal of the adversary, formalized in this section, is to break time synchronization security by causing any client session to complete a session with a time counter such that $|\pi_i^s.\text{time} - \pi_j^t.\text{time}| > \delta$, (where π_j^t is the partner of the session π_i^s such that $\pi_j^t.id = \pi_i^s.pid$, and δ is an accuracy margin) or cause a session π_i^s to accept a protocol run without having a matching session π_j^t . The adversary controls the initialization of the party's clock in each session, and the rate at which the clock advances during each session, with the restriction that during execution of a session the adversary must advance the party and its peer at the same rate.

5.2.1 Matching Conversations and Authentication

Authentication is defined similarly to the approach of Bellare and Rogaway [5], by use of matching conversations. We use the variant of matching conversations employed by Jager et al. [11], and modify the definition to reflect client authentication of stateless servers.

Definition 1 (Matching Conversations). *We say a session π_i^s matches a session π_j^t if $\pi_i^s.\rho \neq \pi_j^t.\rho$ and $\pi_i^s.T$ prefix-matches $\pi_j^t.T$. For two transcripts T and T' , we say that T is a prefix of T' if $|T| \neq 0$ and T' is identical to T for the first $|T|$ messages in T' . Two transcripts T and T' prefix-match if T is a prefix of T' , or T' is a prefix of T .*

Prefix-matching prevents an adversary from trivially winning the experiment by dropping the last protocol message after a session has accepted. Note that since our focus is clients authenticating stateless servers, our authentication definition is one-sided.

Definition 2 (Stateless Server Authentication). *We say that a session π_i^s accepts maliciously if:*

- $\pi_i^s.\alpha = \text{accept}$;
- $\pi_i^s.\rho = \text{client}$;
- no $\text{Reveal}(i, s)$ or $\text{Reveal}(j, t)$ queries were issued before $\pi_i^s.\alpha \leftarrow \text{accept}$ and π_j^t matches π_i^s ;
- no $\text{Reveal}(j, t')$ queries were issued before $\pi_i^s.\alpha \leftarrow \text{accept}$ and $\pi_j^{t'}.T_c = \pi_j^t.T_c$;
- no $\text{Corrupt}(j)$ query was ever issued before $\pi_i^s.\alpha \leftarrow \text{accept}$, where $j = \pi_i^s.pid$;

but there exists no session π_j^t such that π_i^s matches π_j^t .

We define $\text{Adv}_{\mathcal{T}}^{\text{auth}}(\mathcal{A})$ as the probability of \mathcal{A} forcing any session π_i^s of time synchronization protocol \mathcal{T} to accept maliciously.

In the above definition, the first Reveal condition prevents \mathcal{A} from trivially winning the experiment by accessing the session key of the Test session. Similarly the Corrupt condition prevents \mathcal{A} from trivially winning by decrypting the premaster secret with the session partner's public key. The possibility exists for an adversary to trivially win the experiment by replaying client messages to a second session and querying the second session with Reveal. Disallowing Reveal queries in general is clearly too restrictive, so we prevent this in the second Reveal condition by disallowing Reveal queries to server sessions with matching client transcripts.

5.2.2 Correct and Secure Time Synchronization

The goal of a time synchronization protocol is to ensure that the difference between the two parties' clocks is within a specified bound. A protocol is δ -correct if that difference can be bounded in honest executions of the protocol, and δ -accurate secure if that difference can be bounded even in the presence of an adversary.

Definition 3 (δ -Correctness). *A protocol \mathcal{T} satisfies δ -correctness if, in the presence of a passive adversary that faithfully delivers all messages and increments in each partner session symmetrically, then the client and server's*

clocks are within δ of each other. More precisely, in the presence of a passive adversary, for all sessions π_i^s where

- $\pi_i^s.\alpha = \text{accept}$;
- $\pi_i^s.\rho = \text{client}$;
- whenever \mathcal{A} queries $\text{Send}(i, s, m, \vec{\Delta})$ or $\text{Send}(j, t, m', \vec{\Delta}')$, \mathcal{A} also queries $\text{Tick}(j, t, \sum_{i=1}^{\ell} \Delta_i)$ or $\text{Tick}(i, s, \sum_{i=1}^{\ell} \Delta'_i)$, respectively; and
- whenever \mathcal{A} queries $\text{Tick}(i, s, \Delta)$, or $\text{Tick}(j, t, \Delta')$, \mathcal{A} also queries $\text{Tick}(j, t, \Delta)$ or $\text{Tick}(j, t, \Delta')$, respectively;

we must also have that $|\pi_i^s.\text{time} - \pi_j^t.\text{time}| \leq \delta$.

Definition 4 (δ -Accurate Secure Time Synchronization). We say that an adversary \mathcal{A} breaks the δ -accuracy of a time synchronization protocol if when \mathcal{A} terminates, there exists a session π_i^s with partner id $\pi_i^s.\text{pid} = j$ such that:

- $\pi_i^s.\alpha = \text{accept}$;
- $\pi_i^s.\rho = \text{client}$
- \mathcal{A} made no $\text{Corrupt}(j)$ query before $\pi_i^s.\alpha \leftarrow \text{accept}$;
- \mathcal{A} made no $\text{Reveal}(i, s)$ or $\text{Reveal}(j, t)$ query before $\pi_i^s.\alpha \leftarrow \text{accept}$ and π_j^t matches π_i^s ;
- while $\pi_i^s.\alpha = \text{in-progress}$ and \mathcal{A} queried $\text{Send}(i, s, m, \vec{\Delta})$ or $\text{Send}(j, t, m', \vec{\Delta}')$ (where π_i^s matches π_j^t), then \mathcal{A} also queried $\text{Tick}(j, t, \sum_{i=1}^{\ell} \Delta_i)$ or $\text{Tick}(i, s, \sum_{i=1}^{\ell} \Delta'_i)$, respectively;
- while $\pi_i^s.\alpha = \text{in-progress}$ and \mathcal{A} queried $\text{Tick}(i, s, \Delta)$, or $\text{Tick}(j, t, \Delta')$ (where π_i^s matches π_j^t), then \mathcal{A} also queried $\text{Tick}(j, t, \Delta)$ or $\text{Tick}(i, s, \Delta')$, respectively; and
- $|\pi_i^s.\text{time} - \pi_j^t.\text{time}| > \delta$.

The probability an adversary \mathcal{A} has in breaking δ -accuracy of a time synchronization protocol \mathcal{T} is denoted $\text{Adv}_{\mathcal{T}, \delta}^{\text{time}}(\mathcal{A})$.

5.3 Multi-Phase Protocols

Our construction in Section 3 has a single run of the negotiation and key exchange phases, followed by multiple time synchronization executions reusing the negotiated cryptographic algorithms and shared secret key. To model the security of such *multi-phase* time synchronization protocols, we further extend our framework so that a single session can include multiple time synchronization phases. The differences from the model described in the previous section are detailed below.

Per-Session Variables. The following variables are added or changed:

- $n \in \mathbb{N}$: the number of time synchronization phases allowed in this session.

- time_p , for $p \in \{1, \dots, n\}$: the time recorded at the conclusion of phase p .

- $\alpha \in \{\text{accept}_p, \text{reject}_p, \text{in-progress}_p\}$, for $p \in \{1, \dots, n\}$: the status of the session. Note that, when phase p concludes and $\alpha \leftarrow \text{accept}_p$ is set, the party also sets $\text{time}_p \leftarrow \text{time}$.

Adversary Interaction. The adversary can direct the client to run an additional time synchronization phase with a new Resync query, and the client will respond according the protocol specification. The Create query in this setting is also changed:

- $\text{Create}(i, r, t, n)$: Proceeds as for $\text{Create}(i, r, t)$, and also sets $\pi_i^s.n \leftarrow n$.
- $\text{Resync}(i, s, \vec{\Delta})$ - The adversary indicates to a session π_i^s to begin the next time synchronization phase. Party P_i responds according to protocol specification, updating per-session variables and outputting some message m^* if necessary. During message processing, immediately before the ℓ th call to the $\text{Now}()$ procedure, the session's $\pi_i^s.\text{time}$ variable is incremented by Δ_ℓ .

The goal of the adversary is also slightly different to account for the possibility of breaking time synchronization of any given time synchronization phase: the adversary's goal is to cause a client session to have *any* phase where its time is desynchronized from the server's. In particular, for there to be some client instance π_i^s and some phase p such that $|\pi_i^s.\text{time}_p - \pi_j^t.\text{time}_p| > \delta$ where π_j^t is the partner of session π_i^s . Again the adversary in general controls clock ticks and can tick parties at different rates, however must tick clocks at the same rate when phases have switched back to being in-progress.

Definition 5 (δ -Accurate Secure Multi-Phase Time Synchronization). We say that an adversary \mathcal{A} breaks the δ -accuracy of a multi-phase time synchronization protocol if when \mathcal{A} terminates, there exists a phase p session π_i^s with partner id $\pi_i^s.\text{pid} = j$ such that:

- $\pi_i^s.\rho = \text{client}$
- $\pi_i^s.\alpha = \text{accept}_q$ for some $q \geq p$;
- \mathcal{A} did not make a $\text{Corrupt}(j)$ query before $\pi_i^s.\alpha \leftarrow \text{accept}_p$ was set;
- \mathcal{A} did not make a $\text{Reveal}(i, s)$ or $\text{Reveal}(j, t)$ query before $\pi_i^s.\alpha \leftarrow \text{accept}_p$ was set and π_j^t matches π_i^s ;
- while $\pi_i^s.\alpha = \text{in-progress}$ and \mathcal{A} queried $\text{Send}(i, s, m, \vec{\Delta})$ or $\text{Send}(j, t, m', \vec{\Delta}')$, then \mathcal{A} also queried $\text{Tick}(j, t, \sum_{i=1}^{\ell} \Delta_i)$ or $\text{Tick}(i, s, \sum_{i=1}^{\ell} \Delta'_i)$, respectively;
- while $\pi_i^s.\alpha = \text{in-progress}$ and \mathcal{A} queried $\text{Tick}(i, s, \Delta)$, or $\text{Tick}(j, t, \Delta')$, then \mathcal{A} also queried $\text{Tick}(j, t, \Delta)$ or $\text{Tick}(i, s, \Delta')$, respectively; and
- $|\pi_i^s.\text{time}_p - \pi_j^t.\text{time}_p| > \delta$.

The probability an adversary \mathcal{A} has in breaking δ -accuracy of multi-phase time synchronization protocol \mathcal{T} is denoted $\text{Adv}_{\mathcal{T}, \delta}^{\text{multi-time}}(\mathcal{A})$.

6 Security of ANTP

Here we present ANTP correctness and security theorems.

6.1 Correctness

Theorem 1 (Correctness of ANTP). *Fix $E \in \mathbb{N}$. ANTP_E is an E -correct time synchronization protocol as defined in Definition 3.*

Proof. When analyzing ANTP in terms of correctness, we can restrict analysis to data that enters the clock-update procedure as input, as the rest of the protocol is designed to ensure authentication and does not influence the session’s *time* counter. This allows us to narrow our focus to SNTP, which is the time synchronization core of ANTP.

We first focus on a single time synchronization phase. At the beginning of the time synchronization phase of ANTP, the client will send an NTP request (`req`) which contains t_1 , the time the client sent `req`. Note that the adversary is restricted to delivering the messages faithfully as a passive adversary, and also must increment the time of each protocol participant symmetrically. The adversary otherwise has complete control over the passage of time. Thus $\theta_1, \theta_2, \theta_3$ are non-negative but otherwise arbitrary values selected by the adversary (where θ_1 is the propagation time from client to server, θ_2 is server processing time and θ_3 is propagation time from server to client). Thus the client computes the round-trip time of the protocol as: $RTT = (t_4 - t_1) - (t_3 - t_2) = \theta_1 + \theta_3$ and approximates the server-to-client propagation time as $\tilde{\theta}_3 = \frac{1}{2}(\theta_1 + \theta_3)$.

When the client-to-server and server-to-client propagation times are equal ($\theta_1 = \theta_3$) then $\tilde{\theta}_3 = \theta_3$, and the values t_3 and t_2 allow the client to exactly account for θ_2 . The *time* counter is updated by $\text{time} + \text{offset} = t_3 + \tilde{\theta}_3 - t_4$, and upon completion the client’s clock is exactly synchronized with the server’s clock.

When $\theta_1 \neq \theta_3$, we have that $\theta_3 - \tilde{\theta}_3 = \frac{1}{2}(\theta_3 - \theta_1)$, so the statistics t_1, \dots, t_4 do not allow the client to exactly account for client-to-server propagation time θ_3 ; the client’s updated time may be off by up to $\frac{1}{2}(\theta_3 - \theta_1)$. Fortunately, we can bound this value by E : we know that $\frac{1}{2}(\theta_3 - \theta_1) \leq \frac{1}{2}(\theta_1 + \theta_3)$, and furthermore we know that ANTP_E will only accept time synchronization when $\frac{1}{2}(\theta_1 + \theta_3) \leq E$, so in sessions that accept (assuming a passive adversary) we have that the client’s clock is at most $\frac{1}{2}(\theta_3 - \theta_1) \leq E$ different from the server’s clock.

Now moving to the multi-phase setting, we note that this analysis of the correctness of ANTP applies to each

separate time synchronization phase: since the client’s (t_1, t_4) values are only used to calculate the total round-trip time of the time synchronization phase, thus if the rate-of-time for both client and server during the phase is the same, each phase is also E -accurate in the presence of a passive adversary, even if the adversary dramatically changes the rate-of-time for partners between time synchronization phases. \square

6.2 Security

Security of a single 3-phase execution of ANTP in the sense of Definition 4 is given by Theorem 2 below. Security of multiple phases in the sense of Definition 5 follows with a straightforward adaptation.

Intuitively, the bound on the possible error that an \mathcal{A} can introduce without altering packets is as in Section 3. It follows then that if all messages are securely authenticated, and the only inputs to the clock-update procedure are either: authenticated via messages, or the round trip delay RTT ; then any attacker can only introduce at most E error into the clock-update procedure (where $E \geq RTT$).

Theorem 2 (Security of ANTP). *Fix $E \in \mathbb{N}$ and let λ be the length of the nonces in m_1 and m_5 (in our instantiation, $\lambda = 256$). Assuming the key encapsulation mechanism KEM (with keyspace $\mathcal{KEM.K}$) is IND-CCA-secure, the message authentication code MAC is EUF-CMA-secure, the hash function Hash is collision-resistant, and the key derivation function KDF and authenticated encryption scheme AE are secure, then ANTP_E is a E -accurate secure time synchronization protocol as in Definition 4. In particular, there exist algorithms $\mathcal{B}_3, \dots, \mathcal{B}_8$, described in the proof of the theorem, such that, for all adversaries \mathcal{A} , we have*

$$\begin{aligned} \text{Adv}_{\text{ANTP}_E, E}^{\text{time}}(\mathcal{A}) &\leq \frac{n_p^2 n_s^2}{2^{\lambda-2}} + n_p^2 n_s^2 \left(\text{Adv}_{\text{Hash}}^{\text{coll}}(\mathcal{B}_3^{\mathcal{A}}) \right. \\ &\quad + \text{Adv}_{\text{AE}}^{\text{auth-enc}}(\mathcal{B}_4^{\mathcal{A}}) + \text{Adv}_{\text{KEM}}^{\text{ind-cca}}(\mathcal{B}_5^{\mathcal{A}}) \\ &\quad + \text{Adv}_{\text{KDF}}^{\text{kdf}}(\mathcal{B}_6^{\mathcal{A}}) + \text{Adv}_{\text{AE}}^{\text{auth-enc}}(\mathcal{B}_7^{\mathcal{A}}) \\ &\quad \left. + \text{Adv}_{\text{MAC}}^{\text{euf-cma}}(\mathcal{B}_8^{\mathcal{A}}) \right) \end{aligned}$$

where n_p and n_s are the number of parties and sessions created by \mathcal{A} during the experiment.

The standard definitions for security of the underlying primitives and the corresponding advantages $\text{Adv}_{\text{AE}}^{\text{auth-enc}}(\mathcal{A})$, $\text{Adv}_{\text{KEM}}^{\text{ind-cca}}(\mathcal{A})$, $\text{Adv}_{\text{Hash}}^{\text{coll}}(\mathcal{A})$, $\text{Adv}_{\text{MAC}}^{\text{euf-cma}}(\mathcal{A})$, and $\text{Adv}_{\text{KDF}}^{\text{kdf}}(\mathcal{A})$ are given in the full version [6].

Proof. From Theorem 1, ANTP_E is an E -correct time synchronization protocol in the sense of Definition 3. Thus all passive adversaries have probability 0 of breaking E -accuracy of ANTP_E . If we show that the advantage

$\text{Adv}_{\text{ANTP}_E}^{\text{auth}}(\mathcal{A})$ of any adversary \mathcal{A} of breaking authentication security (i.e., to accept without session matching) of ANTP_E is small, then it follows that the advantage of any active adversary \mathcal{A} in breaking E -accuracy of ANTP_E is similarly small. In other words, it immediately is the case that $\text{Adv}_{\text{ANTP}_E, E}^{\text{time}}(\mathcal{A}) \leq \text{Adv}_{\text{ANTP}_E}^{\text{auth}}(\mathcal{A})$.

We now focus on bounding $\text{Adv}_{\text{ANTP}_E}^{\text{auth}}(\mathcal{A})$. In order to show that an active adversary has negligible probability in breaking ANTP_E authentication, we use a proof structured as a sequence of games. We let $\Pr(break_i)$ denote the probability that the adversary causes some session to accept maliciously in game i . We iteratively change the security experiment, and demonstrate that the changes are either failure events with negligible probability of occurring or that if the changes are distinguishable we can construct an adversary capable of breaking an underlying cryptographic assumption. Since the client will only accept synchronization if all three phases are properly authenticated, the advantage of an active adversary is negligible given our cryptographic assumptions.

Game 0. This is the original time synchronization game described in § 4: $\text{Adv}_{\text{ANTP}_E}^{\text{auth}}(\mathcal{A}) = \Pr(break_0)$.

Game 1. In this game, we abort the simulation if any nonce is used in two different sessions by client instances. There are at most $2n_s n_p$ nonces used by client instances, each λ bits. The probability that a collision occurs among these values is $(2n_s n_p)^2 / 2^\lambda$, so:

$$\Pr(break_0) \leq \Pr(break_1) + \frac{n_s^2 n_p^2}{2^{\lambda-2}}$$

Game 2. Here, we guess the first client session to accept maliciously, aborting if incorrect. We select randomly from two indices $(i, s) \leftarrow \$_{\{1, \dots, n_p\} \times \{1, \dots, n_s\}}$ and abort if π_i^s is not the first session to accept maliciously. Now the challenger responds to $\text{Reveal}(i, s)$ queries (if $\pi_i^s.\alpha = \text{accept}$) by aborting the game, as it follows that the guessed session cannot accept maliciously. There are at most $n_p n_s$ client sessions, and we guess the first session to accept maliciously with probability at least $1/n_p n_s$, so $\Pr(break_1) \leq n_p n_s \Pr(break_2)$.

Game 3. Here we guess the partner session to π_i^s , by selecting from two indices $(j, t) \leftarrow \$_{\{1, \dots, n_p\} \times \{1, \dots, n_s\}}$ and abort if π_j^t is not the partner session to π_i^s . Now, the challenger answers $\text{Corrupt}(j)$ and $\text{Reveal}(j, t)$ queries before $\pi_i^s.\alpha \leftarrow \text{accept}$ by aborting the game, as it follows that the guessed session cannot accept maliciously. There are at most $n_p n_s$ server sessions, and we guess the partner of the first session to accept maliciously with probability at least $1/n_p n_s$, so $\Pr(break_2) \leq n_p n_s \Pr(break_3)$.

Game 4. Here we abort if a hash collision occurs, by computing all hash values honestly and aborting if there exists two evaluations $(in, \text{Hash}(in)), (\hat{in}, \text{Hash}(\hat{in}))$ such that $in \neq \hat{in}$ but $\text{Hash}(in) = \text{Hash}(\hat{in})$. The simulator interacts with a Hash-collision challenger, outputting

the collision if found. Thus: $\Pr(break_3) \leq \Pr(break_4) + \text{Adv}_{\text{Hash}}^{\text{coll}}(\mathcal{B}_3^A)$.

Game 5. In this game, we abort if in server session π_j^t the ciphertext received in m_3 is not equal to the ciphertext sent in m_1 but the output of AuthDec_s is not \perp .

We construct an algorithm \mathcal{B}_4^A that simulates Game 4 identically, except to interact with an AE challenger in the following way: When P_j needs to run AuthEnc or AuthDec , \mathcal{B}_4^A uses its oracles to compute the required value. In server session π_j^t , when \mathcal{B}_4^A receives a ciphertext in m_3 that was not equal to the ciphertext sent in m_1 but the output of the AuthDec oracle is not \perp , this corresponds to a ciphertext forgery, and thus: $\Pr(break_4) \leq \Pr(break_5) + \text{Adv}_{\text{AE}}^{\text{auth-enc}}(\mathcal{B}_4^A)$.

Game 6. In this game, sessions π_i^s and π_j^t compute the session key k by applying KDF to a random secret $pms' \leftarrow \$_{\text{KEM.K}}$, rather than the pms that was encapsulated using KEM.Encap and transmitted in ciphertext e . Any algorithm used to distinguish Game 5 from Game 6 can be used to construct an algorithm capable of distinguishing KEM encrypted values via plaintext, thus breaking IND-CCA security of the key encapsulation mechanism.

We construct a simulator \mathcal{B}_5^A that interacts with a KEM challenger. \mathcal{B}_5^A activates party P_j with the public key pk received from the challenger. \mathcal{B}_5^A responds identically to queries from \mathcal{A} as in Game 5, except as follows:

- \mathcal{B}_5^A computes the KEM ciphertext e for the session π_i^s by obtaining a challenge (e, pms) from its KEM challenger.
- \mathcal{B}_5^A computes $\pi_i^s.k \leftarrow \text{KDF}(pms, \dots)$
- In any P_j session where m_3 contains the challenge ciphertext above, \mathcal{B}_5^A computes the session key as $k \leftarrow \text{KDF}(pms, \dots)$.
- In any other P_j session where m_3 does not contain the challenge ciphertext above, \mathcal{B}_5^A queries the ciphertext to its Decap oracle to obtain the premaster secret and uses that as its input to KDF to compute the session key k .
- \mathcal{B}_5^A never needs to answer a $\text{Corrupt}(j)$ query because of Game 3.

When the random bit b sampled by the KEM ind-cca challenger is 0, pms is truly the decapsulation of the ciphertext e , in which case \mathcal{B}_5^A perfectly simulates of Game 5. When $b = 1$, pms is random and independent of e , in which case \mathcal{B}_5^A perfectly simulates Game 6. Observe that \mathcal{B}_5^A never asks the challenge ciphertext e to its decapsulation oracle.

An adversary capable of distinguishing Game 5 from Game 6 can therefore be used to break IND-CCA security of KEM, so $\Pr(break_5) \leq \Pr(break_6) + \text{Adv}_{\text{KEM}}^{\text{ind-cca}}(\mathcal{B}_5^A)$.

Game 7. In this game, we replace the secret key k in sessions π_i^s and π_j^t with a uniformly random value k' from

$\{0,1\}^{l_{\text{KDF}}}$ where l_{KDF} is the length of the KDF output, instead of being computed honestly via $k \leftarrow \text{KDF}(pms, \dots)$.

In Game 6, we replaced the premaster secret value pms with a uniformly random value from $\text{KEM}.\mathcal{K}$. Thus, any algorithm that can distinguish Game 6 from Game 7 can distinguish the output of KDF from random. We explicitly construct such a simulator \mathcal{B}_6^A that interacts with a KDF challenger, and proceeds identically to Game 6, except: when computing k for π_i^s , \mathcal{B}_6^A queries the KDF challenger with pms ; and when computing k for π_j^t , \mathcal{B}_6^A sets $\pi_j^t.k = \pi_i^s.k$. When the random bit b sampled by the KDF challenger is 0, $k = \text{KDF}(pms, \dots)$, and \mathcal{B}_6^A provides a perfect simulation of Game 6. When $b = 1$, $k \leftarrow \{0,1\}^{l_{\text{KDF}}}$ and \mathcal{B}_6^A provides a perfect simulation of Game 7.

An adversary capable of distinguishing Game 6 from Game 7 can therefore distinguish the output of KDF from random, so $\Pr(\text{break}_6) \leq \Pr(\text{break}_7) + \text{Adv}_{\text{KDF}}^{\text{kdf}}(\mathcal{B}_6^A)$.

Game 8. In this game, in session π_j^t we replace the contents of the ciphertext C_2 sent in m_3 with a random string of the same length, and abort if the ciphertext received in m_5 is not equal to the ciphertext sent in m_3 but the output of the AuthDec_s algorithm is not \perp .

We construct an algorithm \mathcal{B}_7^A that interacts with an AE challenger in the following way: \mathcal{B}_7^A acts exactly as in game 7 except for sessions run by party P_j . In session π_j^t , for the computation of C_2 , \mathcal{B}_7^A picks a uniformly random binary string z' of length equal to $z = k\|\text{KDF}\|\text{Hash}\|\text{KEM}\|\text{MAC}$ and submits (z, z') to its AuthEnc oracle. For all other computations that P_j involving AuthEnc_s or AuthDec_s , \mathcal{B}_7^A submits the query its respective AuthEnc or AuthDec oracle.

When the random bit b sampled by the AE challenger is 0, C_2 contains the encryption of z , so \mathcal{B}_7^A provides a perfect simulation of Game 7. When $b = 1$, C_2 contains the encryption of z' , so \mathcal{B}_7^A provides a perfect simulation of Game 8. An adversary capable of distinguishing Game 7 from Game 8 can therefore break the confidentiality of AE and guess b . Additionally, if \mathcal{B}_7^A receives a ciphertext in m_5 that was not equal to the ciphertext sent in m_3 but the output of the AuthDec oracle is not \perp , this corresponds to a ciphertext forgery, and thus \mathcal{B}_7^A has broken the integrity of AE. Thus, $\Pr(\text{break}_7) \leq \Pr(\text{break}_8) + \text{Adv}_{\text{AE}}^{\text{auth-enc}}(\mathcal{B}_7^A)$.

The effect of Game 8 is that, in the target session and its partner, the key used in the MAC computations is independent of the values transmitted.

Game 9. In this game, we abort when the session π_i^s accepts maliciously. We do this by constructing a simulator \mathcal{B}_8^A that interacts with the MAC challenger, but computes τ_1 and τ_2 for π_j^t by querying $h\|m_3\|C_2$ and $m_5\|t_1\|t_2\|t_3$ to the MAC challenger. \mathcal{B}_8^A verifies MAC tags for $\pi_{i^*}^{s^*}$ by again querying $h\|m_3\|C_2$ and $m_5\|t_1\|t_2\|t_3$ to the MAC

challenger and ensuring the MAC challenger's output is equal to the tag to be verified. Note that now that the key k is substituted for the key maintained by the MAC challenger: k was already uniformly random and independent of the protocol run, and by Game 2 and Game 3, the simulator already responds to Reveal queries to π_i^s and π_j^t by aborting the security experiment. Thus these changes to the game are indistinguishable. When $\pi_i^s.\alpha \leftarrow \text{accept}$, \mathcal{B}_8^A checks P_j to see if there is a matching session. Since by Game 1 all protocol flows are unique (by unique nonces), if P_j has no matching session the adversary must have produced a valid MAC tag $\hat{\tau}_1$ or $\hat{\tau}_2$ such that $\text{MAC}(k, h\|m_3\|C_2) = \hat{\tau}_1$ or $\text{MAC}(k, m_5\|t_1\|t_2\|t_3) = \hat{\tau}_2$ and (by Game 8) the key k is uniformly random. \mathcal{B}_8^A submits the appropriate pair $(h\|m_3\|C_2, \hat{\tau}_1), (m_5\|t_1\|t_2\|t_3, \hat{\tau}_2)$ to the MAC challenger and aborts. Thus, $\Pr(\text{break}_8) \leq \Pr(\text{break}_9) + \text{Adv}_{\text{MAC}}^{\text{euf-cma}}(\mathcal{B}_8^A)$.

Analysis of Game 9. We now show that an active adversary has a probability negligibly close to 0 of forcing a client session $\pi_{i^*}^{s^*}$ to accept maliciously in Game 9.

We briefly summarize the changes in games.

1. Nonces no longer collide for honest parties. Each transcript $\pi_i^s.T$ will have unique honest matching session π_j^t .
2. Guess target session; \mathcal{C} aborts if $\text{Reveal}(i, s)$ query asked.
3. Guess partner session; \mathcal{C} aborts if $\text{Corrupt}(j)$ or $\text{Reveal}(j, t)$ query asked.
4. Hash values no longer collide for honest parties. Note h is now unique for each negotiation phase, via Game 1.
5. C_1 is not forged in session π_j^t .
6. Replace premaster secret pms in target session π_i^s with a random value, rather than key encapsulated in KEM ciphertext e . Note k is unique and computed via shared secret data.
7. Replace k with uniformly random data of same length when computing τ . Thus verification of τ in Time Synchronization and Key Exchange phases is done via a uniformly random key, independent of the protocol run.
8. C_2 is not forged in session π_j^t and contains random data.
9. MAC tags in session π_i^s are not forged.

After all of the game changes, π_i^s is a target session where: no $\text{Reveal}(i, s)$ or $\text{Reveal}(j, t)$ queries were issued before $\pi_i^s.\alpha \leftarrow \text{accept}$; no $\text{Corrupt}(j)$ query was ever issued before $\pi_i^s.\alpha \leftarrow \text{accept}$, where $\pi_i^s.pid = j$; and π_i^s only accepts if $\tau_1 = \text{MAC}(k, h\|m_3\|C_2)$ and $\tau_2 = \text{MAC}(k, m_5\|t_1\|t_2\|t_3)$. By unforgeability these tags cannot be generated by \mathcal{A} and by Game 1 the protocol flow of each session is unique. τ_1 and τ_2 verification will

thus only occur if $\pi_i^s.T = \pi_j^t.T$, as τ_1 is over all messages in the negotiation and key exchange phase, and τ_2 is over all messages in the time synchronization phase and thus π_i^s will only accept if $\pi_j^t.T$ prefix-matches $\pi_i^s.T$. Thus, no client session accepts maliciously in Game 9: $\Pr(\text{break}_9) = 0$.

Summing all of the probabilities yields the desired bound, showing that ANTP_E is a E -accurate secure time synchronization protocol. \square

6.3 Multi-Phase Security

Multi-phase security of ANTP_E can be established in a similar way to single-phase security as in the previous section, with minor changes to the games in the proof to enable guessing of the first *phase* session to accept maliciously.

Theorem 3 (Multi-Phase Security of ANTP). *Fix $E, n \in \mathbb{N}$. Under the same assumptions as in Theorem 2, ANTP_E is a E -accurate secure multi-phase time synchronization protocol as defined in Definition 5. In particular, there exist algorithms $\mathcal{B}_3, \dots, \mathcal{B}_8$ described in the proof of Theorem 2, such that, for all adversaries \mathcal{A} , we have that*

$$\begin{aligned} \text{Adv}_{\text{ANTP}_E, E}^{\text{multi-time}}(\mathcal{A}) &\leq \frac{n_p^2 n_s^2}{2^{\lambda-2}} + n_p^2 n_s^2 n \left(\text{Adv}_{\text{Hash}}^{\text{coll}}(\mathcal{B}_3^{\mathcal{A}}) \right. \\ &\quad + \text{Adv}_{\text{AE}}^{\text{auth-enc}}(\mathcal{B}_4^{\mathcal{A}}) + \text{Adv}_{\text{KEM}}^{\text{ind-cca}}(\mathcal{B}_5^{\mathcal{A}}) \\ &\quad + \text{Adv}_{\text{KDF}}^{\text{kdf}}(\mathcal{B}_6^{\mathcal{A}}) + \text{Adv}_{\text{AE}}^{\text{auth-enc}}(\mathcal{B}_7^{\mathcal{A}}) \\ &\quad \left. + \text{Adv}_{\text{MAC}}^{\text{euf-cma}}(\mathcal{B}_8^{\mathcal{A}}) \right) \end{aligned}$$

where n_p, n_s, n are the maximum number of parties, sessions and phases created by \mathcal{A} during the experiment.

Proof. The proof for Theorem 3 is identical to the proof to Theorem 2 except as follows.

A new game is inserted between Game 3 and Game 4 that guesses the first time synchronization phase $p \in \{1, \dots, n\}$ that the target session π_i^s will accept maliciously: by Theorem 2, we know that a session π_i^s will not accept maliciously for time synchronization phase $p = 1$, so by this step we know that π_i^s matches π_j^t up to and including phase $p - 1$.

We also edit the final game (MAC challenger) so that \mathcal{B} aborts if π_i^s accepts maliciously in phase p . We do this by editing the final game in the following way: When processing m_5 for π_j^t in the guessed phase p (we indicate this with m_{5p}) \mathcal{B} will also compute τ_{2p} by querying the MAC challenger with $m_{5p} \| t_{1p} \| t_{2p} \| t_{3p}$, and verifies the τ_{2p} for π_i^s by querying the MAC challenger with $m_{5p} \| t_{1p} \| t_{2p} \| t_{3p}$ and accepting only if the output from the MAC challenger matches the τ_p in m_{6p} . Following the same structure as the proof to Theorem 2, we have that k is a uniformly random key generated independently from the protocol

run and this change is indistinguishable. Verification of τ will only occur if $\pi_i^s.T = \pi_j^t.T$ up to phase p , as τ_1 is over all messages in the negotiation and key exchange phase, and τ_p is over all messages in phase p . \square

7 Discussion

In this work we introduced a new authenticated time synchronization protocol called ANTP, designed to securely synchronize the time of a client and server, using public key infrastructure. Our design allows a server to perform a single public key operation per client during the infrequently performed key exchange phase, and then use only faster symmetric key operations for each subsequent time synchronization request from that client. This efficient design means that the throughput of ANTP time synchronization phases is reduced by a factor of only $1.6\times$ compared to NTP. Our protocol has been designed such that servers sharing the same long-term secret can handle different phases of the same client for load-balancing purposes. Furthermore, the server need not even store per-client state, instead securely offloading storage of that state to the client.

ANTP is accompanied by a provable security analysis showing that it provides secure time synchronization within user-specified accuracy bounds. The analysis is carried out in a new provable security framework. A novel aspect of our new framework, when compared with the long line of work on authentication definitions, is that our framework models an adversary with the ability to control the flow of time, meaning the adversary can initialize different parties' clocks to different times, and even control the rate at which their clocks are advanced. The security framework can be used for the analysis of other time synchronization protocols such as the Network Time Security (NTS) protocol and the Precision Time Protocol (PTP).

Several interesting open problems in the area of secure time synchronization remain. Since ANTP uses public keys, it inherits problems associated with public key infrastructure, such as the dangers of certificate authority compromise. All existing time synchronization protocols that rely on public keys, including ours, need to initially validate the certificate of the time server, specifically that it is within its validity period. While nonces can be combined with OCSP responses to check freshness, this cannot completely solve the “first-boot” problem. A detailed study of denial of service attacks against secure time synchronization protocols including ANTP would also be worthwhile, giving detailed consideration to both the cost of cryptographic operations in practice and the bandwidth amplification afforded by directing protocol responses to a victim.

Abstract: Commodity CPU architectures, such as ARM and Intel CPUs, have started to offer trusted computing features in their CPUs aimed at displacing dedicated trusted hardware. Unfortunately, these CPU architectures raise serious challenges to building trusted systems because they omit providing secure resources outside the CPU perimeter.

This paper shows how to overcome these challenges to build software systems with security guarantees similar to those of dedicated trusted hardware. We present the design and implementation of a firmware-based TPM 2.0 (fTPM) leveraging ARM TrustZone. Our fTPM is the reference implementation of a TPM 2.0 used in millions of mobile devices. We also describe a set of mechanisms needed for the fTPM that can be useful for building more sophisticated trusted applications beyond just a TPM.

1 Introduction

In recent years, commodity CPU architectures have started to offer built-in features for trusted computing. TrustZone on ARM [1] and Software Guard Extensions (SGX) [25] on Intel CPUs offer runtime environments strongly isolated from the rest of the platform’s software, including the OS, applications, and firmware. With these features, CPU manufacturers can offer platforms with a set of security guarantees similar to those provided via dedicated security hardware, such as secure coprocessors, smartcards, or hardware security tokens.

Unfortunately, the nature of these features raises serious challenges for building secure software with guarantees that match those of dedicated trusted hardware. While runtime isolation is important, these features omit many other secure resources present in dedicated trusted hardware, such as storage, secure counters, clocks, and entropy. These omissions raise an important question: *Can we overcome the limitations of commodity CPU se-*

curity features to build software systems with security guarantees similar to those of trusted hardware?

In this work, we answer this question by implementing a software-only Trusted Platform Module (TPM) using ARM TrustZone. We demonstrate that the low-level primitives offered by ARM TrustZone and Intel SGX can be used to build systems with high-level trusted computing semantics. Second, we show that these CPU security features can displace the need for dedicated trusted hardware. Third, we demonstrate that these CPU features can offer backward compatibility, a property often very useful in practice. Google and Microsoft already offer operating systems that leverage commodity TPMs. Building a backwards compatible TPM in software means that no changes are needed to Google and Microsoft operating systems. Finally, we describe a set of mechanisms needed for our software-only TPM that can also be useful for building more sophisticated trusted applications beyond just a TPM.

This paper presents firmware-TPM (fTPM), an end-to-end implementation of a TPM using ARM TrustZone. fTPM provides security guarantees similar, although not identical, to a discrete TPM chip. Our implementation is the reference implementation used in all ARM-based mobile devices running Windows including Microsoft Surface and Windows Phone, comprising millions of mobile devices. fTPM was the first hardware or software implementation to support the newly released TPM 2.0 specification. The fTPM has much better performance than TPM chips and is fully backwards compatible: *no modifications are required to the OS services or applications between a mobile device equipped with a TPM chip and one equipped with an fTPM; all modifications are limited only to firmware and drivers.*

To address the above question, this paper starts with an analysis of ARM TrustZone’s security guarantees. We thoroughly examine the shortcomings of the ARM TrustZone technology needed for building secure services, whether for fTPM or others. We also examine Intel’s

*Currently with ContainerX.

SGX and show that many of TrustZone’s shortcomings remain present.

We present three approaches to overcome the limitations of ARM TrustZone: (1) provisioning additional trusted hardware, (2) making design compromises that do not affect TPM’s security and (3) slightly changing the semantics of a small number of TPM 2.0 commands to adapt them to TrustZone’s limitations. Based on these approaches, our implementation uses a variety of mechanisms, such as *cooperative checkpointing*, *fate sharing*, and *atomic updates*, that help the fTPM overcome the limitations of commodity CPU security features. This paper demonstrates that these limitations can be overcome or compensated for when building a software-only implementation of a dedicated trusted hardware component, such as a TPM chip. The fTPM has been deployed in millions of mobile devices running legacy operating systems and applications originally designed for discrete TPM chips.

Finally, this paper omits some low-level details of our implementation and a more extensive set of performance results. These can be found in the fTPM technical report [44].

2 Trusted Platform Module: An Overview

Although TPMs are more than a decade old, we are seeing a resurgence of interest in TPMs from both industry and the research community. TPMs have had a mixed history, in part due to the initial perception that the primary use for TPMs would be to enable digital rights management (DRM). TPMs were seen as a mechanism to force users to give up control of their own machines to corporations. Another factor was the spotty security record of some the early TPM specifications: TPM version 1.1 [52] was shown to be vulnerable to an unsophisticated attack, known as the *PIN reset* attack [49]. Over time, however, TPMs have been able to overcome their mixed reputation, and are now a mainstream component available in many commodity desktops and laptops.

TPMs provide a small set of primitives that can offer a high degree of security assurance. First, TPMs offer strong machine identities. A TPM can be equipped with a unique RSA key pair whose private key never leaves the physical perimeter of a TPM chip. Such a key can effectively act as a globally unique, unforgeable machine identity. Additionally, TPMs can prevent undesired (i.e., malicious) software rollbacks, can offer isolated and secure storage of credentials on behalf of applications or users, and can attest the identity of the software running on the machine. Both industry and the research community have used these primitives as building blocks in a variety of secure systems. This section presents several such systems.

2.1 TPM-based Secure Systems in Industry

Microsoft. Modern versions of the Windows OS use TPMs to offer features, such as BitLocker disk encryption, virtual smart cards, early launch anti-malware (ELAM), and key and device health attestations.

BitLocker [37] is a full-disk encryption system that uses the TPM to protect the encryption keys. Because the decryption keys are locked by the TPM, an attacker cannot read the data just by removing a hard disk and installing it in another computer. During the startup process, the TPM releases the decryption keys only after comparing a hash of OS configuration values with a snapshot taken earlier. This verifies the integrity of the Windows OS startup process. BitLocker has been offered since 2007 when it was made available in Windows Vista.

Virtual smart cards [38] use the TPM to emulate the functionality of physical smart cards, rather than requiring the use of a separate physical smart card and reader. Virtual smart cards are created in the TPM and offer similar properties to physical smart cards – their keys are not exportable from the TPM, and the cryptography is isolated from the rest of the system.

ELAM [35] enables Windows to launch anti-malware before any third-party drivers or applications. The anti-malware software can be first- or third-party (e.g., Microsoft Windows Defender or Symantec Endpoint Protection). Finally, Windows also uses the TPM to construct attestations of cryptographic keys and device boot parameters [36]. Enterprise IT managers use these attestations to assess the health of devices they manage. A common use is to gate access to high-value network resources based on its attestations.

Google. Modern versions of Chrome OS [22] use TPMs for a variety of tasks, including software and firmware rollback prevention, protecting user data encryption keys, and attesting the mode of a device.

Automatic updates enable a remote party (e.g., Google) to update the firmware or the OS of devices that run Chrome OS. Such devices are vulnerable to “remote rollback attacks”, where a remote attacker replaces newer software, through a difficult-to-exploit vulnerability, with older software, with a well-known and easy-to-exploit vulnerability. Chrome devices use the TPM to prevent software updates to versions older than the current one.

eCryptfs [14] is a disk encryption system used by Chrome OS to protect user data. Chrome OS uses the TPM to rate limit password guessing on the file system encryption key. Any attempt to guess the AES keys requires the use of a TPM, a single-threaded device that

is relatively slow. This prevents parallelized attacks and limits the effectiveness of password brute-force attacks.

Chrome devices can be booted into one of four different modes, corresponding to the state of the developer switch and the recovery switch at power on. These switches may be physically present on the device, or they may be virtual, in which case they are triggered by certain key presses at power on. Chrome OS uses the TPM to attest the device’s current mode to any software running on the machine, a feature used for reporting policy compliance.

More details on the additional ways in which Chrome devices make use of TPMs are described in [22].

2.2 TPM-Based Secure Systems in Research

The research community has proposed many uses for TPMs in recent years.

- **Secure VMs for the cloud:** Software stacks in typical multi-tenant clouds are large and complex, and thus prone to compromise or abuse from adversaries including the cloud operators, which may lead to leakage of security-sensitive data. CloudVisor [58] and Credo [43] are virtualization-approaches that protect the privacy and integrity of customer’s VMs on commodity cloud infrastructure, even when the virtual machine monitor (VMM) or the management VM becomes compromised. These systems require TPMs to attest to cloud customers the secure configuration of the hosts running their VMs.
- **Secure applications, OSs and hypervisors:** Flicker [33], TrustVisor [32], Memoir [41] leverage the TPM to provide various (but limited) forms of runtimes with strong code and data integrity and confidentiality. Code running in these runtimes is protected from the rest of the OS. These systems have small TCBs because they exclude the bulk of the OS.
- **Novel secure functionality:** Pasture [30] is a secure messaging and logging library that provides secure offline data access. Pasture leverages the TPM to provide two safety properties: access-undeniability (a user cannot deny any offline data access obtained by his device without failing an audit) and verifiable-revocation (a user who generates a verifiable proof of revocation of unaccessed data can never access that data in the future). These two properties are essential to an offline video rental service or to an offline logging and revocation service.

Policy-sealed data [47] relies on TPMs to provide a new abstraction for cloud services that lets data be sealed (i.e., encrypted to a customer-defined policy) and then unsealed (i.e., decrypted) only by hosts whose configu-

rations match the policy.

cTPM [9] extends the TPM functionality across several devices as long as they are owned by the same user. cTPM thus offers strong user identities (across all of her devices), and cross-device isolated secure storage.

Finally, mobile devices can leverage a TPM to offer new trusted services [19, 31, 28]. One example is *trusted sensors* whose readings have a high degree of authenticity and integrity. Trusted sensors enable new mobile apps relevant to scenarios in which sensor readings are very valuable, such as finance (e.g., cash transfers and deposits) and health (e.g., gather health data) [48, 56]. Another example is enforcing driver distraction regulations for in-car music or navigation systems [28].

2.3 TPM 2.0: A New TPM Specification

The Trusted Computing Group (TCG) recently defined the specification for TPM version 2.0 [54]. This newer TPM is needed for two key reasons. First, the crypto algorithms in TPM 1.2 [55] have become inadequate. For example, TPM 1.2 only offers SHA-1 and not SHA-2; SHA-1 is now considered weak and cryptographers are reluctant to use it. Another example is the introduction of ECC with TPM 2.0.

The second reason is the lack of an universally-accepted reference implementation of the TPM 1.2 specification. As a result, different TPM 1.2 implementations exhibit slightly different behaviors. The lack of a reference implementation also keeps the TPM 1.2 specification ambiguous. It can be difficult to specify the exact behavior of cryptographic protocols in English. Instead, with TPM 2.0 the specification is the same as the reference implementation. The specification consists of several documents describing the behavior of the codebase, and these documents are derived directly from the TPM 2.0 codebase, thereby ensuring uniform behavior.

Recently, TPM manufacturers have started to release discrete chips implementing TPM 2.0. Also, at least one manufacturer has released a firmware upgrade that can update a TPM 1.2 chip into one that implements both TPM 2.0 and TPM 1.2. Note that although TPM 2.0 subsumes the functionality of TPM 1.2, it is not backwards compatible. A BIOS built to use a TPM 1.2 would not work with a TPM 2.0-only chip. A list of differences between the two versions is provided by the TCG [53].

3 Modern Trusted Computing Hardware

Recognizing the increasing demand for security, modern CPUs have started to incorporate trusted computing features, such as ARM TrustZone [1] and Intel Software Guard Extensions (SGX) [25]. This section presents

the background on ARM TrustZone (including its shortcomings); this background is important to the design of fTPM. Later, Section 12 will describe Intel’s SGX and its shortcomings.

3.1 ARM TrustZone

ARM TrustZone is ARM’s hardware support for trusted computing. It is a set of security extensions found in many recent ARM processors (including Cortex A8, Cortex A9, and Cortex A15). ARM TrustZone provides two virtual processors backed by hardware access control. The software stack can switch between the two states, referred to as “worlds”. One world is called *secure world* (SW), and the other *normal world* (NW). Each world acts as a runtime environment with its own resources (e.g., memory, processor, cache, controllers, interrupts). Depending on the specifics of an individual ARM SoC, a single resource can be strongly partitioned between the two worlds, can be shared across worlds, or assigned to a single world only. For example, most ARM SoCs offer memory curtaining, where a region of memory can be dedicated to the secure world. Similarly, processor, caches, and controllers are often shared across worlds. Finally, I/O devices can be mapped to only one world, although on certain SoCs this mapping can be dynamically controlled by a trusted peripheral.

- **Secure monitor:** The secure monitor is an ARM processor mode that enables context switching between the secure and normal worlds. A special register determines whether the processor core runs code in the secure or non-secure worlds. When the core runs in monitor mode the processor is considered secure regardless of the value of this register.

An ARM CPU has separate banks of registers for each of the two worlds. Each of the worlds can only access their separate register files; cross-world register access is blocked. However, the secure monitor can access non-secure banked copies of registers. The monitor can thus implement context switches between the two worlds.

- **Secure world entry/exit:** By design, an ARM platform always boots into the secure world first. Here, the system firmware can provision the runtime environment of the secure world before any untrusted code (e.g., the OS) has a chance to run. For example, the firmware allocates secure memory for TrustZone, programs the DMA controllers to be TrustZone-aware, and initializes any secure code. The secure code eventually yields to the normal world where untrusted code can start executing.

The normal world uses a special ARM instruction called *smc* (secure monitor call) to transfer control into the secure world. When the CPU executes the *smc* instruction, the hardware switches into the secure monitor,

which performs a secure context switch into the secure world. Hardware interrupts can trap directly into the secure monitor code, which enables flexible routing of those interrupts to either world. This allows I/O devices to map their interrupts to the secure world if desired.

- **Curtained memory:** At boot time, the software running in the secure monitor can allocate a range of physical addresses to the secure world only, creating the abstraction of curtained memory – memory inaccessible to the rest of the system. For this, ARM adds an extra control signal for each of the read and write channels on the main memory bus. This signal corresponds to an extra bit (a 33rd-bit on a 32-bit architecture) called the *non-secure* bit (NS-bit). These bits are interpreted whenever a memory access occurs. If the NS-bit is set, an access to memory allocated to the secure world fails.

3.2 Shortcomings of ARM TrustZone

Although the ARM TrustZone specification describes how the processor and memory subsystem are protected in the secure world and provides mechanisms for securing I/O devices, the specification is silent on how many other resources should be protected. This has led to fragmentation – SoCs offer various forms of protecting different hardware resources for TrustZone, or no protection at all. While there may be major differences between the ARM SoCs offered by different vendors, the observations below held across all the major SoCs vendors when products based on this work shipped.

- **No Trusted Storage:** Surprisingly, the ARM TrustZone specification offers no guidelines on how to implement secure storage for TrustZone. The lack of secure storage drastically reduces the effectiveness of TrustZone as trusted computing hardware.

Naively, one might think that code in TrustZone could encrypt its persistent state and store it on untrusted storage. However, encryption alone is not sufficient because (1) one needs a way to store the encryption keys securely, and (2) encryption cannot prevent rollback attacks.

- **Lack of Secure Entropy and Persistent Counters:** Most trusted systems make use of cryptography. However, the TrustZone specification is silent on offering a secure entropy source or a monotonically increasing persistent counter. As a result, most SoCs lack an entropy pool that can only be read from the secure world, and a counter that can persist across reboots and cannot be incremented by the normal world.

- **Lack of virtualization:** Sharing the processor across two different worlds in a stable manner can be done using virtualization techniques. Although ARM offers virtualization extensions [2], the ARM TrustZone specification

does not mandate them. As a result, many ARM-based SoCs used in mobile devices today lack virtualization support. Virtualizing commodity operating systems on an ARM platform lacking hardware-assistance for virtualization is challenging.

- **Lack of secure clock and other peripherals:** Secure systems often require a secure clock. While TrustZone can protect memory, interrupts, and certain system buses on the SoC, this protection does not extend to the ARM peripheral bus. It is hard to reason about the security guarantees of a peripheral if its controller can be programmed by the normal world, even when its interrupts and memory region are mapped into the secure world. Malicious code could program the peripheral in a way that could make it insecure. For example, some peripherals could be put in “debug mode” to generate arbitrary readings that do not correspond to the ground truth.
- **Lack of access:** Most SoC hardware vendors do not provide access to their firmware. As a result, many developers and researchers are unable to find ways to deploy their systems or prototypes to TrustZone. In our experience, this has seriously impeded the adoption of TrustZone as a trusted computing mechanism.

SoC vendors are reluctant to give access to their firmware. They argue that their platforms should be “locked down” to reduce the likelihood of “hard-to-remove” rootkits. Informally, SoC vendors also perceive firmware access as a threat to their competitiveness. They often incorporate proprietary algorithms and code into their firmware that takes advantage of the vendor-specific features offered by the SoC. Opening firmware to third parties could expose more details about these features to their competitors.

4 High-Level Architecture

Leveraging ARM TrustZone, we implement a trusted execution environment (TEE) that acts as a basic operating system for the secure world. Figure 1 illustrates our architecture, and our system’s trusted computing base (TCB) is shown in the shaded boxes.

At a high-level, the TEE consists of a monitor, a dispatcher, and a runtime where one or more trusted services (such as the fTPM) can run one at a time. The TEE exposes a single trusted service interface to the normal world using shared memory. Our system’s TCB comprises the ARM SoC hardware, the TEE layers, and the fTPM service.

By leveraging the isolation properties of ARM TrustZone, the TEE provides *shielded execution*, a term coined by previous work [5]. With shielded execution, the TEE offers two security guarantees:

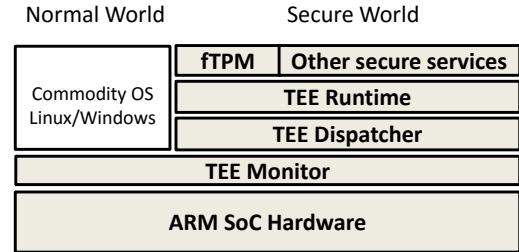

Figure 1: **The architecture of the fTPM.** This diagram is not to scale.

- *Confidentiality:* The whole execution of the fTPM (including its secrets and execution state) is hidden from the rest of the system. Only the fTPM’s inputs and outputs, but no intermediate states, are observable.
- *Integrity:* The operating system cannot affect the behavior of the fTPM, except by choosing to refuse execution or to prevent access to system’s resources (DoS attacks). The fTPM’s commands are always executed correctly according to the TPM 2.0 specification.

4.1 Threat Model and Assumptions

A primary assumption is that the commodity OS running in the Normal World is untrusted and potentially compromised. This OS could mount various attacks to code running in TrustZone, such as making invalid calls to TrustZone (or setting invalid parameters), not responding to requests coming from TrustZone, or responding incorrectly. In handling these attacks, it is important to distinguish between two cases: (1) not handling or answering TrustZone’s requests, or (2) acting maliciously.

The first class of attacks corresponds to *refusing service*, a form of Denial-of-Service attacks. DoS attacks are out of scope according to the TPM 2.0 specification. These attacks cannot be prevented as long as an untrusted commodity OS has access to platform resources, such as storage or network. For example, a compromised OS could mount various DoS attacks, such as erasing all storage, resetting the network card, or refusing to call the *smc* instruction. Although our fTPM will remain secure (e.g., preserves confidentiality and integrity of its data) in the face of these attacks, the malicious OS could starve the fTPM leaving it inaccessible.

However, the fTPM must behave correctly when the untrusted OS makes incorrect requests, returns unusual values (or fails to return at all), corrupts data stored on stable storage, injects spurious exceptions, or sets the platform clock to an arbitrary value.

At the hardware level, we assume that the ARM SoC (including ARM TrustZone) itself is implemented correctly, and is not compromised. An attacker cannot

mount hardware attacks to inspect the contents of the ARM SoC, nor the contents of RAM memory on the platform. However, the adversary has full control beyond the physical boundaries of the processor and memory. They may read the flash storage and arbitrarily alter I/O including network traffic or any sensors found on the mobile device. In other work, we address the issue of physical attacks on the memory of a mobile device [10].

We defend against side-channel attacks that can be mounted by malicious software. Cache collision attacks are prevented because all caches are flushed when the processor context switches to and from the Secure World. Our fTPM implementation’s cryptography library uses constant time cryptography and several other timing attack preventions, such as RSA blinding [27]. However, we do not defend against power analysis or other side-channel attacks that require physical access to hardware or hardware modifications.

We turn our focus on the approaches taken to overcome TrustZone’s shortcomings in the fTPM.

5 Overcoming TrustZone Shortcomings

We used three approaches to overcome the shortcomings of ARM TrustZone’s technology.

- **Approach #1: Hardware Requirements.** Providing secure storage to TEE was a serious concern. One option was to store the TEE’s secure state in the cloud. We dismissed this alternative as not viable because of its drastic impact on device usability. TPMs are used to measure the boot software (including the firmware) on a device. A mobile device would then require cloud connectivity at boot time in order to download the fTPM’s state and start measuring the boot software.

Instead, we imposed additional hardware requirements on device manufacturers to ensure a minimum level of hardware support for the fTPM. Many mobile devices already come equipped with an embedded Multi-Media Controller (eMMC) storage controller that has an (off-SoC) replay-protected memory block (RPMB). The RPMB’s presence, combined with encryption, ensures that TEE can offer storage that meets the needs of all the fTPM’s security properties. Thus, our first hardware requirement for TEE is an eMMC controller with support for RPMB.

Second, we require the presence of hardware fuses accessible only from the secure world. A hardware fuse provides write-once storage. At provisioning time (before being released to a retail store), manufacturers provision our mobile devices by setting the secure hardware fuses with a secure key unique per device. We also require an entropy source accessible from the secure world.

The TEE uses both the secure key and the entropy source to generate cryptographic keys at boot time.

Section 6 provides in-depth details of these three hardware requirements.

- **Approach #2: Design Compromises.** Another big concern was long-running TEE commands. Running inside TrustZone for a long time could jeopardize the stability of the commodity OS. Generally, sharing the processor across two different worlds in a stable manner should be done using virtualization techniques. Unfortunately, many of the targeted ARM platforms lack virtualization support. Speaking to the hardware vendors, we learned that it is unlikely virtualization will be added to their platforms any time soon.

Instead, we compromised and require that no TEE code path can execute for long periods of time. This translates into an fTPM requirement – no TPM 2.0 command can be long running. Our measurements of TPM commands revealed that only one TPM 2.0 command is long running: generating RSA keys. Section 7 presents the compromise made in the fTPM design when an RSA key generation command is issued.

- **Approach #3: Modifying the TPM 2.0 Semantics.** Lastly, we do not require the presence of a secure clock from the hardware vendors. Instead, the platform only has a secure timer that ticks at a pre-determined rate. We thus determined that the fTPM cannot offer any TPM commands that require a clock for their security. Fortunately, we discovered that some (but not all) TPM commands can still be offered by relying on a secure timer albeit with slightly altered semantics. Section 8 will describe all these changes in more depth.

6 Hardware Requirements

6.1 eMMC with RPMB

eMMC stands for embedded Multi-Media Controller, and refers to a package consisting of both flash memory and a flash memory controller integrated on the same silicon die [11]. eMMC consists of the MMC (multimedia card) interface, the flash memory, and the flash memory controller. Later versions of the eMMC standard offer a replay-protected memory block (RPMB) partition. As the name suggests, RPMB is a mechanism for storing data in an authenticated and replay-protected manner.

RPMB’s replay protection utilizes three mechanisms: an authentication key, a write counter, and a nonce.

RPMB Authentication Key: A 32-byte one-time programmable authentication key register. Once written, this register cannot be over-written, erased, or even read. The eMMC controller uses this authentication key to compute HMACs (SHA-256) to protect data integrity.

Programming the RPMB authentication key is done by issuing a specially formatted dataframe. Next, a result read request dataframe must be also issued to check that the programming step succeeded. Access to the RPMB is prevented unless the authentication key has been programmed. Any write/read requests will return a special error code indicating that the authentication key has yet to be programmed.

RPMB Write Counter: The RPMB partition also maintains a counter for the number of authenticated write requests made to RPMB. This is a 32-bit counter initially set to 0. Once it reaches its maximum value, the counter will no longer be incremented and a special bit will be turned on in all dataframes to indicate that the write counter has expired. The correct counter value must be included in each dataframe written to the controller.

Nonce: RPMB allows a caller to label its read requests with 16-byte nonces that are reflected in the read responses. These nonces ensure that reads are fresh.

6.1.1 Protection against replay attacks

To protect writes from replay attacks, each write includes a write counter value whose integrity is protected by an authentication key (the RPMB authentication key), a shared secret provisioned into both the secure world and the eMMC controller. The read request dataframe that verifies a write operation returns the incremented counter value, whose integrity is protected by the RPMB authentication key. This ensures that the write request has been successful.

The role of nonces in read operations protects them against replay attacks. To ensure freshness, whenever a read operation is issued, the request includes a nonce and the read response includes the nonce signed with RPMB authentication key.

6.2 Secure World Hardware Fuses

We required a set of hardware fuses that can be read from the secure world only. These fuses are provisioned with a hard-to-guess, unique-per-device number. This number is used as a seed in deriving additional secret keys used by the fTPM. Section 9 will describe in-depth how the seed is used in deriving secret fTPM keys, such as the secure storage key (SSK).

6.3 Secure Entropy Source

The TPM specification requires a true random number generator (RNG). A true RNG is constructed by having an entropy pool whose entropy is supplied by a hardware

oscillator. The secure world must manage this pool because the TEE must read from it periodically.

Generating entropy is often done via some physical process (e.g., a noise generator). Furthermore, an entropy generator has a *rate of entropy* that specifies how many bits of entropy are generated per second. When the platform is first started, it can take some time until it has gathered “enough” bits of entropy for a seed.

We require the platform manufacturer to provision an entropy source that has two properties: (1) it can be managed by the secure world, and (2) its specification lists a conservative bound on its rate of entropy; this bound is provided as a configuration variable to the fTPM. Upon a platform start, the fTPM waits to initialize until sufficient bits of entropy are generated. For example, the fTPM would need to wait at least 25 seconds to initialize if it requires 500 bits of true entropy bits from a source whose a rate is 20 bits/second.

Alerted to this issue, the TPM 2.0 specification has added the ability to save and restore any accumulated but unused entropy across reboots. This can help the fTPM reduce the wait time for accumulating entropy.

7 Design Compromises

7.1 Background on Creating RSA Keys

Creating an RSA key is a resource-intensive operation for two reasons. First, it requires searching for two large prime numbers, and such a search is theoretically unbounded. Although many optimizations exist on how to search RSA keys efficiently [40], searching for keys is still a lengthy operation. Second, the search must be seeded with a random number, otherwise an attacker could attempt to guess the primes the search produced. Thus the TPM cannot create an RSA key unless the entropy source has produced enough entropy to seed the search.

The TPM can be initialized with a *primary* storage root key (SRK). The SRK’s private portion never leaves the TPM and is used in many TPM commands (such as TPM *seal* and *unseal*). Upon TPM initialization, our fTPM waits to accumulate the entropy required to seed the search for large prime numbers. The fTPM also creates RSA keys upon receiving a *create RSA keys* command¹.

TPM 2.0 checks whether a number is prime using the Miller-Rabin probabilistic primality test [40]. If the test fails, the candidate number is not a prime. However, upon passing, the test offers a probabilistic guarantee – the candidate is likely a prime with high probability. The TPM repeats this test a couple of times to increase

¹This corresponds to the TPM 2.0 TPM2>Create command.

the likelihood the candidate is prime. Choosing a composite number during RSA key creation has catastrophic security consequences because it allows an attacker to recover secrets protected by that key. TPM 2.0 repeats the primality test five times for RSA-1024 keys and four times for all RSA versions with longer keys. This reduces the likelihood of choosing a false prime to a probability lower than 2^{-100} .

7.2 Cooperative Checkpointing

Our fTPM targets several different ARM platforms (from smartphones to tablets) that lack virtualization support, and the minimal OS in our TEE lacks a preemptive scheduler. Therefore, we impose a requirement on services running in the TEE that the transitions to TEE and back must be short to ensure that the commodity OS remains stable. Unfortunately, creating an RSA key is a very long process, often taking in excess of 10 seconds on our early hardware tablets.

Faced with this challenge, we added *cooperative checkpointing* to the fTPM. Whenever a TPM command takes too long, the fTPM checkpoints its state in memory, and returns a special error code to the commodity OS running in the Normal World.

Once the OS resumes running in the Normal World, the OS is free to call back the TPM command and instruct the fTPM to resume its execution. These “resume” commands continue processing until the command completes or the next checkpoint occurs. Additionally, the fTPM also allows all commands to be cancelled. The commodity OS can cancel any TPM command even when in the command is in a checkpointed state. Cooperative checkpointing lets us bypass the lack of virtualization support in ARM, yet continue to offer long-running TPM commands, such as creating RSA keys.

8 Modifying TPM 2.0 Semantics

8.1 Secure Clock

TPMs use secure clocks for two reasons. The first use is to measure lockout durations. Lockouts are time periods when the TPM refuses service. Lockouts are very important to authorizations (e.g., checking a password). If a password is incorrectly entered more than k times (for a small k), the TPM enters lockout and refuses service for a pre-determined period of time. This thwarts dictionary attacks – guessing a password incorrectly more than k times puts the TPM in lockout mode.

The second use of a secure clock in TPMs is for time-bound authorizations, such as the issuing an authorization valid for a pre-specified period of time. For example, the TPM can create a key valid for an hour only. At

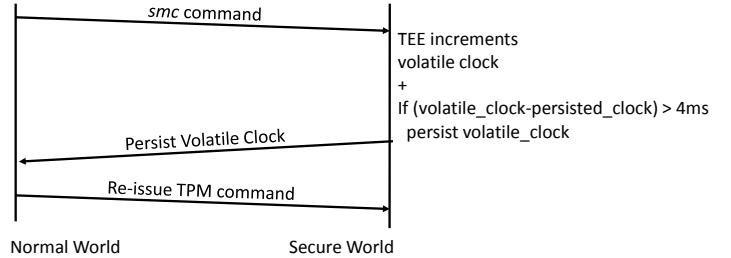

Figure 2: **fTPM clock update.**

the end of an hour, the key becomes unusable.

8.1.1 Requirements of the TPM 2.0 Specification

A TPM 2.0 requirement is the presence of a clock with millisecond granularity. The TPM uses this clock only to measure intervals of time for time-bound authorizations and lockouts. The volatile clock value must be persisted periodically to a specially-designed non-volatile entry called *NVClock*. The periodicity of the persistence is a TPM configuration variable and cannot be longer than 2^{22} milliseconds (~70 minutes).

The combination of these properties ensures that the TPM clock offers the following two guarantees: 1. *the clock advances while the TPM is powered*, 2. *the clock never rolls backwards more than NVClock update periodicity*. The only time when the clock can roll backward is when the TPM loses power right before persisting the NVClock value. Upon restoring power, the clock will be restored from NVClock and thus rolled back. The TPM also provides a flag that indicates the clock may have been rolled back. This flag is cleared when the TPM can guarantee the current clock value could not have been rolled back.

Given these guarantees, the TPM can measure time only while the platform is powered up. For example, the TPM can measure one hour of time as long as the platform does not reboot or shutdown. However, the clock can advance slower than wall clock *but only due to a reboot*. Even in this case time-bound authorizations are secure because they do not survive reboots by construction: in TPM 2.0, a platform reboot automatically expires all time-bound authorizations.

8.1.2 Fate Sharing

The main difficulty in building a secure clock in the fTPM is that persisting the clock to storage requires the cooperation of the (untrusted) OS. The OS could refuse to perform any writes that would update the clock. This would make it possible to roll back the clock arbitrarily just by simply rebooting the platform.

The fate sharing model suggests that it is acceptable to lose the clock semantics of the TPM as long as the TPM itself becomes unusable. Armed with this principle, we designed the fTPM’s secure clock to be the first piece of functionality the fTPM executes on *all* commands. The fTPM refuses to provide any functionality until the clock is persisted. Figure 2 illustrates how the fTPM updates its clock when the TEE is scheduled to run.

The fTPM implementation does not guarantee that the clock cannot be rolled back arbitrarily. For example, an OS can always refuse to persist the fTPM’s clock for a long time, and then reboot the platform effectively rolling back the clock. However, fate sharing guarantees that the fTPM services commands *if and only if* the clock behaves according to the TPM specification.

8.2 Dark Periods

The diversity of mobile device manufacturers raised an additional challenge for implementing the fTPM. A mobile device boot cycle starts by running firmware developed by one (of the many) hardware manufacturers, and then boots a commodity OS. The fTPM must provide functionality throughout the entire boot cycle. In particular, both Chrome and Windows devices issue TPM *Unseal* commands after the firmware finishes running, but before the OS starts booting. These commands attempt to unseal the decryption keys required for decrypting the OS loader. At this point, the fTPM cannot rely on external secure storage because the firmware has unloaded its storage drivers while the OS has yet to load its own. We refer to this point as a “dark period”.

TPM Unseal uses storage to record a failed unseal attempt. After a small number of failed attempts, the TPM enters lockout and refuses service for a period of time. This mechanism rate-limits the number of attempts to guess the unseal authorization (e.g., Windows lets users enter a PIN number to unseal the OS loader using BitLocker). The TPM maintains a counter of failed attempts and requires persisting it each time the counter increments. This eliminates the possibility of an attacker brute-forcing the unseal authorization and rebooting the platform without persisting the counter. Figures 3, 4, and 5 illustrate three timelines: a TPM storing its failed attempts counter to stable storage, a TPM without stable storage being attacked with by a simple reboot, and the fTPM solution to dark periods based on the dirty bit.

8.2.1 Modifying the Semantics of Failed Tries

We address the lack of storage during a dark period by making a slight change in how the TPM 2.0 interprets the failed tries counter. At platform boot time, before entering any possible dark periods, the fTPM persists

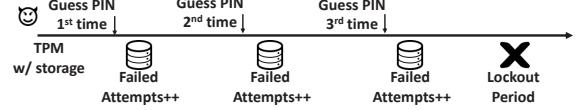

Figure 3: **TPM with storage (no dark period).** TPM enters lockout if adversary makes too many guess attempts. This sequence of steps is secure.

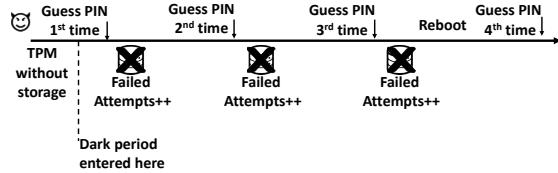

Figure 4: **TPM during a dark period (no stable storage).** Without storing the failed attempts counter, the adversary can simply reboot and avoid TPM lockout. This sequence of steps is insecure.

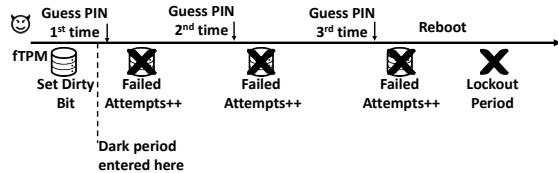

Figure 5: **fTPM during a dark period (no stable storage).** fTPM sets the dirty bit before entering a dark period. If reboot occurs during the dark period, fTPM enters lockout automatically. This sequence of steps is secure.

a *dirty bit*. If for any reason the fTPM is unable to persist the dirty bit, it refuses to offer service. If the dark period is entered and the unseal succeeds, the OS will start booting successfully and load its storage drivers. Once storage becomes available again, the dirty bit is cleared. However, the dirty bit remains uncleared should the mobile device reboot during a dark period. In this case, when the fTPM initializes and sees that the bit is dirty, the fTPM cannot distinguish between a legitimate device reboot (during a dark period) and an attack attempting to rollback the failed tries counter. Conservatively, the fTPM assumes it is under attack, the counter is immediately incremented to the maximum number of failed attempts, and the TPM enters lockout.

This change in semantics guarantees that an attack against the counter remains ineffective. The trade-off is that a legitimate device reboot during a dark period puts the TPM in lockout. The TPM cannot unseal until the lockout duration expires (typically several minutes).

Alerted to this problem, the TPM 2.0 designers have added a form of the *dirty bit* to their specification, called

the *non-orderly* or *unordered bit* (both terms appear in the specification). Unfortunately, they did not adopt the idea of having a small number of tries before the TPM enters lockout mode. Instead, the specification dictates that the TPM enters lockout as soon as a failed unsealed attempt cannot be recorded to storage. Such a solution impacts usability because it locks the TPM as soon as the user has entered an incorrect PIN or password.

9 Providing Storage to Secure Services

The combination of encryption, the RPMB, and hardware fuses is sufficient to build trusted storage for the TEE. Upon booting the first time, TEE generates a symmetric RPMB key and programs it into the RPMB controller. The RPMB key is derived from existing keys available on the platform. In particular, we construct a secure storage key (SSK) that is unique to the device and derived as following:

$$SSK := KDF(HF, DK, UUID) \quad (1)$$

where KDF is a one-way key derivation function, HF is the value read from the hardware fuses, DK is a device key available to both secure and normal worlds, and UUID is the device’s unique identifier.

The SSK is used for authenticated reads and writes of all TEE’s persistent state (including the fTPM’s state) to the device’s flash memory. Before being persisted, the state is encrypted with a key available to TrustZone only. Encryption ensures that all fTPM’s state remains confidential and integrity protected. The RPMB’s authenticated reads and writes ensure that fTPM’s state is also resilient against replay attacks.

9.1 Atomic Updates

TEE implements atomic updates to the RPMB partition. Atomic updates are necessary for fTPM commands that require multiple separate write operations. If these writes are not executed atomically, TEE’s persistent state could become inconsistent upon a failure that leaves the secure world unable to read its state.

The persisted state of the fTPM consists of a sequence of blocks. TEE stores two copies of each block: one representing the committed version of the state block and one its shadow (or uncommitted) version. Each block id X has a corresponding block whose id is $X + N$, where N is the size of fTPM’s state. The TEE also stores a bit vector in its first RPMB block. Each bit in this vector indicates which block is committed: if the i bit is 0 then the i th block committed id is X , otherwise is $X + N$. In this way, all pending writes to shadow blocks are committed using a single atomic write operation of the bit vector.

Figure 6: **RMPB blocks.** Bit vector mechanism used for atomic updates.

Allocating the first RPMB entry to the bit vector limits the size of the RPMB partition to 256KB (the current eMMC specification limits the size of a block to 256 bytes). If that size is insufficient, an extra layer of indirection can extend the bit vector mechanism to support up to 512MB ($256 * 8 * 256 * 8 = 1,048,576$ blocks).

Figure 6 illustrates the bit vector mechanism for atomic updates. On the left, the bit vector shows which block is committed (bit value 0) and which block is shadow (bit value 1). The committed blocks are shown in solid color.

In the future, we plan to improve the fTPM’s performance by offering transactions to fTPM commands. All writes in a transaction are cached in memory and persisted only upon commit. The commit operation first updates the shadow version of changed blocks, and then updates the metadata in a single atomic operation to make shadow version for updated blocks the committed version. A command that updates secure state must either call commit or abort before returning. Abort is called implicitly if commit fails, where shadow copy is rolled back to the last committed version, and an error code is returned. In this scenario, the command must implement rollback of any in-memory data structure by itself.

10 Performance Evaluation

This paper answers two important questions on performance²:

1. What is the overhead of long-running fTPM commands such as *create RSA keys*? The goal is to shed light on the fTPM implementation’s performance when seeking prime numbers for RSA keys.

2. What is the performance overhead of typical fTPM commands, and how does it compare to the performance of a discrete TPM chip? TPM chips have notoriously slow microcontrollers [33]. In contrast, fTPM commands execute on full-fledged ARM cores.

10.1 Methodology

To answer these questions, we instrumented four off-the-shelf commodity mobile devices equipped with fTPMs and three machines equipped with discrete TPMs. We keep these devices’ identities confidential, and refer to

²The fTPM technical report presents additional results of the performance evaluation [44].

fTPM Device	Processor Type
Device # fTPM ₁	1.2 GHz Cortex-A7
Device # fTPM ₂	1.3 GHz Cortex-A9
Device # fTPM ₃	2 GHz Cortex-A57
Device # fTPM ₄	2.2 GHz Cortex-A57

Table 1: Description of fTPM-equipped devices used the evaluation.

them as fTPM₁ through fTPM₄, and dTPM₁ through dTPM₃. All mobile devices are commercially available both in USA and the rest of the world and can be found in the shops of most cellular carriers. Similarly, the discrete TPM 2.0 chips are commercially available. Table 1 describes the characteristics of the mobile ARM SoC processors present in the fTPM-equipped devices. The only modifications made to these devices’ software is a form of device unlock that lets us load our own test harness and gather the measurement results. These modifications do not interfere with the performance of the fTPM running on the tablet.

Details of TPM 2.0 Commands. To answer the questions raised by our performance evaluation, we created a benchmark suite in which we perform various TPM commands and measure their duration. We were able to use timers with sub-millisecond granularity for all our measurements, except for device fTPM₂. Unfortunately, device fTPM₂ only exposes a timer with a 15-ms granularity to our benchmark suite, and we were not able to unlock its firmware to bypass this limitation.

Each benchmark test was run ten times in a row. Although this section presents a series of graphs that answer our performance evaluation questions, an interested reader can find all the data gathered in our benchmarks in the fTPM technical report [44].

- **Create RSA keys:** This TPM command creates an RSA key pair. When this command is issued, a TPM searches for prime numbers, creates the private and public key portions, encrypts the private portion with a root key, and returns both portions to the caller. We used 2048-bit RSA keys in all our experiments. We chose 2048-bit keys because they are the smallest key size still considered secure (1024-bit keys are considered insecure and their use has been deprecated in most systems).

- **Seal and unseal:** The TPM Seal command takes in a byte array, attaches a policy (such as a set of Platform Configuration Register (PCR) values), encrypts with its own storage key, and returns it to the caller. The TPM Unseal command takes in an encrypted blob, checks the policy, and decrypts the blob if the policy is satisfied by the TPM state (e.g., the PCR values are the same as at seal time). We used a ten-byte input array to Seal, and we set an empty policy.

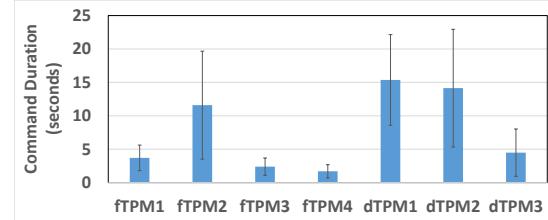

Figure 7: Latency of create RSA-2048 keys on various fTPM and dTPM platforms.

- **Sign and verify:** These TPM commands correspond to RSA sign and verify. We used a 2048-bit RSA key for RSA operations and SHA-256 for integrity protection.
- **Encryption and decryption:** These TPM commands correspond to RSA encryption and decryption. We used a 2048-bit RSA key for RSA operations, OAEP for padding, and SHA-256 for integrity protection.
- **Load:** This TPM command loads a previously-created RSA key into the TPM. This allows subsequent command, such as signing and encryption, to use the preloaded key. We used a 2048-bit RSA key in our TPM Load experiments.

10.2 Overhead of RSA Keys Creation

Figure 7 shows the latency of a TPM create RSA-2048 keys command across all our seven devices. As expected, creating RSA keys is a lengthy command taking several seconds on all platforms. These long latencies justify our choice of using cooperative checkpointing (see Section 7) in the design of the fTPM to avoid leaving the OS suspended for several seconds at a time.

Second, the performance of creating keys can be quite different across devices. fTPM₂ takes a much longer time than all other devices equipped with an fTPM. This is primarily due to the variations in the firmware performance across these devices – some manufacturers spend more time optimizing the firmware running on their platforms than others. Even more surprisingly, the discrete TPM 2.0 chips also have very different performance characteristics: dTPM₃ is much faster than dTPM₁ and dTPM₂. Looking at the raw data (shown in [44]), we believe that dTPM₃ searches for prime numbers in the background, even when no TPM command is issued, and maintains a cache of prime numbers.

Figure 7 also shows that the latency of creating keys has high variability due to how quickly prime numbers are found. To shed more light into the variability of finding prime numbers, we instrumented the fTPM codebase to count the number of prime candidates considered when creating an RSA 2048 key pair. For each test, all candidates are composite numbers (and thus discarded)

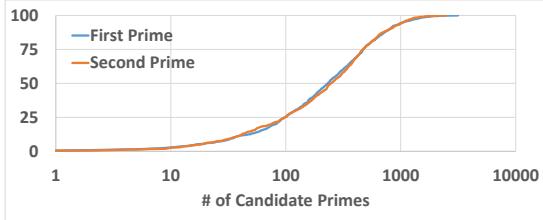

Figure 8: Performance of searching for primes.

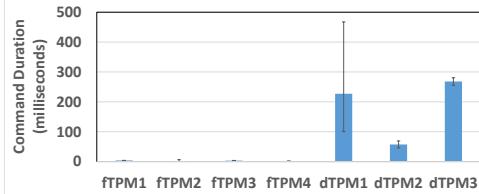

Figure 9: Performance of TPM seal command.

Figure 10: Performance of TPM unseal command.

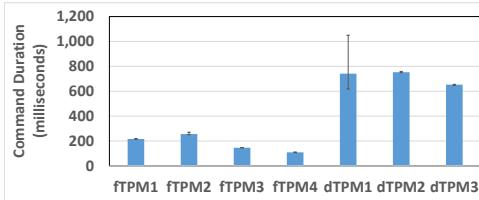

Figure 11: Performance of TPM sign command.

except for the last number. We repeated this test 1,000 times. We plot the cumulative distribution function of the number of candidates for each of the two primes (p and q) in Figure 8. These results demonstrate the large variability in the number of candidate primes considered. While, on average, it takes about 200 candidates until a prime is found (the median was 232 and 247 candidates for p and q , respectively), sometimes a single prime search considers and discards thousands of candidates (the worst case was 3,145 and 2,471 for p and q , respectively).

10.3 Comparing fTPMs to dTPMs

Figures 9–15 show the latencies of several common TPM 2.0 commands. The main result is that fTPMs are much faster than their discrete counterparts. On average, the slowest fTPM is anywhere between 2.4X (for decrypt

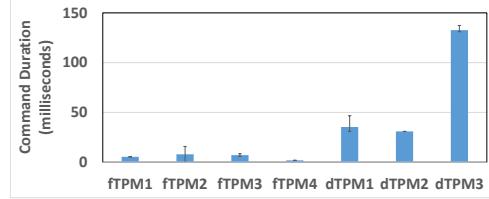

Figure 12: Performance of TPM verify command.

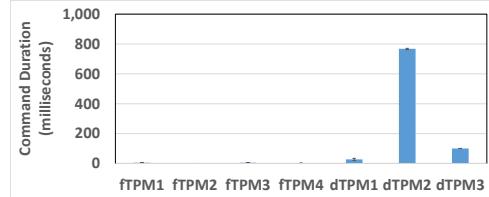

Figure 13: Performance of TPM encrypt command.

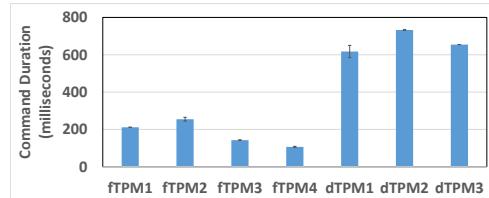

Figure 14: Performance of TPM decrypt command.

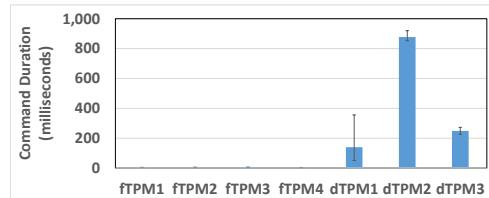

Figure 15: Performance of TPM load command.

tion) and 15.12X (for seal) faster than the fastest dTPM. This is not surprising because fTPMs run their code on ARM Cortex processors, whereas discrete chips are relegated to using much slower microprocessors. The fTPM technical report illustrates these vast performance improvements in even greater detail [44].

These performance results are encouraging. Traditionally, TPMs have not been used for bulk data cryptographic operations due to their performance limitations. With firmware TPMs however, the performance of these operations is limited only by processor speed and memory bandwidth. Furthermore, fTPMs could become even faster by taking advantage of crypto accelerators. Over time, we anticipate that crypto operations will increasingly abandon the OS crypto libraries in favor of the fTPM. This provides increased security as private keys never have to leave TrustZone’s secure perimeter.

10.4 Evaluation Summary

In summary, our evaluation shows that (1) the firmware TPM has better performance than discrete TPM chips, and (2) creating RSA keys is a lengthy operation with high performance variability.

11 Security Analysis

The fTPM’s security guarantees are not identical to those of a discrete TPM chip. This section examines these differences in greater depth.

On- versus off-chip. Discrete TPM chips connect to the CPU via a serial bus; this bus represents a new attack surface because it is externally exposed to an attacker with physical access to the main board. Early TPM chips were attached to the I²C bus, one of the slower CPU buses, that made it possible for an attacker to intercept and issue TPM commands [49]. Modern TPM specifications have instructed the hardware manufacturers to attach the TPM chip to a fast CPU bus and to provide a secure *platform reboot signal*. This signal must guarantee that the TPM reboots (e.g., resets its volatile registers) *if and only if* the platform reboots.

In contrast, by running in the device’s firmware, the fTPM sidesteps this attack surface. The fTPM has no separate bus to the CPU. The fTPM reads its state from secure storage upon initialization, and stores all its state in the CPU and the hardware-protected DRAM.

Memory attacks. By storing its secrets in DRAM, the fTPM is vulnerable to a new class of physical attacks – memory attacks that attempt to read secrets from DRAM. There are different avenues to mount memory attacks, such as cold boot attacks [23, 39], attaching a bus monitor to monitor data transfers between the CPU and system RAM [21, 17, 18], or mounting DMA attacks [6, 8, 42].

In contrast, discrete TPM chips do not make use of the system’s DRAM and are thus resilient to such attacks. However, there is a corresponding attack that attempts to remove the chip’s physical encasing, expose its internal dies, and thus read its secrets. Previous research has already demonstrated the viability of such attacks (typically referred to as *decapping* the TPM), although they remain quite expensive to mount in practice [26].

The fTPM’s susceptibility to memory attacks has led us to investigate inexpensive counter-measures. Sentry is a prototype that demonstrates how the fTPM can become resilient to memory attacks. Sentry retrofits ARM-specific mechanisms designed for embedded systems but still present in today’s mobile devices, such as L2 cache locking or internal RAM [10]. Note that in contrast with TrustZone, Intel SGX [25] provides hardware encryption

of DRAM, which protects against memory attacks.

Side-channel attacks. Given that certain resources are shared between the secure and normal worlds, great care must be given to side-channel attacks. In contrast, a discrete TPM chip is immune to side-channel attacks that use caching, memory, or CPU because these resources are not shared with the untrusted OS.

a. Caches, memory, and CPU: The ARM TrustZone specification takes great care to reduce the likelihood of cache-based side-channel attacks for shared resources [1]. Cache-based side-channel attacks are difficult because caches are always invalidated during each transition to and from the secure world. Memory is statically partitioned between the two worlds at platform initialization time; such a static partitioning reduces the likelihood of side-channel attacks. Finally, the CPU also invalidates all its registers upon each crossing to and from the secure world.

b. Time-based attacks: The TPM 2.0 specification takes certain precautions against time-based attacks. For example, the entire cryptography subsystem of TPM 2.0 uses constant time functions – the amount of computation needed by a cryptographic function does not depend on the function’s inputs. This makes the fTPM implementation as resilient to time-based side-channel attacks as its discrete chip counterpart.

12 Discussion

Most of ARM TrustZone’s shortcomings stem from the nature of this technology: it is a standalone CPU-based security mechanism. CPU extensions alone are insufficient in many practical scenarios. As described earlier in Section 3.2, trusted systems need additional hardware support, such as support for trusted storage, secure counters, and secure peripherals.

Unfortunately, CPU designers continue to put forward CPU extensions aimed at building trusted systems that suffer from similar limitations. This section’s goal is to describe these limitations in the context of a new, up-and-coming technology called Intel Software Guard Extensions (SGX). In the absence of additional hardware support for trusted systems, our brief discussion of SGX will reveal shortcomings similar to those of TrustZone.

12.1 Intel SGX Shortcomings

Intel SGX [25] is a set of extensions to Intel processors designed to build a sandboxing mechanism for running application-level code isolated from the rest of the system. Similar to ARM TrustZone’s secure world, with Intel SGX applications can create *enclaves* protected from the OS and the rest of the platform software. All memory

allocated to an enclave is hardware encrypted (unlike the secure world in ARM). Unlike ARM TrustZone, SGX does not offer any I/O support; all interrupts are handled by the untrusted code.

SGX has numerous shortcomings for trusted systems such as the fTPM:

1. Lack of trusted storage. While code executing inside an enclave can encrypt its state, encryption cannot protect against rollback attacks. Currently, the Intel SGX specification lacks any provision to rollback protection against persisted state.

2. Lack of a secure counter. A secure counter is important when building secure systems. For example, a rollback-resilient storage system could be built using encryption and a secure counter. Unfortunately, it is difficult for a CPU to offer a secure counter without hardware assistance beyond the SGX extensions (e.g., an eMMC storage controller with an RPMB partition).

3. Lack of secure clock. SGX leaves out any specification of a secure clock. Again, it is challenging for the CPU to offer a secure clock without extra hardware.

4. Side-channel dangers. SGX enclaves only protect code running in ring 3. This means that an untrusted OS is responsible for resource management tasks, which opens up a large surface for side-channel attacks. Indeed, recent work has demonstrated a number of such attacks against Intel SGX [57].

13 Related Work

Previous efforts closest to ours are Nokia OnBoard credentials (ObC), Mobile Trusted Module (MTM), and previous software implementations of TPMs. ObC [29] is a trusted execution runtime environment leveraging Nokia’s implementation of ARM TrustZone. ObC can execute programs written in a modified variant of the LUA scripting language or written in the underlying runtime bytecode. Different scripts running in ObC are protected from each other by the underlying LUA interpreter. A more recent similar effort ported the .NET framework to TrustZone [45, 46] using techniques similar to ObC.

While the fTPM serves as the reference implementation of a firmware TPM for ARM TrustZone, ObC is a technology proprietary to Nokia. Third-parties need their code signed by Nokia to allow it to run inside TrustZone. In contrast, the fTPM offers TPM 2.0 primitives to any application. While TPM primitives are less general than a full scripting language, both researchers and industry have already used TPMs in many secure systems demonstrating its usefulness. Recognizing the TPM platform’s flexibility, ObC appears to have recently started to offer primitives more compatible with those of the TPM specification [15].

The Mobile Trusted Module (MTM) [51] is a specification similar to a TPM but aimed solely at mobile devices. Previous work investigated possible implementations of MTM for mobile devices equipped with secure hardware, such as ARM TrustZone, smartcards, and Java SecureElements [12, 13]. These related works acknowledged upfront that the limitations of ARM TrustZone for implementation MTM remain future work [12]. Unfortunately, MTMs have not gone past the specification stage in the Trusted Computing Group. As a result, we are unaware of any systems that make use of MTMs. If MTMs were to become a reality, our techniques would remain relevant in building a firmware MTM.

A more recent article presents a high-level description of the work needed to implement TPM 2.0 both in hardware and in software [34]. Like the fTPM, the article points out the need of using a replay-protected memory block partition to protect against replay attacks. However, this article appeared much later, after the fTPM was launched in mobile devices. It is unclear whether any implementation of their architecture exists.

IBM has been maintaining a software implementation of TPM 1.2 [24]. An independent effort implemented a TPM 1.2 emulator without leveraging any secure hardware [50]. This emulator was aimed at debugging scenarios and testbeds. We are unaware of efforts to integrate any of these earlier implementations into mobile devices.

Another area of related work is building virtualized TPM implementations. Virtual TPMs are needed in virtualized environments where multiple guest operating systems might want to share the physical TPM without having to trust each other. Several designs of virtual TPMs have been proposed [7, 16].

Finally, a recent survey describes additional efforts in building trusted runtime execution environments for mobile devices based on various forms of hardware, including physically uncloneable functions, smartcards, and embedded devices [4]. A recent industrial consortium called GlobalPlatform [20] has also started to put together a standard for trusted runtime execution environments on various platforms, including ARM [3].

14 Conclusions

This paper demonstrates that the limitations of CPU-based security architectures, such as ARM TrustZone, can be overcome to build software systems with security guarantees similar to those of dedicated trusted hardware. We use three different approaches to overcome these challenges: requiring additional hardware support, making design compromises without affecting security, and slightly changing command semantics.

This paper describes a software-only implementation of a TPM chip. Our software-only TPM requires no

application-level changes or changes to OS components (other than drivers). Our implementation is the reference implementation of TPM 2.0 used in millions of smartphones and tablets.

Acknowledgements We would like to thank Andrew Baumann, Weidong Cui, Roxana Geambasu, Jaeyeon Jung, and Angelos Keromytis for feedback on earlier drafts of this paper. We are also grateful to Jiajing Zhu for her help with the TPM 2.0 simulator, and numerous other collaborators who contributed to the firmware TPM effort. Finally, we would like to thank the anonymous reviewers for their feedback on the submission.

Sanctum: Minimal Hardware Extensions for Strong Software Isolation

Victor Costan, Ilia Lebedev, and Srinivas Devadas
victor@costan.us, ilebedev@mit.edu, devadas@mit.edu
MIT CSAIL

Abstract

Sanctum offers the same promise as Intel’s Software Guard Extensions (SGX), namely strong provable isolation of software modules running concurrently and sharing resources, but protects against an important class of additional software attacks that infer private information from a program’s memory access patterns. Sanctum shuns unnecessary complexity, leading to a simpler security analysis. We follow a principled approach to eliminating entire attack surfaces through isolation, rather than plugging attack-specific privacy leaks. Most of Sanctum’s logic is implemented in trusted software, which does not perform cryptographic operations using keys, and is easier to analyze than SGX’s opaque microcode, which does.

Our prototype targets a Rocket RISC-V core, an open implementation that allows any researcher to reason about its security properties. Sanctum’s extensions can be adapted to other processor cores, because we do not change any major CPU building block. Instead, we add hardware at the interfaces between generic building blocks, without impacting cycle time.

Sanctum demonstrates that strong software isolation is achievable with a surprisingly small set of minimally invasive hardware changes, and a very reasonable overhead.

1 Introduction

Today’s systems rely on an operating system kernel, or a hypervisor (such as Linux or Xen, respectively) for software isolation. However **each** of the last three years (2012-2014) witnessed over 100 new security vulnerabilities in Linux [1, 11], and over 40 in Xen [2].

One may hope that formal verification methods can produce a secure kernel or hypervisor. Unfortunately, these codebases are far outside our verification capabilities: Linux and Xen have over *17 million* [6] and 150,000 [4] lines of code, respectively. In stark contrast, the seL4

formal verification effort [26] spent *20 man-years* to cover 9,000 lines of code.

Given Linux and Xen’s history of vulnerabilities and uncertain prospects for formal verification, a prudent system designer cannot include either in a TCB (trusted computing base), and must look elsewhere for a software isolation mechanism.

Fortunately, Intel’s Software Guard Extensions (SGX) [5, 36] has brought attention to the alternative of providing software isolation primitives in the CPU’s hardware. This avenue is appealing because the CPU is an unavoidable TCB component, and processor manufacturers have strong economic incentives to build correct hardware.

Unfortunately, although the SGX design includes a vast array of defenses against a variety of software and physical attacks, it fails to offer meaningful software isolation guarantees. The SGX threat model protects against all direct attacks, but excludes “side-channel attacks”, even if they can be performed via software alone.

Furthermore, our analysis [13] of SGX reveals that it is impossible for anyone but Intel to reason about SGX’s security properties, because significant implementation details are not covered by the publicly available documentation. This is a concern, as the myriad of security vulnerabilities [16, 18, 39, 50–54] in TXT [22], Intel’s previous attempt at securing remote computation, show that securing the machinery underlying Intel’s processors is incredibly challenging, even in the presence of strong economic incentives.

Our main contribution is a software isolation scheme that addresses the issues raised above: Sanctum’s isolation provably defends against known software side-channel attacks, including cache timing attacks and passive address translation attacks. Sanctum is a co-design that combines **minimal** and **minimally invasive** hardware modifications with a trusted software **security monitor** that is amenable to rigorous analysis and does not perform cryptographic operations using keys.

We achieve minimality by reusing and lightly modi-

fying existing, well-understood mechanisms. For example, our per-enclave page tables implementation uses the core’s existing page walking circuit, and requires very little extra logic. Sanctum is minimally invasive because it does not require modifying any major CPU building block. We only add hardware to the interfaces between blocks, and do not modify any block’s input or output. Our use of conventional building blocks limits the effort needed to validate a Sanctum implementation.

We demonstrate that memory access pattern attacks by malicious software can be foiled without incurring unreasonable overheads. Sanctum cores have the same clock speed as their insecure counterparts, as we do not modify the CPU core critical execution path. Using a straightforward page-coloring-based cache partitioning scheme with Sanctum adds a few percent of overhead in execution time, which is orders of magnitude lower than the overheads of the ORAM schemes [21, 43] that are usually employed to conceal memory access patterns.

All layers of Sanctum’s TCB are open-sourced at <https://github.com/pwnall/sanctum> and unencumbered by patents, trade secrets, or other similar intellectual property concerns that would disincentivize security researchers from analyzing it. Our prototype targets the Rocket Chip [29], an open-sourced implementation of the RISC-V [47, 49] instruction set architecture, which is an open standard. Sanctum’s software stack bears the MIT license.

To further encourage analysis, most of our security monitor is written in portable C++ which, once rigorously analyzed, can be used across different CPU implementations. Furthermore, even the non-portable assembly code can be reused across different implementations of the same architecture.

2 Related Work

Sanctum’s main improvement over SGX is preventing software attacks that analyze an isolated container’s memory access patterns to infer private information. We are particularly concerned with cache timing attacks [7], because they can be mounted by unprivileged software sharing a computer with the victim software.

Cache timing attacks are known to retrieve cryptographic keys used by AES [8], RSA [10], Diffie-Hellman [27], and elliptic-curve cryptography [9]. While early attacks required access to the victim’s CPU core, recent sophisticated attacks [35, 56] target the last-level cache (LLC), which is shared by all cores in a socket. Recently, [37] demonstrated a cache timing attack that uses JavaScript code in a page visited by a web browser.

Cache timing attacks observe a victim’s memory access patterns at cache line granularity. However, recent work shows that private information can be gleaned even

from the page-level memory access pattern obtained by a malicious OS that simply logs the addresses seen by its page fault handler [55].

XOM [30] introduced the idea of having sensitive code and data execute in isolated containers, and placed the OS in charge of resource allocation without trusting it. Aegis [44] relies on a trusted security kernel, handles untrusted memory, and identifies the software in a container by computing a cryptographic hash over the initial contents of the container. Aegis also computes a hash of the security kernel at boot time and uses it, together with the container’s hash, to attest a container’s identity to a third party, and to derive container keys. Unlike XOM and Aegis, Sanctum protects the memory access patterns of the software executing inside the isolation containers from software threats.

Sanctum only considers software attacks in its threat model (§ 3). Resilience against physical attacks can be added by augmenting a Sanctum processor with the countermeasures described in other secure architectures, with associated increased performance overheads. Aegis protects a container’s data when the DRAM is untrusted through memory encryption and integrity verification; these techniques were adopted and adapted by SGX. Ascend [20] and GhostRider [32] use Oblivious RAM [21] to protect a container’s memory access patterns against adversaries that can observe the addresses on the memory bus. An insight in Sanctum is that these overheads are unnecessary in a software-only threat model.

Intel’s Trusted Execution Technology (TXT) [22] is widely deployed in today’s mainstream computers, due to its approach of trying to add security to a successful CPU product. After falling victim to attacks [51, 54] where a malicious OS directed a network card to access data in the protected VM, a TXT revision introduced DRAM controller modifications that selectively block DMA transfers, which Sanctum also does.

Intel’s SGX [5, 36] adapted the ideas in Aegis and XOM to multi-core processors with a shared, coherent last-level cache. Sanctum draws heavy inspiration from SGX’s approach to memory access control, which does not modify the core’s critical execution path. We reverse-engineered and adapted SGX’s method for verifying an OS-conducted TLB shoot-down. At the same time, SGX has many security issues that are solved by Sanctum, which are stated in this paper’s introduction.

Iso-X [19] attempts to offer the SGX security guarantees, without the limitation that enclaves may only be allocated in a DRAM area that is carved off exclusively for SGX use, at boot time. Iso-X uses per-enclave page tables, like Sanctum, but its enclave page tables require a dedicated page walker. Iso-X’s hardware changes add overhead to the core’s cycle time, and do not protect against cache timing attacks.

SecureME [12] also proposes a co-design of hardware modifications and a trusted hypervisor for ensuring software isolation, but adapts the on-chip mechanisms generally used to prevent physical attacks, in order to protect applications from an untrusted OS. Just like SGX, SecureME is vulnerable to memory access pattern attacks.

The research community has brought forward various defenses against cache timing attacks. PLcache [28, 46] and the Random Fill Cache Architecture (RFill, [34]) were designed and analyzed in the context of a small region of sensitive data, and scaling them to protect a potentially large enclave without compromising performance is not straightforward. When used to isolate entire enclaves in the LLC, RFill performs at least 37%-66% worse than Sanctum.

RPcache [28, 46] trusts the OS to assign different hardware process IDs to mutually mistrusting entities, and its mechanism does not directly scale to large LLCs. The non-monopolizable cache [15] uses a well-principled partitioning scheme, but does not completely stop leakage, and relies on the OS to assign hardware process IDs. CATALYST [33] trusts the Xen hypervisor to correctly tame Intel’s Cache Allocation Technology into providing cache pinning, which can only secure software whose code and data fits into a fraction of the LLC.

Sanctum uses very simple cache partitioning [31] based on page coloring [24, 45], which has proven to have reasonable overheads. It is likely that sophisticated schemes like ZCache [40] and Vantage [41] can be combined with Sanctum’s framework to yield better performance.

3 Threat Model

Sanctum isolates the software inside an **enclave** from other software on the same computer. All outside software, including privileged system software, can only interact with an enclave via a small set of primitives provided by the security monitor. Programmers are expected to move the sensitive code in their applications into enclaves. In general, an enclave receives encrypted sensitive information from outside, decrypts the information and performs some computation on it, and then returns encrypted results to the outside world.

We assume that an attacker can compromise any operating system and hypervisor present on the computer executing the enclave, and can launch rogue enclaves. The attacker knows the target computer’s architecture and micro-architecture. The attacker can analyze passively collected data, such as page fault addresses, as well as mount active attacks, such as direct or DMA memory probing, and cache timing attacks.

Sanctum’s isolation protects the integrity and privacy of the code and data inside an enclave against any practical **software** attack that relies on observing or interacting

with the enclave software via means outside the interface provided by the security monitor. In other words, we do not protect enclaves that leak their own secrets directly (e.g., by writing to untrusted memory) or by timing their operations (e.g., by modulating their completion times). In effect, Sanctum solves the security problems that emerge from sharing a computer among mutually distrusting applications.

This distinction is particularly subtle in the context of cache timing attacks. We do not protect against attacks like [10], where the victim application leaks information via its public API, and the leak occurs even if the victim runs on a dedicated machine. We *do* protect against attacks like Flush+Reload [56], which exploit shared hardware resources to interact with the victim via methods outside its public API.

Sanctum also defeats attackers who aim to compromise an OS or hypervisor by running malicious applications and enclaves. This addresses concerns that enclaves provide new attack vectors for malware [14, 38]. We assume that the benefits of meaningful software isolation outweigh enabling a new avenue for frustrating malware detection and reverse engineering [17].

Lastly, Sanctum protects against a malicious computer owner who attempts to lie about the security monitor running on the computer. Specifically, the attacker aims to obtain an attestation stating that the computer is running an uncompromised security monitor, whereas a different monitor had been loaded in the boot process. The uncompromised security monitor must not have any known vulnerability that causes it to disclose its cryptographic keys. The attacker is assumed to know the target computer’s architecture and micro-architecture, and is allowed to run any combination of malicious security monitor, hypervisor, OS, applications and enclaves.

We do not prevent timing attacks that exploit bottlenecks in the cache coherence directory bandwidth or in the DRAM bandwidth, deferring these to future work.

Sanctum does not protect against denial-of-service (DoS) attacks by compromised system software: a malicious OS may deny service by refusing to allocate any resources to an enclave. We *do* protect against malicious enclaves attempting to DoS an uncompromised OS.

We assume correct underlying hardware, so we do not protect against software attacks that exploit hardware bugs (fault-injection attacks), such as rowhammer [25, 42].

Sanctum’s isolation mechanisms exclusively target software attacks. § 2 mentions related work that can harden a Sanctum system against some physical attacks. Furthermore, we consider software attacks that rely on sensor data to be physical attacks. For example, we do not address information leakage due to power variations, because software would require a temperature or current sensor to carry out such an attack.

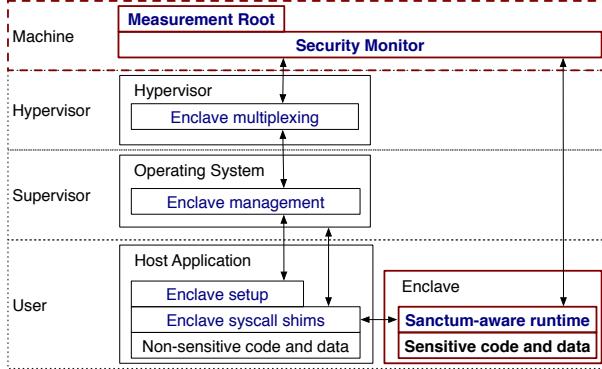

Figure 1: Software stack on a Sanctum machine; The blue text represents additions required by Sanctum. The bolded elements are in the software TCB.

4 Programming Model Overview

By design, Sanctum’s programming model deviates from SGX as little as possible, while providing stronger security guarantees. We expect that application authors will link against a Sanctum-aware runtime that abstracts away most aspects of Sanctum’s programming model. For example, C programs would use a modified implementation of the `libc` standard library. Due to space constraints, we describe the programming model assuming that the reader is familiar with SGX as described in [13].

The software stack on a Sanctum machine, shown in Figure 1, resembles the SGX stack with one notable exception: SGX’s microcode is replaced by a trusted software component, the **security monitor**, which is protected from compromised system software, as it runs at the highest privilege level (machine level in RISC-V).

We relegate the management of computation resources, such as DRAM and execution cores, to untrusted system software (as does SGX). In Sanctum, the security monitor checks the system software’s allocation decisions for correctness and commits them into the hardware’s configuration registers. For simplicity, we refer to the software that manages resources as an *OS (operating system)*, even though it may be a combination of a hypervisor and a guest OS kernel.

An enclave stores its code and private data in parts of DRAM that have been allocated by the OS exclusively for the enclave’s use (as does SGX), which are collectively called **the enclave’s memory**. Consequently, we refer to the regions of DRAM that are not allocated to any enclave as **OS memory**. The security monitor tracks DRAM ownership, and ensures that no piece of DRAM is assigned to more than one enclave.

Each Sanctum enclave uses a range of virtual memory addresses (EVRANGE) to access its memory. The enclave’s memory is mapped by the enclave’s own page ta-

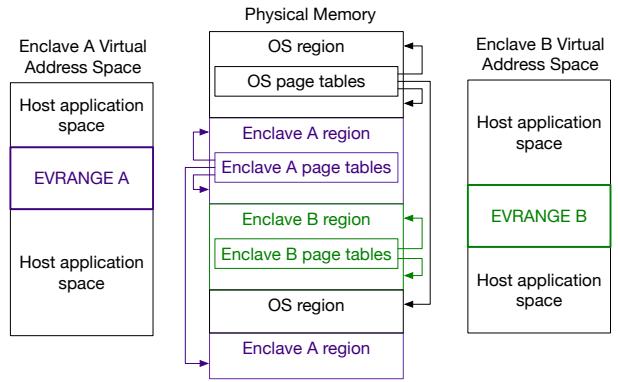

Figure 2: Per-enclave page tables

bles, which are stored in the enclave’s memory (Figure 2). This makes private the page table dirty and accessed bits, which can reveal memory access patterns at page granularity. Exposing an enclave’s page tables to the untrusted OS leaves the enclave vulnerable to attacks such as [55].

The enclave’s virtual address space outside EVRANGE is used to access its host application’s memory, via the page tables set up by the OS. Sanctum’s hardware extensions implement dual page table lookup (§ 5.2), and make sure that an enclave’s page tables can only point into the enclave’s memory, while OS page tables can only point into OS memory (§ 5.3).

Sanctum supports multi-threaded enclaves, and enclaves must appropriately provision for thread state data structures. Enclave threads, like their SGX cousins, run at the lowest privilege level (user level in RISC-V), meaning a malicious enclave cannot compromise the OS. Specifically, enclaves may not execute privileged instructions; address translations that use OS page tables generate page faults when accessing supervisor pages.

The per-enclave metadata used by the security monitor is stored in dedicated DRAM regions (**metadata regions**), each managed at the page level by the OS, and each includes a page map that is used by the security monitor to verify the OS’ decisions (much like the EPC and EPCM in SGX, respectively). Unlike SGX’s EPC, the metadata region pages only store enclave and thread metadata. Figure 3 shows how these structures are weaved together.

Sanctum considers system software to be untrusted, and governs transitions into and out of enclave code. An enclave’s host application **enters an enclave** via a security monitor call that locks a thread state area, and transfers control to its entry point. After completing its intended task, the enclave code **exits** by asking the monitor to unlock the thread’s state area, and transfer control back to the host application.

Enclaves cannot make system calls directly: we cannot trust the OS to restore an enclave’s execution state, so the

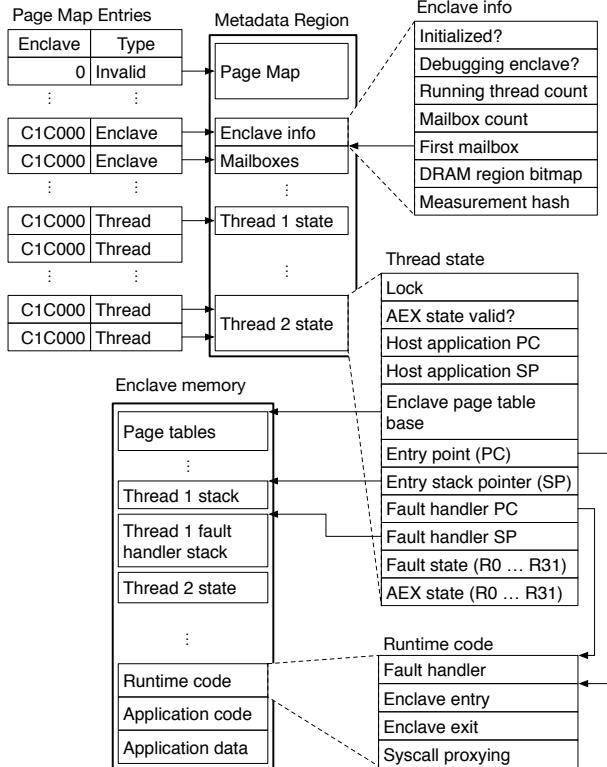

Figure 3: Enclave layout and data structures

enclave’s runtime must ask the host application to proxy syscalls such as file system and network I/O requests.

Sanctum’s security monitor is the first responder for interrupts: an interrupt received during enclave execution causes an *asynchronous enclave exit* (AEX), whereby the monitor saves the core’s registers in the current thread’s AEX state area, zeroes the registers, exits the enclave, and dispatches the interrupt as if it was received by the code entering the enclave.

Unlike SGX, resuming enclave execution after an AEX means re-entering the enclave using its normal entry point, and having the enclave’s code ask the security monitor to restore the pre-AEX execution state. Sanctum enclaves are aware of asynchronous exits so they can implement security policies. For example, an enclave thread that performs time-sensitive work, such as periodic I/O, may terminate itself if it ever gets preempted by an AEX.

The security monitor configures the CPU to dispatch all faults occurring within an enclave directly to the enclave’s designated fault handler, which is expected to be implemented by the enclave’s runtime (SGX sanitizes and dispatches faults to the OS). For example, a libc runtime would translate faults into UNIX signals which, by default, would exit the enclave. It is possible, though not advisable for performance reasons (§ 6.3), for a runtime to handle page faults and implement demand paging

securely, and robust against the attacks described in [55].

Unlike SGX, we isolate each enclave’s data throughout the system’s cache hierarchy. The security monitor flushes per-core caches, such as the L1 cache and the TLB, whenever a core jumps between enclave and non-enclave code. *Last-level cache* (LLC) isolation is achieved by a simple partitioning scheme supported by Sanctum’s hardware extensions (§ 5.1).

Sanctum’s strong isolation yields a simple security model for application developers: *all computation that executes inside an enclave, and only accesses data inside the enclave, is protected from any attack mounted by software outside the enclave*. All communication with the outside world, including accesses to non-enclave memory, is subject to attacks.

We assume that the enclave runtime implements the security measures needed to protect the enclave’s communication with other software modules. For example, any algorithm’s memory access patterns can be protected by ensuring that the algorithm only operates on enclave data. The runtime can implement this protection simply by copying any input buffer from non-enclave memory into the enclave before computing on it.

The enclave runtime can use Native Client’s approach [57] to ensure that the rest of the enclave software only interacts with the host application via the runtime to mitigate potential security vulnerabilities in enclave software.

The lifecycle of a Sanctum enclave closely resembles the lifecycle of its SGX equivalent. An enclave is created when its host application performs a system call asking the OS to create an enclave from a dynamically loadable module (.so or .d11 file). The OS invokes the security monitor to assign DRAM resources to the enclave, and to load the initial code and data pages into the enclave. Once all the pages are loaded, the enclave is marked as initialized via another security monitor call.

Our software attestation scheme is a simplified version of SGX’s scheme, and reuses a subset of its concepts. The data used to initialize an enclave is cryptographically hashed, yielding the enclave’s *measurement*. An enclave can invoke a secure inter-enclave messaging service to send a message to a privileged *attestation enclave* that can access the security monitor’s attestation key, and produces the attestation signature.

5 Hardware Modifications

5.1 LLC Address Input Transformation

Figure 4 depicts a physical address in a toy computer with 32-bit virtual addresses and 21-bit physical addresses, 4,096-byte pages, a set-associative LLC with 512 sets and 64-byte lines, and 256 KB of DRAM.

The location where a byte of data is cached in the

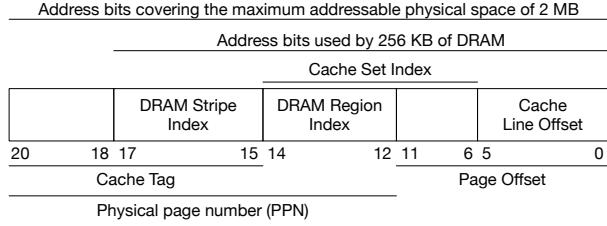

Figure 4: Interesting bit fields in a physical address

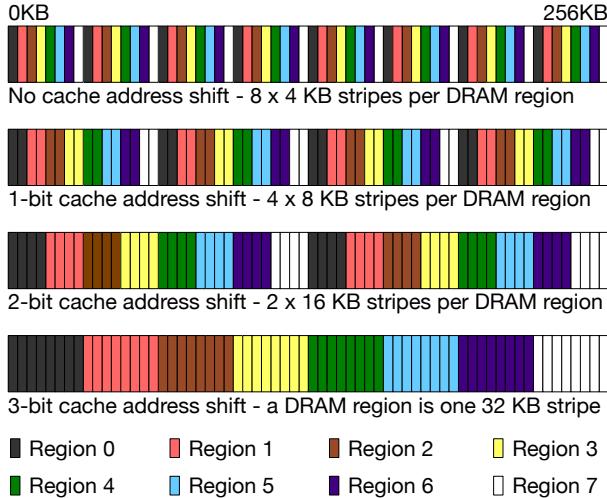

Figure 5: Address shift for contiguous DRAM regions

LLC depends on the low-order bits in the byte's physical address. The *set index* determines which of the LLC lines can cache the line containing the byte, and the *line offset* locates the byte in its cache line. A virtual address's low-order bits make up its *page offset*, while the other bits are its *virtual page number* (VPN). Address translation leaves the page offset unchanged, and translates the VPN into a *physical page number* (PPN), based on the mapping specified by the page tables.

We define the **DRAM region index** in a physical address as the intersection between the PPN bits and the cache index bits. This is the maximal set of bits that impact cache placement *and* are determined by privileged software via page tables. We define a **DRAM region** to be the subset of DRAM with addresses having the same DRAM region index. In Figure 4, for example, address bits [14...12] are the DRAM region index, dividing the physical address space into 8 DRAM regions.

In a typical system without Sanctum's hardware extensions, DRAM regions are made up of multiple continuous **DRAM stripes**, where each stripe is exactly one page long. The top of Figure 5 drives this point home, by showing the partitioning of our toy computer's 256 KB of DRAM into DRAM regions. The fragmentation of

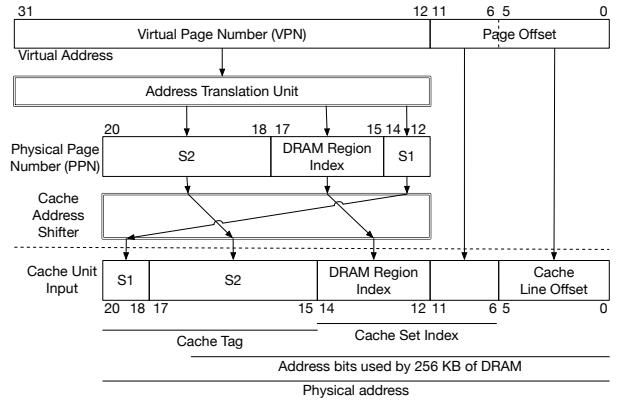

Figure 6: Cache address shifter, 3 bit PPN rotation

DRAM regions makes it difficult for the OS to allocate contiguous DRAM buffers, which are essential to the efficient DMA transfers used by high performance devices. In our example, if the OS only owns 4 DRAM regions, the largest contiguous DRAM buffer it can allocate is 16 KB.

We observed that, up to a certain point, circularly shifting (rotating) the PPN of a physical address to the right by one bit, before it enters the LLC, doubles the size of each DRAM stripe and halves the number of stripes in a DRAM region, as illustrated in Figure 5.

Sanctum takes advantage of this effect by adding a **cache address shifter** that circularly shifts the PPN to the right by a certain amount of bits, as shown in Figures 6 and 7. In our example, configuring the cache address shifter to rotate the PPN by 3 yields contiguous DRAM regions, so an OS that owns 4 DRAM regions could hypothetically allocate a contiguous DRAM buffer covering half of the machine's DRAM.

The cache address shifter's configuration depends on the amount of DRAM present in the system. If our example computer could have 128 KB - 1 MB of DRAM, its cache address shifter must support shift amounts from 2 to 5. Such a shifter can be implemented via a 3-position variable shifter circuit (series of 8-input MUXes), and a fixed shift by 2 (no logic). Alternatively, in systems with known DRAM configuration (embedded, SoC, etc.), the shift amount can be fixed, and implemented with no logic.

5.2 Page Walker Input

Sanctum's per-enclave page tables require an enclave page table base register `eptbr` that stores the physical address of the currently running enclave's page tables, and has similar semantics to the page table base register `ptbr` pointing to the operating system-managed page tables. These registers may only be accessed by the Sanctum security monitor, which provides an API call for the OS

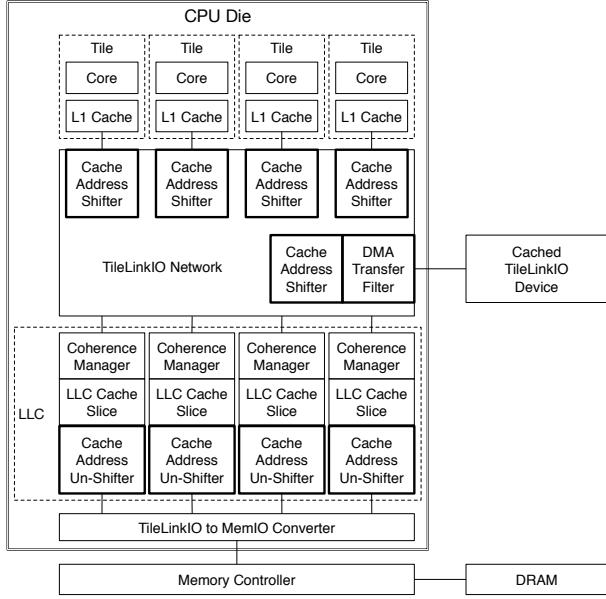

Figure 7: Sanctum’s cache address shifter and DMA transfer filter logic in the context of a Rocket uncore

to modify `ptbr`, and ensures that `eptbr` always points to the current enclave’s page tables.

The circuitry handling TLB misses switches between `ptbr` and `eptbr` based on two registers that indicate the current enclave’s EVRANGE, namely `evbase` (enclave virtual address space base) and `evmask` (enclave virtual address space mask). When a TLB miss occurs, the circuit in Figure 8 selects the appropriate page table base by ANDing the faulting virtual address with the mask register and comparing the output against the base register. Depending on the comparison result, either `eptbr` or `ptbr` is forwarded to the page walker as the page table base address.

5.3 Page Walker Memory Accesses

In modern high-speed CPUs, address translation is performed by a hardware **page walker** that traverses the page tables when a TLB miss occurs. The page walker’s latency greatly impacts the CPU’s performance, so it is implemented as a finite-state machine (FSM) that reads page table entries by issuing DRAM read requests using physical addresses, over a dedicated bus to the L1 cache.

Unsurprisingly, page walker modifications require a lot of engineering effort. At the same time, Sanctum’s security model demands that the page walker only references enclave memory when traversing the enclave page tables, and only references OS memory when translating the OS page tables. Fortunately, we can satisfy these requirements without modifying the FSM. Instead, the security monitor configures the circuit in Figure 9 to ensure that

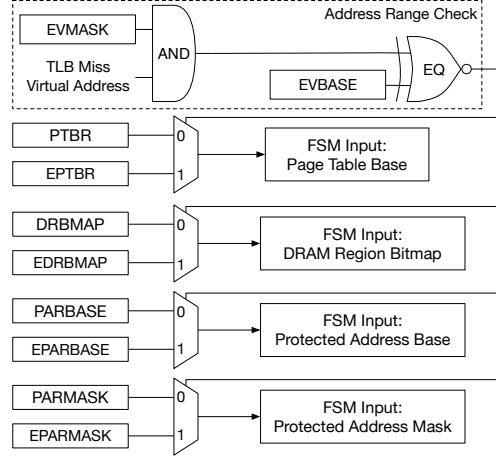

Figure 8: Page walker input for per-enclave page tables

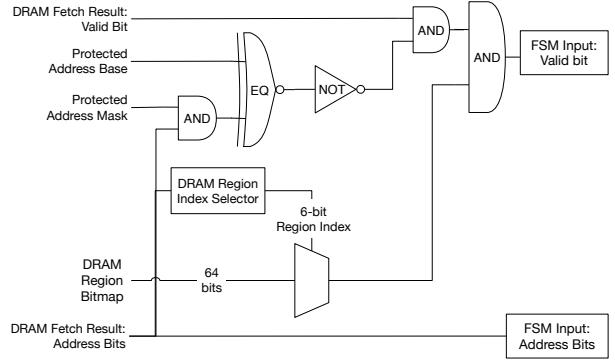

Figure 9: Hardware support for per-enclave page tables: check page table entries fetched by the page walker.

the page tables only point into allowable memory.

Sanctum’s security monitor must guarantee that `ptbr` points into an OS DRAM region, and `eptbr` points into a DRAM region owned by the enclave. This secures the page walker’s initial DRAM read. The circuit in Figure 9 receives each page table entry fetched by the FSM, and sanitizes it before it reaches the page walker FSM.

The security monitor configures the set of DRAM regions that page tables may reference by writing to a DRAM region bitmap (`drbmap`) register. The sanitization circuitry extracts the DRAM region index from the address in the page table entry, and looks it up in the DRAM region bitmap. If the address does not belong to an allowable DRAM region, the sanitization logic forces the page table entry’s valid bit to zero, which will cause the page walker FSM to abort the address translation and signal a page fault.

Sanctum’s security monitor and its attestation key are stored in DRAM regions allocated to the OS. For security reasons, the OS must not be able to modify the monitor’s

code, or to read the attestation key. Sanctum extends the page table entry transformation described above to implement a Protected Address Range (PAR) for each set of page tables.

Each PAR is specified using a base register (`parbase`) register and a mask register (`parmask`) with the same semantics as the variable Memory Type Range registers (MTRRs) in the x86 architecture. The page table entry sanitization logic in Sanctum's hardware extensions checks if each page table entry points into the PAR by ANDing the entry's address with the PAR mask and comparing the result with the PAR base. If a page table entry is seen with a protected address, its valid bit is cleared, forcing a page fault.

The above transformation allows the security monitor to set up a memory range that cannot be accessed by other software, and which can be used to securely store the monitor's code and data. Entry invalidation ensures no page table entries are fetched from the protected range, which prevents the page walker FSM from modifying the protected region by setting accessed and dirty bits.

All registers above are replicated, as Sanctum maintains separate OS and enclave page tables. The security monitor sets up a protected range in the OS page tables to isolate its own code and data structures (most importantly its private attestation key) from a malicious OS.

Figure 10 shows Sanctum’s logic inserted between the page walker and the cache unit that fetches page table entries.

5.4 DMA Transfer Filtering

We whitelist a DMA-safe DRAM region instead of following SGX’s blacklist approach. Specifically, Sanctum adds two registers (a base, dmarbase and an AND mask, dmarmask) to the DMA arbiter (memory controller). The range check circuit shown in Figure 8 compares each DMA transfer’s start and end addresses against the allowed DRAM range, and the DMA arbiter drops transfers that fail the check.

6 Software Design

Sanctum's chain of trust, discussed in § 6.1, diverges significantly from SGX. We replace SGX's microcode with a software security monitor that runs at a higher privilege level than the hypervisor and the OS. On RISC-V, the security monitor runs at machine level. Our design only uses one privileged enclave, the signing enclave, which behaves similarly to SGX's Quoting Enclave.

6.1 Attestation Chain of Trust

Sanctum has three pieces of trusted software: the measurement root, which is burned in on-chip ROM, the security monitor (§ 6.2), which must be stored alongside

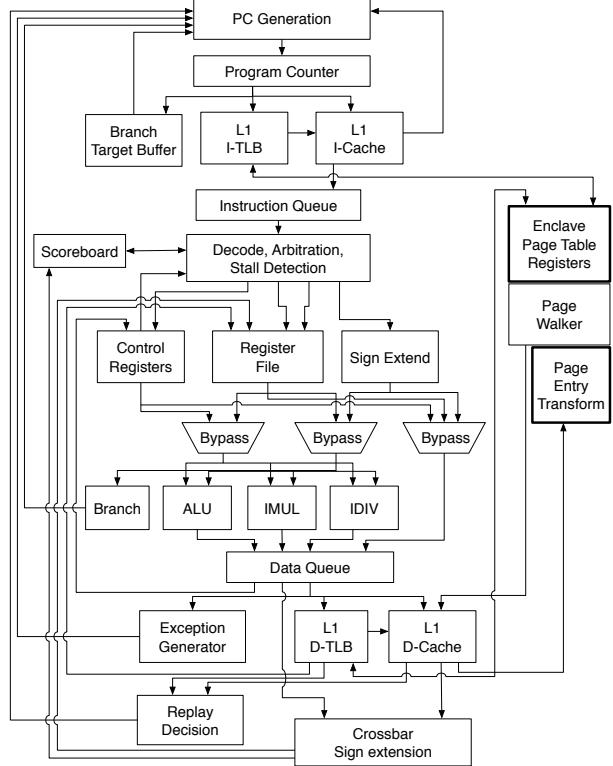

Figure 10: Sanctum’s page entry transformation logic in the context of a Rocket core

the computer's firmware (usually in flash memory), and the signing enclave, which can be stored in any untrusted storage that the OS can access.

We expect the trusted software to be amenable to rigorous analysis: our implementation of a security monitor for Sanctum is written with verification in mind, and has fewer than 5 kloc of C++, including a subset of the standard library and the cryptography for enclave attestation.

6.1.1 The Measurement Root

The measurement root (`mroot`) is stored in a ROM at the top of the physical address space, and covers the reset vector. Its main responsibility is to compute a cryptographic hash of the security monitor and generate a monitor attestation key pair and certificate based on the monitor's hash, as shown in Figure 11.

The security monitor is expected to be stored in non-volatile memory (such as an SPI flash chip) that can respond to memory I/O requests from the CPU, perhaps via a special mapping in the computer's chipset. When `mroot` starts executing, it computes a cryptographic hash over the security monitor. `mroot` then reads the processor's key derivation secret, and derives a symmetric key based on the monitor's hash. `mroot` will eventually hand

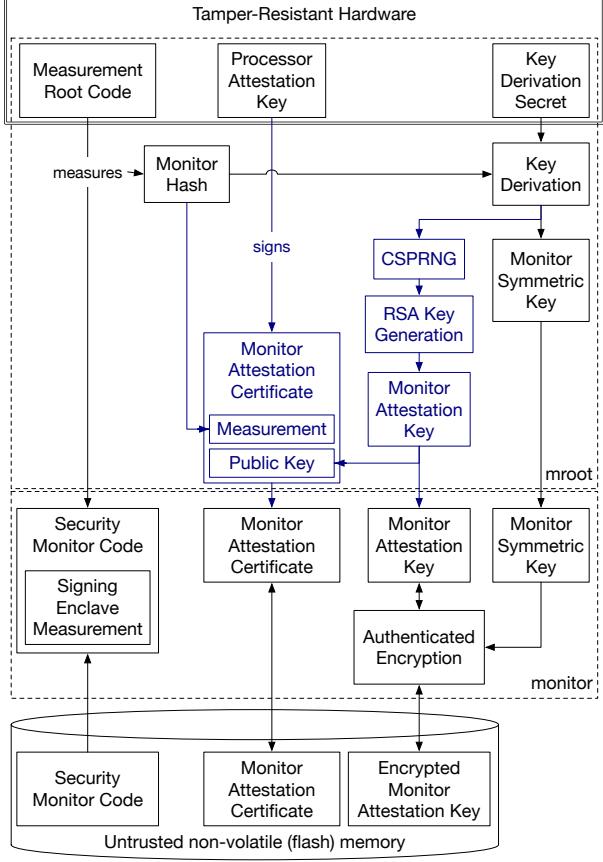

Figure 11: Sanctum’s root of trust is a measurement root routine burned into the CPU’s ROM. This code reads the security monitor from flash memory and generates an attestation key and certificate based on the monitor’s hash. Asymmetric key operations, colored in blue, are only performed the first time a monitor is used on a computer.

down the key to the monitor.

The security monitor contains a header that includes the location of an attestation key existence flag. If the flag is not set, the measurement root generates a monitor attestation key pair, and produces a monitor attestation certificate by signing the monitor’s public attestation key with the processor’s private attestation key. The monitor attestation certificate includes the monitor’s hash.

`mroot` generates a symmetric key for the security monitor so it may encrypt its private attestation key and store it in the computer’s SPI flash memory chip. When writing the key, the monitor also sets the monitor attestation key existence flag, instructing future boot sequences not to regenerate a key. The public attestation key and certificate can be stored unencrypted in any untrusted memory.

Before handing control to the monitor, `mroot` sets a lock that blocks any software from reading the processor’s symmetric key derivation seed and private key until a reset

occurs. This prevents a malicious security monitor from deriving a different monitor’s symmetric key, or from generating a monitor attestation certificate that includes a different monitor’s measurement hash.

The symmetric key generated for the monitor is similar in concept to the Seal Keys produced by SGX’s key derivation process, as it is used to securely store a secret (the monitor’s attestation key) in untrusted memory, in order to avoid an expensive process (asymmetric key attestation and signing). Sanctum’s key derivation process is based on the monitor’s measurement, so a given monitor is guaranteed to get the same key across power cycles. The cryptographic properties of the key derivation process guarantee that a malicious monitor cannot derive the symmetric key given to another monitor.

6.1.2 The Signing Enclave

In order to avoid timing attacks, the security monitor does not compute attestation signatures directly. Instead, the signing algorithm is executed inside a signing enclave, which is a security monitor module that executes in an enclave environment, so it is protected by the same isolation guarantees that any other Sanctum enclave enjoys.

The signing enclave receives the monitor’s private attestation key via an API call. When the security monitor receives the call, it compares the calling enclave’s measurement with the known measurement of the signing enclave. Upon a successful match, the monitor copies its attestation key into enclave memory using a data-independent sequence of memory accesses, such as `memcpy`. This way, the monitor’s memory access pattern does not leak the private attestation key.

Sanctum’s signing enclave authenticates another enclave on the computer and securely receives its attestation data using mailboxes (§ 6.2.5), a simplified version of SGX’s local attestation (reporting) mechanism. The enclave’s measurement and attestation data are wrapped into a software attestation signature that can be examined by a remote verifier. Figure 12 shows the chain of certificates and signatures in an instance of software attestation.

6.2 Security Monitor

The security monitor receives control after `mroot` finishes setting up the attestation measurement chain.

The monitor provides API calls to the OS and enclaves for **DRAM region allocation** and **enclave management**. The monitor guards sensitive registers, such as the page table base register (`ptbr`) and the allowed DMA range (`dmabase` and `dmarmask`). The OS can set these registers via monitor calls that ensure the register values are consistent with the current DRAM region allocation.

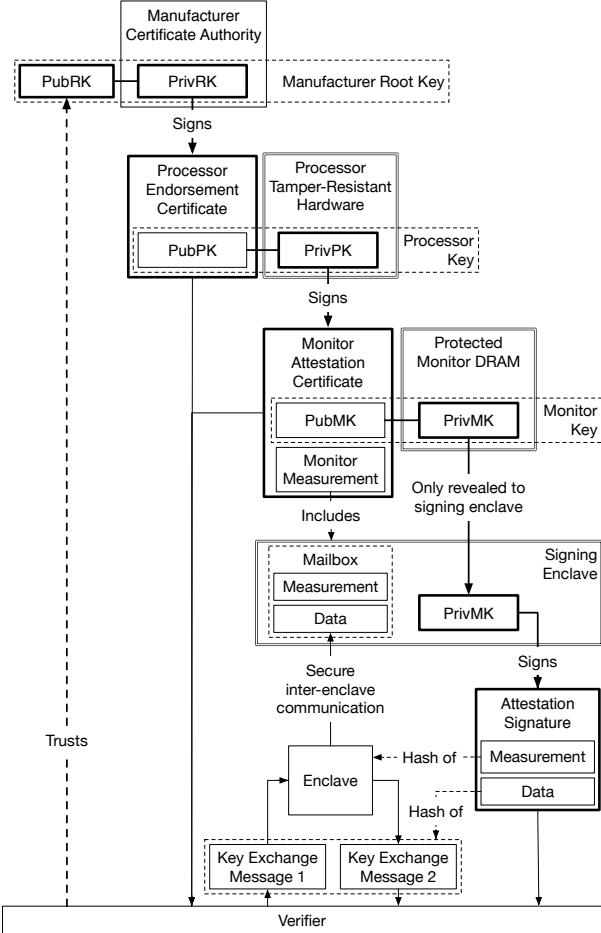

Figure 12: The certificate chain behind Sanctum’s software attestation signatures

6.2.1 DRAM Regions

Figure 13 shows the DRAM region allocation state transition diagram. After the system boots up, all DRAM regions are allocated to the OS, which can free up DRAM regions so it can re-assign them to enclaves or to itself. A DRAM region can only become free after it is blocked by its owner, which can be the OS or an enclave. While a DRAM region is blocked, any address translations mapping to it cause page faults, so no new TLB entries will be created for that region. Before the OS frees the blocked region, it must flush all the cores’ TLBs, to remove any stale entries for the region.

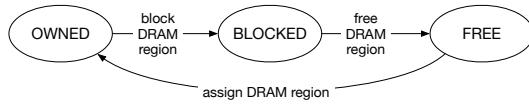

Figure 13: DRAM region allocation states and API calls

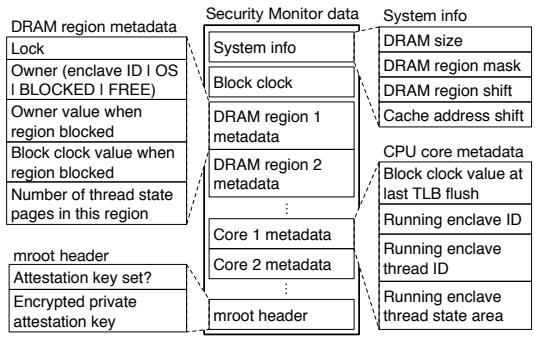

Figure 14: Security monitor data structures

The monitor ensures that the OS performs TLB shootdowns, using a global *block clock*. When a region is blocked, the block clock is incremented, and the current block clock value is stored in the metadata associated with the DRAM region (shown in Figure 3). When a core’s TLB is flushed, that core’s flush time is set to the current block clock value. When the OS asks the monitor to free a blocked DRAM region, the monitor verifies that no core’s flush time is lower than the block clock value stored in the region’s metadata. As an optimization, freeing a region owned by an enclave only requires TLB flushes on the cores running that enclave’s threads. No other core can have TLB entries for the enclave’s memory.

The region blocking mechanism guarantees that when a DRAM region is assigned to an enclave or the OS, no stale TLB mappings associated with the DRAM region exist. The monitor uses the MMU extensions described in § 5.2 and § 5.3 to ensure that once a DRAM region is assigned, no software other than the region’s owner may create TLB entries pointing inside the DRAM region. Together, these mechanisms guarantee that the DRAM regions allocated to an enclave cannot be accessed by the operating system or by another enclave.

6.2.2 Metadata Regions

Since the security monitor sits between the OS and enclave, and its APIs can be invoked by both sides, it is an easy target for timing attacks. We prevent these attacks with a straightforward policy that states the security monitor is never allowed to access enclave data, and is not allowed to make memory accesses that depend on the attestation key material. The rest of the data handled by the monitor is derived from the OS’ actions, so it is already known to the OS.

A rather obvious consequence of the policy above is that after the security monitor boots the OS, it cannot perform any cryptographic operations that use keys. For example, the security monitor cannot compute an attestation signature directly, and defers that operation to a sign-

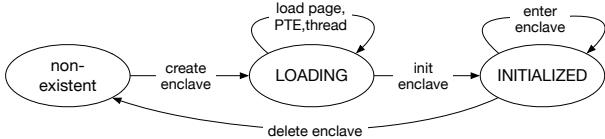

Figure 15: Enclave states and enclave management API calls

ing enclave (§ 6.1.2). While it is possible to implement some cryptographic primitives without performing data-dependent accesses, the security and correctness proofs behind these implementations are non-trivial. For this reason, Sanctum avoids depending on any such implementation.

A more subtle aspect of the access policy outlined above is that the metadata structures that the security monitor uses to operate enclaves cannot be stored in DRAM regions owned by enclaves, because that would give the OS an indirect method of accessing the LLC sets that map to enclave’s DRAM regions, which could facilitate a cache timing attack.

For this reason, the security monitor requires the OS to set aside at least one DRAM region for enclave metadata before it can create enclaves. The OS has the ability to free up the metadata DRAM region, and regain the LLC sets associated with it, if it predicts that the computer’s workload will not involve enclaves.

Each DRAM region that holds enclave metadata is managed independently from the other regions, at page granularity. The first few pages of each region contain a page map that tracks the enclave that tracks the usage of each metadata page, specifically the enclave that it is assigned to, and the data structure that it holds.

Each metadata region is like an EPC region in SGX, with the exception that our metadata regions only hold special pages, like Sanctum’s equivalent of SGX’s Secure Enclave Control Structure (SECS) and the Thread Control Structure (TCS). These structures will be described in the following sections.

The data structures used to store Sanctum’s metadata can span multiple pages. When the OS allocates such a structure in a metadata region, it must point the monitor to a sequence of free pages that belong to the same DRAM region. All the pages needed to represent the structure are allocated and released in one API call.

6.2.3 Enclave Lifecycle

The lifecycle of a Sanctum enclave is very similar to that of its SGX counterparts, as shown in Figure 15.

The OS creates an enclave by issuing a *create enclave* call that creates the enclave metadata structure, which is Sanctum’s equivalent of the SECS. The enclave metadata

structure contains an array of mailboxes whose size is established at enclave creation time, so the number of pages required by the structure varies from enclave to enclave. § 6.2.5 describes the contents and use of mailboxes.

The *create enclave* API call initializes the enclave metadata fields shown in Figure 3, and places the enclave in the LOADING state. While the enclave is in this state, the OS sets up the enclave’s initial state via monitor calls that assign DRAM regions to the enclave, create hardware threads and page table entries, and copy code and data into the enclave. The OS then issues a monitor call to transition the enclave to the INITIALIZED state, which finalizes its measurement hash. The application hosting the enclave is now free to run enclave threads.

Sanctum stores a measurement hash for each enclave in its metadata area, and updates the measurement to account for every operation performed on an enclave in the LOADING state. The policy described in § 6.2.2 does not apply to the secure hash operations used to update enclave’s measurement, because all the data used to compute the hash is already known to the OS.

Enclave metadata is stored in a metadata region (§ 6.2.2), so it can only be accessed by the security monitor. Therefore, the metadata area can safely store public information with integrity requirements, such as the enclave’s measurement hash.

While an OS loads an enclave, it is free to map the enclave’s pages, but the monitor maintains its page tables ensuring all entries point to non-overlapping pages in DRAM owned by the enclave. Once an enclave is initialized, it can inspect its own page tables and abort if the OS created undesirable mappings. Simple enclaves do not require specific mappings. Complex enclaves are expected to communicate their desired mappings to the OS via out-of-band metadata not covered by this work.

Our monitor ensures that page tables do not overlap by storing the last mapped page’s physical address in the enclave’s metadata. To simplify the monitor, a new mapping is allowed if its physical address is greater than that of the last, constraining the OS to map an enclave’s DRAM pages in monotonically increasing order.

6.2.4 Enclave Code Execution

Sanctum closely follows the threading model of SGX enclaves. Each CPU core that executes enclave code uses a thread metadata structure, which is our equivalent of SGX’s TCS combined with SGX’s State Save Area (SSA). Thread metadata structures are stored in a DRAM region dedicated to enclave metadata in order to prevent a malicious OS from mounting timing attacks against an enclave by causing AEXes on its threads. Figure 16 shows the lifecycle of a thread metadata structure.

The OS turns a sequence of free pages in a metadata

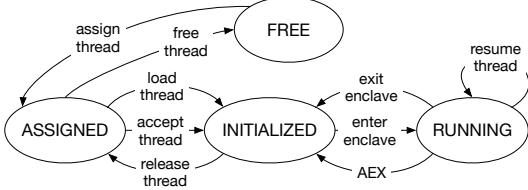

Figure 16: Enclave thread metadata structure states and thread-related API calls

region into an uninitialized thread structure via an *allocate thread* monitor call. During enclave loading, the OS uses a *load thread* monitor call to initialize the thread structure with data that contributes to the enclave’s measurement. After an enclave is initialized, it can use an *accept thread* monitor call to initialize its thread structure.

The application hosting an enclave starts executing enclave code by issuing an *enclave enter* API call, which must specify an initialized thread structure. The monitor honors this call by configuring Sanctum’s hardware extensions to allow access to the enclave’s memory, and then by loading the program counter and stack pointer registers from the thread’s metadata structure. The enclave’s code can return control to the hosting application voluntarily, by issuing an *enclave exit* API call, which restores the application’s PC and SP from the thread state area and sets the API call’s return value to `ok`.

When performing an AEX, the security monitor atomically tests-and-sets the *AEX state valid* flag in the current thread’s metadata. If the flag is clear, the monitor stores the core’s execution state in the thread state’s AEX area. Otherwise, the enclave thread was resuming from an AEX, so the monitor does not change the AEX area. When the host application re-enters the enclave, it will resume from the previous AEX. This reasoning avoids the complexity of SGX’s state stack.

If an interrupt occurs while the enclave code is executing, the security monitor’s exception handler performs an AEX, which sets the API call’s return value to `async_exit`, and invokes the standard interrupt handling code. After the OS handles the interrupt, the enclave’s host application resumes execution, and re-executes the *enter enclave* API call. The enclave’s thread initialization code examines the saved thread state, and seeing that the thread has undergone an AEX, issues a *resume thread* API call. The security monitor restores the enclave’s registers from the thread state area, and clears the AEX flag.

6.2.5 Mailboxes

Sanctum’s software attestation process relies on *mailboxes*, which are a simplified version of SGX’s local attestation mechanism. We could not follow SGX’s approach

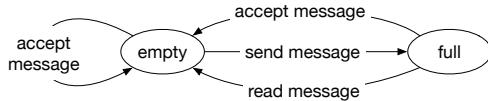

Figure 17: Mailbox states and security monitor API calls related to inter-enclave communication

because it relies on key derivation and MAC algorithms, and our timing attack avoidance policy (§ 6.2.2) states that the security monitor is not allowed to perform cryptographic operations that use keys.

Each enclave’s metadata area contains an array of mailboxes, whose size is specified at enclave creation time, and covered by the enclave’s measurement. Each mailbox goes through the lifecycle shown in Figure 17.

An enclave that wishes to receive a message in a mailbox, such as the signing enclave, declares its intent by performing an *accept message* monitor call. The API call is used to specify the mailbox that will receive the message, and the identity of the enclave that is expected to send the message.

The sending enclave, which is usually the enclave wishing to be authenticated, performs a *send message* call that specifies the identity of the receiving enclave, and a mailbox within that enclave. The monitor only delivers messages to mailboxes that expect them. At enclave initialization, the expected sender for all mailboxes is an invalid value (all zeros), so the enclave will not receive messages until it calls *accept message*.

When the receiving enclave is notified via an out-of-band mechanism that it has received a message, it issues a *read message* call to the monitor, which moves the message from the mailbox into the enclave’s memory. If the API call succeeds, the receiving enclave is assured that the message was sent by the enclave whose identity was specified in the *accept message* call.

Enclave mailboxes are stored in metadata regions (§ 6.2.2), which cannot be accessed by any software other than the security monitor. This guarantees the privacy, integrity, and freshness of the messages sent via the mailbox system.

Our mailbox design has the downside that both the sending and receiving enclave need to be alive in DRAM in order to communicate. By comparison, SGX’s local attestation can be done asynchronously. In return, mailboxes do not require any cryptographic operations, and have a much simpler correctness argument.

6.2.6 Multi-Core Concurrency

The security monitor is highly concurrent, with fine-grained locks. API calls targeting two different enclaves may be executed in parallel on different cores. Each

DRAM region has a lock guarding that region’s metadata. An enclave is guarded by the lock of the DRAM region holding its metadata. Each thread metadata structure also has a lock guarding it, which is acquired when the structure is accessed, but also while the metadata structure is used by a core running enclave code. Thus, the *enter enclave* call acquires a slot lock, which is released by an *enclave exit* call or by an AEX.

We avoid deadlocks by using a form of optimistic locking. Each monitor call attempts to acquire all the locks it needs via atomic test-and-set operations, and errors with a `concurrent_call` code if any lock is unavailable.

6.3 Enclave Eviction

General-purpose software can be enclaved without source code changes, provided that it is linked against a runtime (e.g., *libc*) modified to work with Sanctum. Any such runtime would be included in the TCB.

The Sanctum design allows the operating system to over-commit physical memory allocated to enclaves, by collaborating with an enclave to page some of its DRAM regions to disk. Sanctum does not give the OS visibility into enclave memory accesses, in order to prevent private information leaks, so the OS must decide the enclave whose DRAM regions will be evicted based on other activity, such as network I/O, or based on a business policy, such as Amazon EC2’s spot instances.

Once a victim enclave has been decided, the OS asks the enclave to block a DRAM region (cf. Figure 13), giving the enclave an opportunity to rearrange data in its RAM regions. DRAM region management can be transparent to the programmer if handled by the enclave’s runtime. The presented design requires each enclave to always occupy at least one DRAM region, which contains enclave data structures and the memory management code described above. Evicting all of a live enclave’s memory requires an entirely different scheme that is deferred to future work.

The security monitor does not allow the OS to forcibly reclaim a single DRAM region from an enclave, as doing so would leak memory access patterns. Instead, the OS can delete an enclave, after stopping its threads, and reclaim all its DRAM regions. Thus, a small or short-running enclave may well refuse DRAM region management requests from the OS, and expect the OS to delete and restart it under memory pressure.

To avoid wasted work, large long-running enclaves may elect to use demand paging to overcommit their DRAM, albeit with the understanding that demand paging leaks page-level access patterns to the OS. Securing this mechanism requires the enclave to obfuscate its page faults via periodic I/O using oblivious RAM techniques, as in the Ascend processor [20], applied at page rather than cache line granularity, and with integrity verification.

This carries a high overhead: even with a small chance of paging, an enclave must generate periodic page faults, and access a large set of pages at each period. Using an analytic model, we estimate the overhead to be upwards of 12ms per page per period for a high-end 10K RPM drive, and 27ms for a value hard drive. Given the number of pages accessed every period grows with an enclave’s data size, the costs are easily prohibitive. While SSDs may alleviate some of this prohibitive overhead, and will be investigated in future work, currently Sanctum focuses on securing enclaves without demand paging.

Enclaves that perform other data-dependent communication, such as targeted I/O into a large database file, must also use the periodic oblivious I/O to obfuscate their access patterns from the operating system. These techniques are independent of application business logic, and can be provided by libraries such as database access drivers.

7 Security Argument

Our security argument rests on two pillars: the enclave isolation enforced by the security monitor, and the guarantees behind the software attestation signature. This section outlines correctness arguments for each of these pillars.

Sanctum’s isolation primitives protect enclaves from outside software that attempts to observe or interact with the enclave software via means outside the interface provided by the security monitor. We prevent direct attacks by ensuring that the memory owned by an enclave can only be accessed by that enclave’s software. More subtle attacks are foiled by also isolating the structures used to access the enclave’s memory, such as the enclave’s page tables and the caches that hold enclave data.

7.1 Protection Against Direct Attacks

The correctness proof for Sanctum’s DRAM isolation can be divided into two sub-proofs that cover the hardware and software sides of the system. First, we need to prove that the page walker modifications described in § 5.2 and § 5.3 behave according to their descriptions. Thanks to the small sizes of the circuits involved, this sub-proof can be accomplished by simulating the circuits for all logically distinct input cases. Second, we must prove that the security monitor configures Sanctum’s extended page walker registers in a way that prevents direct attacks on enclaves. This part of the proof is significantly more complex, but it follows the same outline as the proof for SGX’s memory access protection presented in [13].

The proof revolves around a main invariant stating that all TLB entries in every core are consistent with the programming model described in § 4. The invariant breaks down into three cases that match [13], after substituting DRAM regions for pages.

7.2 Protection Against Subtle Attacks

Sanctum also protects enclaves from software attacks that attempt to exploit side channels to obtain information indirectly. We focus on proving that Sanctum protects against the attacks mentioned in § 2, which target the page fault address and cache timing side-channels.

The proof that Sanctum foils page fault attacks is centered around the claims that each enclave’s page fault handler and page tables and page fault handler are isolated from all other software entities on the computer. First, all the page faults inside an enclave’s EVRANGE are reported to the enclave’s fault handler, so the OS cannot observe the virtual addresses associated with the faults. Second, page table isolation implies that the OS cannot access an enclave’s page tables and read the access and dirty bits to learn memory access patterns.

Page table isolation is a direct consequence of the claim that Sanctum correctly protects enclaves against direct attacks, which was covered above. Each enclave’s page tables are stored in DRAM regions allocated to the enclave, so no software outside the enclave can access these page tables.

The proof behind Sanctum’s cache isolation is straightforward but tedious, as there are many aspects involved. We start by peeling off the easier cases, and tackle the most difficult step of the proof at the end of the section. Our design assumes the presence of both per-core caches and a shared LLC, and each cache type requires a separate correctness argument. Per-core cache isolation is achieved simply by flushing per-core caches at every transition between enclave and non-enclave mode. To prove the correctness of LLC isolation, we first show that enclaves do not share LLC lines with outside software, and then we show that the OS cannot indirectly reach into an enclave’s LLC lines via the security monitor.

Showing that enclaves do not share LLC lines with outside software can be accomplished by proving a stronger invariant that states at all times, any LLC line that can potentially cache a location in an enclave’s memory cannot cache any location outside that enclave’s memory. In steady state, this follows directly from the LLC isolation scheme in § 5.1, because the security monitor guarantees that each DRAM region is assigned to exactly one enclave or to the OS.

Last, we focus on the security monitor, because it is the only piece of software outside an enclave that can access the enclave’s DRAM regions. In order to claim that an enclave’s LLC lines are isolated from outside software, we must prove that the OS cannot use the security monitor’s API to indirectly modify the state of the enclave’s LLC lines. This proof is accomplished by considering each function exposed by the monitor API, as well as the monitor’s hardware fault handler. The latter is considered to be under OS control because in a worst case

scenario, a malicious OS could program peripherals to cause interrupts as needed to mount a cache timing attack.

7.3 Operating System Protection

Sanctum protects the operating system from direct attacks against malicious enclaves, but does not protect it against subtle attacks that take advantage of side-channels. Our design assumes that software developers will transition all sensitive software into enclaves, which are protected even if the OS is compromised. At the same time, a honest OS can potentially take advantage of Sanctum’s DRAM regions to isolate mutually mistrusting processes.

Proving that a malicious enclave cannot attack the host computer’s operating system is accomplished by first proving that the security monitor’s APIs that start executing enclave code always place the core in unprivileged mode, and then proving that the enclave can only access OS memory using the OS-provided page tables. The first claim can be proven by inspecting the security monitor’s code. The second claim follows from the correctness proof of the circuits in § 5.2 and § 5.3. Specifically, each enclave can only access memory either via its own page tables or the OS page tables, and the enclave’s page tables cannot point into the DRAM regions owned by the OS.

These two claims effectively show that Sanctum enclaves run with the privileges of their host application. This parallels SGX, so all arguments about OS security in [13] apply to Sanctum as well. Specifically, malicious enclaves cannot DoS the OS, and can be contained using the mechanisms that currently guard against malicious user software.

7.4 Security Monitor Protection

The security monitor is in Sanctum’s TCB, so the system’s security depends on the monitor’s ability to preserve its integrity and protect its secrets from attackers. The monitor does not use address translation, so it is not exposed to any attacks via page tables. The monitor also does not protect itself from cache timing attacks, and instead avoids making any memory accesses that would reveal sensitive information.

Proving that the monitor is protected from direct attacks from a malicious OS or enclave can be accomplished in a few steps. First, we invoke the proof that the circuits in § 5.2 and § 5.3, are correct. Second, we must prove that the security monitor configures Sanctum’s extended page walker registers correctly. Third, we must prove that the DRAM regions that contain monitor code or data are always allocated to the OS.

Since the monitor is exposed to cache timing attacks from the OS, Sanctum’s security guarantees rely on proofs that the attacks would not yield any information that the OS does not already have. Fortunately, most of the secu-

riety monitor implementation consists of acknowledging and verifying the OS’ resource allocation decisions. The main piece of private information held by the security monitor is the attestation key. We can be assured that the monitor does not leak this key, as long as we can prove that the monitor implementation only accesses the key when it is provided to the signing enclave (§ 6.1.2), that the key is provided via a data-independent memory copy operation, such as `memcpy`, and that the attestation key is only disclosed to the signing enclave.

7.5 The Security of Software Attestation

The security of Sanctum’s software attestation scheme depends on the correctness of the measurement root and the security monitor. `mroot`’s sole purpose is to set up the attestation chain, so the attestation’s security requires the correctness of the entire `mroot` code. The monitor’s enclave measurement code also plays an essential role in the attestation process, because it establishes the identity of the attested enclaves, and is also used to distinguish between the signing enclave and other enclaves. Sanctum’s attestation also relies on mailboxes, which are used to securely transmit attestation data from the attested enclave to the signing enclave.

8 Performance Evaluation

While we propose a high-level set of hardware and software to implement Sanctum, we focus our evaluation on the concrete example of a 4-core RISC-V system generated by Rocket Chip [29]. Sanctum conveniently isolates concurrent workloads from one another, so we can examine its overhead via individual applications on a single core, discounting the effect of other running software.

8.1 Experiment Design

We use a Rocket-Chip generator modified to model Sanctum’s additional hardware (§ 5) to generate a 4-core 64-bit RISC-V CPU. Using a cycle-accurate simulator for this machine, coupled with a custom Sanctum cache hierarchy simulator, we compute the program completion time for each benchmark, in cycles, for a variety of DRAM region allocations. The Rocket chip has an in-order single issue pipeline, and does not make forward progress on a TLB or cache miss, which allows us to accurately model a variety of DRAM region allocations efficiently.

We use a vanilla Rocket-Chip as an insecure baseline, against which we compute Sanctum’s overheads. To produce the analysis in this section, we simulated over 250 billion instructions against the insecure baseline, and over 275 billion instructions against the Sanctum simulator. We compute the completion time for various enclave configurations from the simulator’s detailed event log.

Our cache hierarchy follows Intel’s Skylake [23] server models, with 32KB 8-way set associative L1 data and instruction caches, 256KB 8-way L2, and an 8MB 16-way LLC partitioned into core-local slices. Our cache hit and miss latencies follow the Skylake caches. We use a simple model for DRAM accesses and assume unlimited DRAM bandwidth, and a fixed cycle latency for each DRAM access. We also omit an evaluation of the on-chip network and cache coherence overhead, as we do not make any changes that impact any of these subsystems.

Using the hardware model above, we benchmark the integer subset of SPECINT 2006 [3] benchmarks (unmodified), specifically `perlbench`, `bzip2`, `gcc`, `mcf`, `gobmk`, `hmmer`, `sjeng`, `libquantum`, `h264ref`, `omnetpp`, and `astar_base`. This is a mix of memory and compute-bound long-running workloads with diverse locality.

We simulate a machine with 4GB of memory that is divided into 64 DRAM regions by Sanctum’s cache address indexing scheme. Scheduling each benchmark on Core 0, we run it to completion, while the other cores are idling. While we do model its overheads, we choose not to simulate a complete Linux kernel, as doing so would invite a large space of parameters of additional complexity. To this end, we modify the RISC-V proto kernel [48] to provide the few services used by our benchmarks (such as filesystem io), while accounting for the expected overhead of each system call.

8.2 Cost of Added Hardware

Sanctum’s hardware changes add relatively few gates to the Rocket chip, but do increase its area and power consumption. Like SGX, we avoid modifying the core’s critical path: while our addition to the page walker (as analyzed in the next section) may increase the latency of TLB misses, it does not increase the Rocket core’s clock cycle, which is competitive with an ARM Cortex-A5 [29].

As illustrated at the gate level in Figures 8 and 9, we estimate Sanctum to add to Rocket hardware 500 (+0.78%) gates and 700 (+1.9%) flip-flops per core. Precisely, 50 gates for cache index calculation, 1000 gates and 700 flip-flops for the extra address page walker configuration, and 400 gates for the page table entry transformations. DMA filtering requires 600 gates (+0.8%) and 128 flip-flops (+1.8%) in the uncore. We do not make any changes to the LLC, and exclude it from the percentages above (the LLC generally accounts for half of chip area).

8.3 Added Page Walker Latency

Sanctum’s page table entry transformation logic is described in § 5.3, and we expect it can be combined with the page walker FSM logic within a single clock cycle.

Nevertheless, in the worst case, the transformation logic would add a pipeline stage between the L1 data

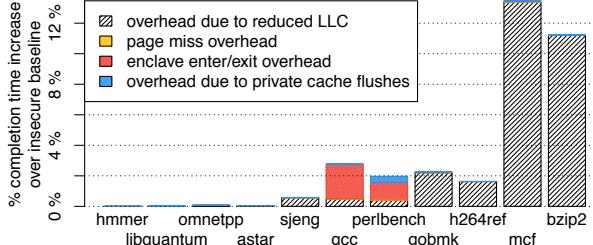

Figure 18: Detail of enclave overhead with a DRAM region allocation of 1/4 of LLC sets.

cache and the page walker. This logic is small and combinational, and significantly simpler than the ALU in the core’s execute stage. In this case, every memory fetch issued by the page walker would experience a 1-cycle latency, which adds 3 cycles of latency to each TLB miss.

The overheads due to additional cycles of TLB miss latency are negligible, as quantified in Figure 18 for SPECINT benchmarks. All TLB-related overheads contribute less than 0.01% slowdown relative to completion time of the insecure baseline. This overhead is insignificant relative to the overheads of cache isolation: TLB misses are infrequent and relatively expensive, several additional cycles makes little difference.

8.4 Security Monitor Overhead

Invoking Sanctum’s security monitor to load code into an enclave adds a one-time setup cost to each isolated process, relative to running code without Sanctum’s enclave. This overhead is amortized by the duration of the computation, so we discount it for long-running workloads.

Entering and exiting enclaves is more expensive than hardware context switches: the security monitor must flush TLBs and L1 caches to avoid leaking private information. Given an estimated cycle cost of each system call in a Sanctum enclave, and in an insecure baseline, we show the modest overheads due to enclave context switches in Figure 18. Moreover, a sensible OS is expected to minimize the number of context switches by allocating some cores to an enclave and allowing them to execute to completion. We therefore also consider this overhead to be negligible for long-running computations.

8.5 Overhead of DRAM Region Isolation

The crux of Sanctum’s strong isolation is caching DRAM regions in distinct sets. When the OS assigns DRAM regions to an enclave, it confines it to a part of the LLC. An enclaved thread effectively runs on a machine with fewer LLC sets, impacting its performance. Note, however, that Sanctum does not partition private caches, so a thread can utilize its core’s entire L1/L2 caches and TLB.

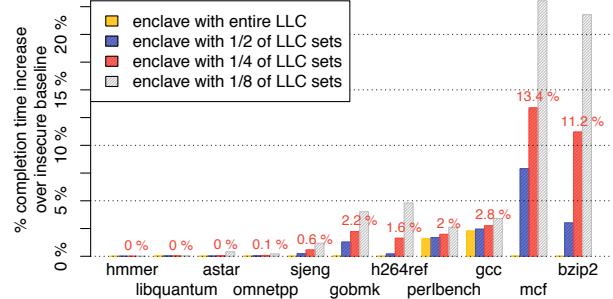

Figure 19: Overhead of enclaves of various size relative to an ideal insecure baseline.

Figure 19 shows the completion times of the SPECINT workloads, each normalized to the completion time of the same benchmark running on an ideal insecure OS that allocates the entire LLC to the benchmark. Sanctum excels at isolating compute-bound workloads operating on sensitive data. SPECINT’s large, multi-phase workloads heavily exercise the entire memory hierarchy, and therefore paint an accurate picture of a worst case for our system. *mcf*, in particular, is very sensitive to the available LLC size, so it incurs noticeable overheads when being confined to a small subset of the LLC. Figure 18 further underlines that the majority of Sanctum’s enclave overheads stem from a reduction in available LLC sets.

We consider *mcf*’s 23% decrease in performance when limited to 1/8th of the LLC to be a very pessimistic view of our system’s performance, as it explores the case where the enclave uses a quarter of CPU power (a core), but 1/8th of the LLC. For a reasonable allocation of 1/4 of DRAM regions (in a 4-core system), enclaves add under 3% overhead to most memory-bound benchmarks (with the exception of *mcf* and *bzip*, which rely on a very large LLC), and do not encumber compute-bound workloads.

9 Conclusion

Sanctum shows that strong provable isolation of concurrent software modules can be achieved with low overhead. This approach provides strong security guarantees against an insidious software threat model including cache timing and memory access pattern attacks. With this work, we hope to enable a shift in discourse in secure hardware architecture away from plugging specific security holes to a principled approach to eliminating attack surfaces.

Abstract

Protected-module architectures such as Intel SGX provide strong isolation guarantees to sensitive parts of applications while the system is up and running. Unfortunately systems in practice crash, go down for reboots or lose power at unexpected moments in time. To deal with such events, additional security measures need to be taken to guarantee that stateful modules will either recover their state from the last stored state, or fail-stop on detection of tampering with that state. More specifically, protected-module architectures need to provide a security primitive that guarantees that (1) attackers cannot present a stale state as being fresh (i.e. rollback protection), (2) once a module accepted a specific input, it will continue execution on that input or never advance, and (3) an unexpected loss of power must never leave the system in a state from which it can never resume execution (i.e. liveness guarantee).

We propose Ariadne, a solution to the state-continuity problem that achieves the theoretical lower limit of requiring only a single bit flip of non-volatile memory per state update. Ariadne can be easily adapted to the platform at hand. In low-end devices where non-volatile memory may wear out quickly and the bill of materials (BOM) needs to be minimized, Ariadne can take optimal use of non-volatile memory. On SGX-enabled processors, Ariadne can be readily deployed to protect stateful modules (e.g., as used by Haven and VC³).

1 Introduction

Computing devices have become ever more diverse, ranging from cloud computing platforms and super computers to embedded systems used in Internet of Things (IoT) applications. The familiar multi-level approach to security where a more privileged layer has full control over software running on top, is ill-suited for many of these applications; clients of cloud providers may

fear rogue employees or government subpoenas targeting their provider that may reside in a different country [7]. On embedded devices paging and privilege layers may be too power/energy expensive to be applied.

Protected-module architectures (PMAs) take another, non-hierarchical approach. After almost a decade of research [5, 6, 8, 9, 11–13, 22, 27, 28, 30, 31, 41, 45, 48, 49], two key primitives have emerged: isolation and key derivation. The *isolation* mechanism ensures that a protected module is completely isolated from any other piece of code running on the system, including other protected modules. Only when the instruction pointer points to a memory location within the module, can a module’s memory regions be accessed. All other attempts from different locations are blocked by the architecture. Only a module’s entry points are an exception and can be accessed from any location. Once an entry point is called, the instruction pointer points within the module’s memory region and its secrets can be accessed.

A *key derivation mechanism* provides a unique, unforgeable key for each protected module. It is usually derived from a platform specific key – that can only be accessed directly by the platform itself – and the measurement of the module when it was created. This implies that only identical modules can derive the same cryptographic key. An attacker modifying the module before it was properly isolated, will cause a variation in the module’s measurement and eventually in the cryptographic key that was derived. This makes it ideal to seal data to a specific module. Data can be integrity and confidentiality protected by the derived key, and stored on disk. As only the identical module can derive the same key, the stored sensitive data cannot be accessed by an attacker.

Related work showed that these minimal requirements are small enough to be implemented directly in hardware [31], even for embedded devices [8, 12, 22, 30]. With the arrival of Intel Skylake CPUs in August 2015, equipped with Intel Software Guard eXtensions (SGX) [3, 18, 29], PMAs are now available on commod-

ity devices.

In parallel, research was conducted on how the security properties provided by PMAs can be leveraged to provide provable security guarantees. Agten et al. [2] and others in subsequent work [1, 33, 34] showed that by adding limited security checks at runtime, fully-abstract compilation can be guaranteed; all security properties that hold at source-code level, can be guaranteed at machine-code level too. This makes reasoning about security properties much easier.

Unfortunately an important security requirement has received little attention. Many security properties only hold while the system is up and running. In practice machines crash, go down for reboots and lose power at unexpected moments in time. To account for such events, stateful protected modules must securely store their state. Parno et al. [32] showed that this is a non-trivial task. Sealing a module’s state before it is handed over to the untrusted operating system and written to disk, is insufficient. Additional security measures need to be taken to ensure that: (1) a protected module’s state can never be rolled back to a previous, stale state, (2) once a module accepted input, it must either (eventually) finish its execution or never advance at all and (3) unexpected loss of power at any moment in time should never result in a system that cannot be resumed after reboot.

State continuity solutions must take the platform specifications and use case at hand into account. Existing solutions [32, 46] rely on an uninterruptible power source (UPS) or risk wearing out non-volatile memory. Such approaches are acceptable in higher-end applications (e.g., in a cloud setting [7, 40]). On other platforms [35, 36] a UPS may not be available on commercial off-the-shelf (COTS) devices and may lead to significant increases in the bill-of-materials (BOM). In such cases wear and tear on non-volatile memory must be minimized to increase longevity of the device. We present a proven-secure solution to state-continuity and show that it can be applied on a large range of platforms.

More specifically, we make following contributions:

- We present Ariadne, a solution to the state-continuity problem that achieves the mathematical lower-bound of only a single bit flip per state update.
- We show that Ariadne can be easily adapted to reduce wear on EEPROM/NAND flash memory.
- We demonstrate that Ariadne can be applied immediately on the SGX/ME platform, without any hardware modifications. This is particularly important as SGX modules (called enclaves) are destroyed when the system is suspended or hibernated. In addition we compare the use of the Intel Manage-

ment Engine (ME) to the TPM chip to store freshness information and show that no clear winner exists; much depends on the use case and the available hardware.

The remainder of this paper is structured as follows. In the next section we discuss our attack model and the security properties we need to provide in detail. Section 3 builds upon related work and shows that the state-continuity problem can be easily reduced to that of state-continuous storage. Ariadne’s algorithm and its optimizations are discussed in Section 4. We evaluate its security in Section 5. Two possible implementations are discussed and evaluated in Section 6. Finally we discuss related work and conclude in Sections 7 and 8.

2 Problem Definition

2.1 Attack Model

Our goal is to provide state-continuity support to protected-module architectures, without (significantly) increasing their attack surface. As such, we assume the following. First, an attacker is able to compromise the complete (untrusted) software stack. As untrusted operating system services are used to store and retrieve module states, this implies that these states can be replayed.

Second, an attacker is able to halt execution at any moment in time because she has complete control over the system’s power supply, or because she can launch other attacks leading to similar results. Especially Intel SGX is vulnerable to such attacks. To protect the system from malicious or badly behaving enclaves, execution control is returned to the kernel whenever an interrupt occurs while an enclave is executing. Regardless of how such attacks are executed, we will refer to them as “power-interruption attacks”.

2.2 Security Properties

In order to build a secure and reliable system, it is paramount that we are able to provide three security properties. First, we need to provide rollback prevention; an attacker must not be able to provide a stale state of a module and have it accepted as being fresh. Especially in DRM/ERM contexts such security guarantees are important. Consider as an example a document that should only be printed a limited number of times. Such limitations can be guaranteed easily by first checking and decrementing a monotonic counter before the document is printed.

Second, a module’s execution needs to be continuous. Once a module accepted input, it needs to eventually finish its execution based on that input and output all com-

puted results, or it must never advance at all. This property is related to rollback-prevention, but is much stricter. Rollback-prevention may guarantee for example that an X509 certificate authority (CA) does not provide two different certificates with the same serial number. But in practice it is also important that every certificate is accounted for; for every serial number the CA should be able to prove which (if any) unique certificate it signed. Failure to do so may break trust [17] that it did not provide rogue certificates.

Third, we must also be able to guarantee liveness of the system. Unexpected crashes or loss of power at *any* moment in time, must not result in a system that will never be able to recover. Note that this is not an availability guarantee. We only consider interrupts in execution that may occur even if the system is not under attack. We cannot guarantee availability: a kernel-level attacker can easily prevent a system from ever resuming its previous state by erasing the fresh state from disk, enter an endless crash-reboot cycle, or erasing the system’s boot image.

3 Background: State-Continuous Storage is Sufficient

Related work [32, 46] already showed that the state-continuity problem can be reduced to that of state-continuous storage. We take the same approach. We first introduce `libariadne`, a library providing state-continuous storage in Section 3.1. Sections 3.2 and 3.3 discuss how this library should be used and introduce a running example.

3.1 libariadne’s Interface

We provide programmers with the `libariadne` library that can be linked with a protected module. It provides an interface of three functions.

The `void store_state(Blob *blob, String f_format)` function stores the provided data in `blob` in a file on disk. To enable easy recovery of the fresh state, we require that `f_format` is a format string which includes an integer conversion specifier (i.e., “%i”). The library will internally replace the conversion specifier with the value of a monotonic counter. Note that this is only for practical reasons, an attacker changing the filename may prevent the module from ever being resumed, but it will never result in a rollback attack.

The `Blob *retrieve_state(String f_format)` function will attempt to read a file with a matching filename, verify its integrity and freshness and return its content. When this verification step fails for any reason `NULL` is returned.

In case an attacker deletes the fresh data from disk – or simply when the hard drive got damaged and

needed replacement – the fresh data is permanently lost. The `void purge_state(Blob *init, String format)` function can resolve the situation by allowing the programmer to specify an initial, public state of the module. As this results in a loss of any previously stored sensitive data, this operation does not violate state continuity.

3.2 Security Considerations of the libariadne Library

With `libariadne` providing state-continuous storage, protected modules writers can easily guarantee rollback prevention and continuous execution [32, 46] by ensuring that modules adhere to two principles:

Requirement 1: Store Input Before Processing *Before* processing any input, protected modules must store their current state, with the received input and called entry point.¹

Requirement 2: Only Deterministic Protected Modules Any source of non-determinism (e.g., `rdrand` instructions) needs to be considered input, and thus following Requirement 1 stored before being used.

These requirements ensure that when a protected-module is interrupted during execution (e.g., due to a power failure), it will restart the computation based on the *same* input when the module is resumed. Since modules are deterministic, it will either reach an identical state as when power was lost, or its execution is interrupted again before it reaches that state.

3.3 Running Example: A PIN-Protected Secret

Consider a module that protects access to a secret. Only when a user presents a valid PIN, will the secret be returned. To mitigate brute-force attacks, we need to be able to guarantee that a user/attacker can make at most three failed attempts before being locked out indefinitely.

The implementation of the module is presented in listing 1. Whenever the module is loaded in memory, the `on_load` function is called implicitly, and an attempt is made to retrieve the last stored state (line 8). If `libariadne`’s `retrieve_state` function finds a freshly stored file, the module’s state is restored and execution of the last called entry point is restarted. Eventually the module will end up in the same state as when the module was interrupted.

If on the other hand no matching file can be found, it is corrupted, or it is stale, `retrieve_state` will return

¹Alternatively we could have opted to state-continuously store the state only right before the module returns output. Unfortunately this is hard in practice as any sources of output need to be considered (e.g., calls to unprotected memory, and timing and page-fault channels [59]).

```

1 #include <libariadne/interface.h>
2
3 static int tries_left;
4 static String pin;
5 static String secret;
6
7 void on_load( void ) {
8     Blob *blob = retrieve_state( "state_%i.pkg" );
9
10    if ( blob != NULL ){
11        // restart computation using state & input in blob
12        ...
13    } else
14        reset();
15 }
16
17 void entry_point reset( void ) {
18     Blob *blob = new Blob( &reset || tries_left || pin ||
19         secret );
20     purge_state( blob, "state_%i.pkg" );
21     pin = "0000";
22     secret = "publicly-known secret";
23     tries_left = 3;
24 }
25
26 String entry_point get_secret( String p ) {
27     Blob *blob = new Blob( &get_secret || p || tries_left ||
28         pin || secret );
29     store_state( blob, "state_%i.pkg" );
30
31     if ( tries_left <= 0 )
32         return "Locked out";
33
34     if ( pin == p ) {
35         tries_left = 3;
36         return secret;
37     } else {
38         --tries_left;
39         return "Incorrect PIN";
40     }
41 }
42 bool entry_point set_pin( String p_old, String p_new ){...}
43 bool entry_point set_secret( String p, String s_new ){...}

```

Listing 1: A running example: A PIN-protected secret. The `||` operator is used to denote concatenation.

NULL. It is up to the module writers to handle such situations. In this case the module is `reset` to a known good initial state (line 14), at the cost of losing the protected secret indefinitely. The same `reset` entry point can be called when the user exhausted her 3 access attempts. Note that the `reset` function stores the previous `tries_left`, `pin` and `secret` within the created blob. While this is not required given that the function will al-

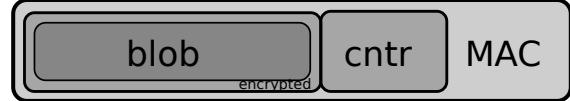

Figure 1: Layout of a package. A module’s state and input is confidentiality and integrity protected. The enclosed `cntr` value enables Ariadne to determine freshness.

ways set these variables to a known-good value, it does *not* enable an avenue of attack; Ariadne will always ensure that the `reset` function will be called upon recovery.

When `on_load` successfully retrieved and resumed the fresh state, the user can attempt to access the secret by calling the `get_secret` entry point and providing it with a PIN. When she hasn’t exhausted her number of guesses yet, the provided PIN `p` is verified (line 32). When the correct PIN is provided, the `tries_left` variable is reset and the secret is returned. Otherwise `tries_left` is decremented and an error string is returned. The entry points `set_pin` and `set_secret` – offering the obvious functionality to the user – use identical security measures to protect against brute-force attacks.

4 Ariadne

We describe Ariadne in three steps. In Section 4.1 we provide a scheme for state-continuous storage based on a monotonic counter. In Sections 4.2 and 4.3 we propose alternative counter encodings that will lead to a minimal approach to state continuity.

We will only focus on state-continuity guarantees for a single module. Related work [32, 46] showed that support for an unlimited amount of modules can be added easily by (1) using a single state-continuous module to provide secure, state-continuous storage for other modules and (2) inter-module communication. For completeness, we elaborate in Appendix B.

4.1 State-Continuity based on a Monotonic Counter

Guaranteeing state continuity based only on a single monotonic counter to keep track of the fresh state, is a hard problem. Developers of protected modules may be tempted to re-use solutions borrowed from anti-replay security measures, but these are flawed.

Strawman Solutions Generally two approaches are considered. In one approach the monotonic counter is incremented first. Afterwards, the state of the module is confidentiality protected, appended with the counter

value and the whole is integrity protected. Figure 1 displays the resulting *package* graphically. When the system crashes, only the package with an encapsulated counter value equal to the monotonic counter is accepted as being fresh. This approach has the obvious problem that a crash before the new package was written to disk, prevents the system from recovering; liveness cannot be guaranteed.

Alternatively, first storing the package with the next counter value *before* the monotonic counter is incremented also fails. Repeated crashes before the monotonic counter was incremented, enables the creation of multiple packages with the same counter values but different user input. This enables dictionary-style attacks and thus breaks rollback prevention and continuity guarantees. We elaborate on both attacks in Appendix A.

Key Observations Ariadne relies on two important observations. First, the isolation guarantees of protected module architectures ensure that an attacker cannot jump within the middle of a module. During execution we are thus able to assemble guarantees that may not hold when power is lost unexpectedly.

Second, an attacker is extremely restricted in the valid packages she can get access to. The MAC included in the package prevents her from crafting her own packages, or modifying existing ones. To ensure liveness, we need to write new packages to disk before incrementing the monotonic counter. An attacker can abuse this behavior by crashing the system before the counter is incremented. But this implies that at any moment in time, she has at most access to packages with an enclosed counter value smaller than one increment of the monotonic counter.

Ariadne’s key insight is that during recovery from a crash, we need to store the fresh package and increment the monotonic counter *twice* before the encapsulated state is resumed.

A Secure Solution Let’s re-use the PIN-protected module to describe our solution. Assume that the module is up and running. When a user requests access to the secret by calling `get_secret` (listing 1, line 25), the input and state of the module is placed in a new blob and the `store_state` function is called. Listing 2 displays its implementation. To ensure liveness, a new package is created with the next counter value and stored on disk. Finally the monotonic counter is incremented.

When the module needs to be re-loaded in memory, its `on_load` function is called implicitly (listing 1, line 7) and the `retrieve_state` library function is called to retrieve its fresh state. A package is read from disk and only accepted as being fresh *iff* its MAC value is verified successfully and its enclosed counter value matches with the value of the monotonic counter (listing 2, line 13-19).

```

1 #include <libariadne/interface.h>
2
3 void store_state( Blob *blob, String f_format ){
4     Package *pkg = create_pkg( blob, hwcntr.value() + 1 );
5     hdd.write( pkg, f_format, hwcntr.value() + 1 );
6     hwcntr.inc();
7 }
8
9 Blob *retrieve_state( String f_format ){
10    Package *pkg;
11    Blob *blob;
12
13    pkg = hdd.read( f_format, hwcntr.value() );
14
15    if ( pkg == NULL || !auth( pkg, get_mac_key() ) )
16        return NULL;
17

```

Listing 2: Ariadne: State-Continuity based on a monotonic counter

Now that we determined that the package read from disk is fresh, we can resume the execution of the module. But before doing so, we need to guarantee that no other packages exist with the same counter value. We already observed that an attacker may have packages with an encapsulated counter value of one increment larger than the monotonic counter. Incrementing the monotonic counter twice will thus guarantee that all attacker’s pack-

ages are seen as stale in the future. Only incrementing the counter once is not sufficient. We describe an attack against this scheme in Appendix A.3. To guarantee liveness, new packages are written to disk before the monotonic counter is incremented.

To restart a module from a known-good state, `purge_state` can be called (listing 2, line 38). Similar to the `retrieve_state` function, we need to guarantee that when the function returns, there only exists a single package that will be accepted as being fresh. Hence, in this function too we need to increment the monotonic counter twice. However, since this function can always be restarted, liveness is no longer a concern. We can therefore omit storing a new package before we increment the monotonic counter for the first time (line 39).

Skipping Unprocessed Input A careful reader may have noticed that it is possible for an attacker to force the creation of packages with the same enclosed counter value but with different user input. We will show that this does not break state continuity.

Let’s use the PIN-protected module again as an example. The attempted attack goes as follows: the attacker calls the `get_secret` function and provides a PIN p . After the module assembled a `Blob` structure containing the current state of the module, the provided input and the entry point used (listing 1, line 27), the `store_state` library function is called. There the attacker crashes the system right before the monotonic counter is incremented (listing 2, line 6). Since a new package was already written to disk, she now possesses a package with enclosed the next value of the monotonic counter and the provided PIN p .

The attacker now has two options. Neither will break state continuity. The first option is to resume the system without any interference. As the newly written package is not seen as being fresh (the monotonic counter in non-volatile memory was not yet incremented) PIN guess p will be discarded. As this guess was never compared to the real PIN code, the attacker did not learn any new information and state-continuity remains guaranteed.

Alternatively, the attacker lets the system reboot but crashes the module immediately after the non-volatile counter is incremented for the first time in the `retrieve_state` function (Listing 2, line 26). When the system now recovers again, the package with PIN guess p will be seen as being fresh. As no input was processed by the module after this guess was made, state-continuity is also guaranteed in this case. As input can only be skipped until the module completes its `retrieve_state` function, repeated crashes during `retrieve_state` will also not break state continuity.

4.2 State-Continuity by Flipping Bits

Related work [32, 46] relied on the irreversibility of hash values to keep track of freshness information. In order to avoid that unexpected loss of power while the hash value is being updated may lead to corrupted non-volatile memory, both approaches required a 2-phase commit protocol. We take a different approach. We use the state-continuity approach based on monotonic counters in the previous section, but use a counter encoding that only requires a single bit flip per state update. In the next section we will show that in practical implementations we can guarantee that these operations can be implemented atomically, and we thus avoid a need of a 2-phase commit protocol altogether. As every solution to state-continuity requires at least a single flip to be recorded, we reached a theoretical lower limit.

Balanced Gray codes provides such an encoding, with the additional benefit that every bit is (almost) equally used. Construction of these codes with arbitrary lengths is non-trivial. In 2008 a constructive proof of their existence was presented by Mary Flahive [14] but to the best of our knowledge never implemented. We present a fast algorithm with fixed, limited, memory consumption.

4.2.1 Terminology

Gray codes ensure that two adjacent code words differ in only a single digit. For example:

$$\{0\underline{0}, \underline{0}1, 1\underline{1}, \underline{1}0\} \quad (1)$$

and

$$\{00\underline{0}, \underline{0}01, 01\underline{1}, \underline{0}10, 11\underline{0}, \underline{1}11, 10\underline{1}, \underline{1}00\} \quad (2)$$

are two- and three-digit Gray codes, respectively. Moreover, these encodings are cyclic as the same property applies to the last and first code word. The underlined digits in encoding 1 and 2 are the *transition digits* and show which digit is changed in the next code word. The transition count of a digit is the number of times that digit is used. For example, digit 0 in encoding 2 is used twice.² The collection of these transition counts is called the transition spectrum of the Gray code (i.e., $(2, 2)$ and $(2, 2, 4)$ for encoding 1 and 2 respectively). When all transition counts are equal (t.i. $2^n/n$ with n the length of the Gray code), the encoding is said to be *uniform* or *completely balanced*. Obviously this can only be achieved when $2^n/n$ is an integer. In other cases *cyclic balanced Gray Codes* can be constructed where the difference of any pair of transition counts is at most two:

$$\forall 0 \leq i, j < n : |TC_n(j) - TC_n(i)| \leq 2 \quad (3)$$

²We follow the convention that Gray codes start with digit 0 on the left hand side.

4.2.2 Construction

Let's use the construction of a 5-bit balanced Gray code as a running example. The algorithm is displayed in Figure 2. Balanced Gray Codes of length n are constructed recursively from $n - 2$ bit balanced Gray Codes. The balanced 2 and 3-bit Gray codes of encoding 1 and 2 are used as base cases. Each iteration consists of three steps. In the first step, a $2^{n-2} \times 2^2$ grid is constructed. The rows are annotated with all $n - 2$ digit Gray codes. The number of columns is fixed for any n and columns are annotated with 2-digit codes. A given vertex now represents an n -bit Gray code by concatenating the Gray code of the row and the column. By construction, two (toroidally) adjacent vertices will now represent adjacent Gray codes. Every Hamiltonian cycle found in this grid now represents an encoding, but care needs to be taken to ensure that it is balanced.

In the second step we partition the grid such that the transition counts within each partition can be easily calculated. Partitions are represented as black boxes in Figure 2. Calculation where a new partition needs to be started is discussed in Section 4.2.3. For now note that we will ensure that (1) new partitions will always start at the first and last row and (2) the number of partitions is even.

Finally, the Hamiltonian cycle is constructed starting with Gray code 00000. With the exception of the last two partitions, each partition is traversed in the same way: visit every vertex in the column before moving to the next column. Whenever an edge of a partition is reached, the horizontal/vertical direction is inverted.

Let's take the fourth partition – the first partition containing more than one row – as an example. The partition is started at vertex with Gray code word 01011 when we were in the third column and going from right to left. The graph is continued by first traversing all rows down the current partition. The digit on the edge is the transition digit used to create the next Gray code. When the partition's end is reached (vertex 11011), we move to the next column (vertex 11001) and the rows in the partition are revisited in reversed order. When the start of the partition is reached again (vertex 01001), the last column is selected and each row is again traversed. Finally, the end of the partition is reached (vertex 11000).

The last and second to last partition are constructed differently as shown in Figure 2. We will show that the created notch in the last two partitions ensures that each partition has exactly the same properties.

4.2.3 Computing Partition Sizes

Based on the construction of the Hamiltonian cycle, we can easily derive the transition counts $TC_n(i)$ of each transition digit i of the resulting n -digit Gray code. We

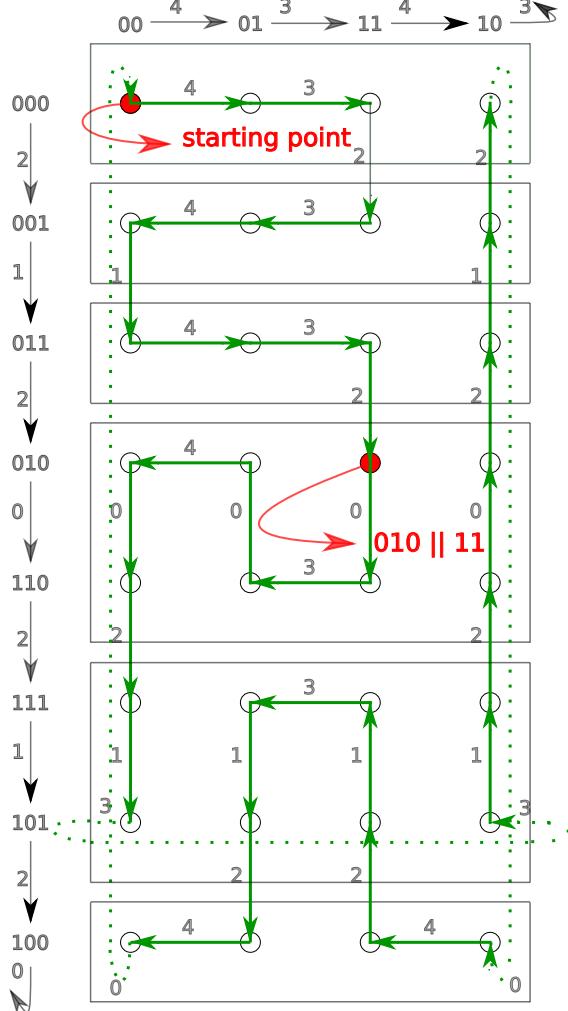

Figure 2: Balanced n -bit Gray Codes can be constructed from $n - 2$ balanced Gray Codes

apply a separate reasoning for digits i smaller than $n - 2$ (vertical arrows) and digits $n - 2$ and $n - 1$ (horizontal arrows).

Within a partition vertical arrows are always used 4 times. When a vertical arrow is used as a *connecting digit* – connecting two partitions – it is used twice. This totals the transition counts for these digits to: $4(TC_{n-2}(i) - m_{n-2}(i)) + 2m_{n-2}(i)$ where $m_{n-2}(i)$ is the multiplicity of digit i ; the number of times transition digit i is used as a connecting digit.

Transition digits $n - 2$ and $n - 1$ are represented by horizontal arrows in Figure 2. For standard partitions each is used once per partition. The second to last partition uses $n - 2$ twice, but $n - 1$ isn't used. In the last partition the opposite happens; $n - 1$ is used twice, but $n - 2$ isn't used. For the entire graph, transition digits $n - 2$ and $n - 1$ are thus used L times, with L the number

of partitions. As each partition is connected to the next with a connecting digit, we know that $L = \sum_{i=0}^{n-2} m_{n-2}(i)$. The transition counts for the generated Gray code is thus:

$$TC_n(i) = \begin{cases} 4TC_{n-2}(i) - 2m_{n-2}(i) & \text{if } i < n-2 \\ \sum_{i=0}^{n-2} m_{n-2}(i) & \text{if } i \geq n-2 \end{cases} \quad (4)$$

Flahive [14] showed that a set of connecting digits can always be found such that a balanced Gray code is constructed.

4.2.4 Generating Balanced Gray Codes

Flahive's construction guarantees that we will generate a balanced Gray code when transition digit i is used as a connecting digit between partitions exactly $m_{n-2}(i)$ times. Unfortunately implementing it directly is not possible for large n ; keeping track of each partition would quickly consume too much memory. Instead we only precompute $m_{n-2}(i)$ for each $0 \leq i < n-2$ and apply a greedy algorithm that will exhaust each m_i as fast as possible.

Let's reuse the construction of a 5-digit balanced Gray code as an example. Solving equation 4 so that a balanced Gray code is constructed (see equation 3), we get $TC_n(i) = (6, 6, 8, 6, 6)$ with $m_{n-2}(i) = (1, 1, 4)$.

In order to find a graph that fulfills these requirements, we keep track of the size of the current partition, at which row and column we are currently at, in which horizontal and vertical direction we are going and for each transition digit how many connecting digits are still available. Starting at vertex 00000 going in a downwards and right direction (see Figure 2), we calculate (recursively) the transition digit going downward (t.i. 2). As transition digit 2 still needs to be used (4 times) as a connecting digit, we decide to stop the current partition immediately, revert the vertical direction taken and switch columns instead.

Similarly, at vertex 01011 we determine that 0 would be used as a transition digit if we do not terminate the partition. While this transition digit was not yet used as a connecting digit and it should be used once, we do not stop the current partition. Indeed, by construction transition digit 0 is always used as a connecting digit between the last and first partition.

It is important to note that the metadata (in the order of KB) used to generate the next Gray codes, can be included in the package written to disk. Close examination of libariadne's implementation shows that in order to determine whether a package is fresh, we only need to compare the package's counter with the hardware monotonic counter (listing 2, line 18). In other words, we only need access to the Gray codes' metadata after we have already determined that the package is fresh.

4.3 Optimizing for Program-Erase Cycles

Being able to provide state-continuity guarantees by only flipping a single bit per state update, isn't just a theoretical result. It enables various additional optimizations. Let's assume that we use EEPROM/NAND flash memory to store the monotonic counter as an example.

EEPROM is 1980s technology that is still used in some TPM chips [4, 43, 44]. For most applications however it has been replaced by flash memory (e.g., Intel's Management Engine (ME) [37]) because it is cheaper to manufacture for bigger memory sizes. This however comes at a cost; while EEPROM is byte accessible, NAND flash memory needs to be addressed in bigger units. Read and write operations are page-based of usually 2KB to 8KB. Erase commands on the hand operate on blocks of 32-128 pages. [55]

Both EEPROM and flash memory have the disadvantage that they age. Every time the memory is written to or erased, high voltages are applied that eventually will damage the device oxide. Eventually memory cells will be in a stuck-at state, or fail to retain their information over longer periods of time. The number of program/erase (P/E) cycles that can reliably be issued, depends heavily on the manufacturing process (density, single/multi-layer cells, etc.), but typically ranges between 5,000 and 500,000 cycles. [42]

Being provided with different commands to write and erase memory gives us an opportunity to optimize our encoding scheme further. Erasing a block will set all memory cells to 1, while subsequent write commands will set the selected cells to 0. This implies that we can keep issuing write commands until all bits are zeroed out. This significantly reduces the number of erase cycles required and thus increases the memory's longevity.

Our encoding scheme works in two steps and is displayed in Figure 3. First, we apply a Gray code encoding of the monotonic counter used in Section 4.1. In the second step each bit of the resulting Gray code is stored over b blocks of p pages each containing c memory cells and encoded as the number of bits set modulo 2. Each bit flip of the Gray code thus only requires a single write command to one of the pages, which will only touch a single memory cell.

At this low level we must also take unexpected loss of power into consideration; a write/erase command may be interrupted. For write commands this is a non-issue. Since they only affect a single memory cell (t.i. 1 bit), loss of power during their execution will always have a similar effect as a loss of power before or after the command was issued. Both cases are handled at the higher level of the algorithm.

Erase commands in contrast, may not be atomic. Loss of power may leave a memory block in an inconsistent

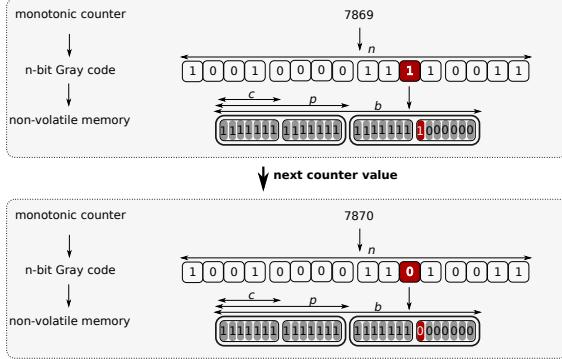

Figure 3: We optimize for write-limited non-volatile memory in two steps: (1) encoding the monotonic counter as an n -bit Gray code and (2) storing each bit in b blocks of p pages each containing c memory cells.

state and gaps in the bit pattern shown in Figure 3 may emerge. As memory content is aggregated to a single bit of a Gray code, such events are at the level of the Ariadne algorithm similar to a crash of the system before or after the counter was incremented. We only need to ensure that each (non-interrupted) write command flips a bit. This can be achieved easily by keeping a local copy of non-volatile memory that is read during the recovery phase.

5 Security Evaluation

Rollback prevention To verify that Ariadne ensures state-continuous execution, we modeled the execution of a module φ :

$$\varphi(\text{State}\varphi, \text{Input}) \rightarrow \text{State}\varphi$$

and proved that even under attack steps, φ is never called with a stale state, or with the same state with different input.

More specifically, we modeled the state of a machine \mathcal{S} as a tuple (H, C, t, P, φ, g) containing a set of packages written to disk H and a monotonic counter C . A term t represents a small program that calls the Ariadne protected module φ in an infinite loop. A set of packages P is kept representing all packages generated by Ariadne. Ghost state g keeps track of (g_{state}, g_i) , the last module state and input that was provided to φ as input.

Based on the state space \mathcal{S} , we built a state machine with a step relation $S_M \subseteq \mathcal{S} \times \mathcal{S}$ where every step is

either a program step or an attack step:

$$S_M = \{(s, s') \in \mathcal{S} \times \mathcal{S} \mid \begin{aligned} &\text{program_step } s \text{ } s' \\ &\vee \text{inc_counter_step } s \text{ } s' \\ &\vee \text{modify_hdd_step } s \text{ } s' \\ &\vee \text{crash } s \text{ } s' \end{aligned}\}$$

Program steps simply take one evaluation step of term t . Attack steps on the other hand include:

- **inc_counter_step s s'** : An attacker may advance the monotonic counter. This may prevent the module from ever resuming its state, but it must not break state continuity.
- **modify_hdd_step s s'** : An attacker can modify the contents of the hard disk drive. When the program t reads a package from disk after a crash, it may not receive the last, fresh package.
- **crash s s'** : The system may crash at any point in time. This will immediately reset the program t to its initial state.

Our proof uses rely-guarantee reasoning [20] to show that starting from a known good state s_0 and taking any number of steps in S_M , we will only take allowed steps. A step is allowed when the module φ is called with as input state $(\varphi(s))(g(s))$, the resulting state of the last call to φ . By definition not calling the module $(g'(s) = g(s))$ or purging the module $(g(s') = (s_0, i_0))$ are also allowed:

$$A = \{(s, s') \in S_M \mid \begin{aligned} &\text{state}(g(s')) = (\varphi(s))(g(s)) \\ &\vee g'(s) = g(s) \\ &\vee g(s') = (s_0, i_0) \end{aligned}\}$$

In total the proof³ consists of 74 definitions, 74 lemmas and totals 4,823 lines. The optimizations proposed in Sections 4.2 and 4.3 were not modeled.

Liveness property Recall that we also required that an unexpected crash should never let the system end up in a state where it could never advance from. This property is trivially met: the system can only get stuck when it requires access to a package it did not yet store. Since Ariadne ensures that the package with the next counter value is always committed to disk before the counter in non-volatile memory is updated, such situations can never occur.

³The proof is available for download at <https://distrinet.cs.kuleuven.be/software/sce/ariadne.html>

6 Applications

We already showed that by relying only on a monotonic counter, we can easily optimize our solution, but which optimizations are best applied, depends heavily on the platform and the security guarantees required. We provide two examples, both on the x86 platform.

6.1 TPM NVRAM to Store Freshness Information

On the x86 platform the TPM chip provides an obvious location to store freshness information: it offers many security primitives, is already widely available on commodity devices and is secure against all but sophisticated hardware attacks. Especially the latter is important in a digital rights management (DRM) setting where the client may not be fully trusted, or when the device may get physically stolen by an attacker.

6.1.1 Platform Considerations

Using the TPM, we have two options. We could use the monotonic counters that are directly provided by the TPM to implement the basic Ariadne algorithm from Section 4.1. Unfortunately, in order to ensure that “[the counter does] not wear out in the first 7 years of operation”, TPM chips may throttle the speed at which it may be incremented. To comply to the TPMv1.2 specification [53], TPMs only “must be able to increment at least once every 5 seconds.” Fortunately TPMs already report on their throttling mechanism, but timeouts between increments may render it unacceptable for some use cases.

Alternatively, we could use TPM NVRAM to store the monotonic counter. While the specification does not require writing operations to be throttled, many TPM implementations rely on EEPROM for NVRAM storage [4, 43, 44], which may cause repeated NVRAM write operations to “prematurely wear out the TPM.” [53] The counter encodings presented in Sections 4.2 and 4.3 can optimize for longevity of this type of memory, but TPM firmware may need to be updated to report the type of memory used, their access granularity and the number of program/erase cycles that are supported.

Independent of whether we use the TPM’s native monotonic counters or NVRAM, the number of supported counters is extremely limited. We take the same approach as related work [32, 46] and introduce an indirection. Only a unique *Theseus* module will access the TPM chip directly to store freshness information. Other modules link to a `libariadne_n` library – a slightly modified version of `libariadne` – that uses the *Theseus* instance to (state-continuously) store a monotonic counter. We elaborate on this construct in Appendix B.

Care must be taken that only a single instance of the *Theseus* module exists at any point in time. Failure to do so may enable race conditions on the monotonic counter and the same module state may be recovered by multiple module instances. From that point on, an attacker is able to break state continuity trivially by providing different input to the various instances with identical state. Many protected-module architectures [8, 30, 48] allow modules to access their module ID; a unique ID per boot cycle starting at value 0. This makes it trivial to ensure that only a single (*Theseus*) module exists; if *Theseus* at initialization-time determines that it received an ID different from zero, it could simply abort.

Intel SGX is a particular case that does not provide such functionality. In this case a static TPM PCR register could be used instead. When the *Theseus* module starts, it could first extend a static PCR (e.g., PCR 8) with a random value. As static PCRs can never be set to a specific value and only be reset by rebooting the platform, any deviation of the expected resulting value would indicate that a previous instance may have started already.

6.1.2 Implementation

We implemented⁴ our prototype on top of Fides [48], an open-source, hypervisor-based protected-module architecture. Table 1 displays the breakdown of the *Theseus* module and the `libariadne_n` library. It is shown that Ariadne’s algorithm is fairly small with only 503 LoCs [56]. The use of balanced Gray codes adds 908 LoCs in total of which 583 LoCs are used to provide static, precomputed metadata. As could be expected, the implementation to balance writes to non-volatile memory is with only 163 LoCs much smaller. Most source code is required to access the TPM chip (1,934 LoCs), perform cryptographic computations (3,237 LoCs), or use basic functions on top of Fides (3,442 LoCs). This results in a total line count for *Theseus* of 10,399 LoCs. `libariadne_n` is with 7,291 LoCs a bit smaller.

6.1.3 Performance Evaluation

To benchmark TPM operations, `libariadne_n` and the *Theseus* module, we used a Dell Optiplex 7010 desktop system. It is equipped with an Intel Core i7-3770 CPU (Ivy Bridge) running at 3.40GHz, a TPMv1.2 chip and an SSD drive. It used the generic 3.16.0-31 Linux kernel.

TPM Microbenchmarks We performed benchmarks of various TPM operations (see Figure 4). To force the TPM into a defensive mode and protect itself against possibly wearing out non-volatile memory, we executed

<i>Total</i>	<i>7,058</i>	<i>3,341</i>

Table 1: Breakdown of the source code of **libariadne_n** and **Theseus**.

every operation 1,050 times. The first 50 timings were later discarded to avoid recording timing results before any defense mechanism kicked in. As expected, commands that do not require access to non-volatile memory, performed well. Polling the TPM for hardware specific information using a TPM.GetCapability command finished with only 12.00ms (stdev 2.43) per command significantly faster than any other command. Reading and extending a PCR value took with 24.00ms twice as long (stdev 4.55 and 0.01, resp.).

Other commands such as incrementing a monotonic counter and reading and writing to TPM NVRAM require the creation of an OIAP session. For each benchmark we created a single authorization session and kept the session open for the entire benchmark. Creating and closing a session are thus not included in the measurements, but cost 24.05ms (stdev 0.66) and 23.95ms (stdev 0.01) respectively. Incrementing the same monotonic counter 1,050 times without any interruption between increments, cost with 95.99ms (stdev 5.79) significantly more. To determine whether its performance was throttled to protect against wearing out, we re-executed the same benchmark but with a 5 seconds interval between increments. As expected given that the TPM reports that it does not throttle its speed, the new benchmark provided similar results (95.91ms/inc, stdev 5.41).

We performed similar benchmarks for writing to TPM NVRAM. Each write command only wrote a single zero byte and finished in 144.00ms (stdev 4.26). Introducing a 5 second interval between two write operations did not increase performance and finished in 143.91ms (stdev 3.96). Even though none of these recorded write operations actually required physical writes to TPM NVRAM

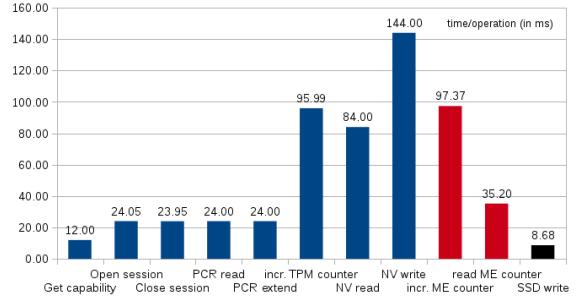

Figure 4: Microbenchmark results (in ms) of various TPM, ME and SSD operations.

as the same data was provided in every command, reading from TPM NVRAM performed much better at “only” 84.00ms (stdev 2.11). The extremely slow operation of our TPM chips is best illustrated by the performance of the SSD drive. Creating a 1 byte file is with only 8.68 ms (stdev 3.08) significantly faster than accessing TPM NVRAM.

Incrementing a monotonic counter is much faster than writing to TPM NVRAM. We attribute this difference to a wear leveling mechanism within the TPM chip. We tested the presence of such a mechanism on an unused Broadcom TPM chip. We allocated 4 regions of 64 bytes and wrote intermittent 0x00 and 0xff bytes until these regions failed to retain their contents. Regions broke respectively after 1,450K, 621K, 493K and 301K writes. Without the presence of a wear leveling mechanism, we would have expected that all regions would have failed after an equal amount of write cycles.

In Sections 4.2 and 4.3 we showed that we can minimize the number of program/erase cycles required to implement a counter. Most importantly, we showed that a 2-phase commit protocol to address sudden loss of power during increments is not required. Using these optimizations, we expect that we can further reduce the time required to increment a monotonic counter. We recommend TPM vendors to enable TPM owners to take responsibility of TPM NVRAM wear leveling and expose write/erase commands explicitly.

Benchmarking Theseus and libariadne_n We implemented a state-continuous module that keeps track of a virtual counter. The module was advanced 1,050 times, and we again discarded the first 50 timing results.

When this module accessed TPM NVRAM directly, advancing the counter took 152.01ms (stdev 3.73) in total (see Table 2). As expected, updating freshness information in TPM NVRAM is with 93.68% of the total time by far the most time-costly operation. Calculating the next Gray code, creating the package to store on disk

(in ms)	TPM	SSD	Comp.
Virt. Cntr. (NVRAM)	142.40	9.36	0.25
Virt. Cntr. (Thesius)	145.68	21.91	0.40

Table 2: Benchmark results of Theseus and libariadne.n

and the overhead introduced by our protected-module architecture, is with 0.25ms negligible.

When the same module used the Theseus module to store freshness information, performance was impacted marginally. Writing the state update of Theseus to TPM NVRAM is with 145.68ms still responsible for 86.72% of the total time required. Communication with the Theseus module caused the time attributed to computation to increase to 0.40ms, but remains negligible. Now that not one but two packages need to be stored on the SSD drive, time lost due to SSD overhead increased from 9.36ms to 21.91ms.

6.2 Intel ME to Provide State-Continuity to Intel SGX

In contrast to earlier provided specifications [18], it became clear with the publication of the Intel SGX SDK [19] in December 2015, that SGX enclaves *can* easily access monotonic counters. It appears that these counters are stored on the management engine (ME) [37], not on non-volatile memory within the CPU package.

Platform Considerations With Intel ME readily available on recent Intel systems it is an interesting location to keep freshness information. Unfortunately it comes with significant downsides compared to an SGX/TPM approach, at least from an academic point of view. First, Intel ME uses a separate processor on the platform control hub (PCH) running its own kernel and processes (e.g., Intel AMT, EPID, etc.). SGX enclaves can access the ME by calling a platform-specific enclave (PSE) that uploads a Java applet through the generic Dynamic Application Loader (DAL) interface [37]. Unfortunately, this re-introduces a TCB of probably a considerable size.

Second, it is unclear how the ME is protected against physical attacks, one of the key selling points of Intel SGX. Related work showed [57] that the ME firmware is only integrity protected and may be accessed through physical attacks [52]. It is unclear how sensitive data stored in the ME is replay protected and whether additional security measures were added in the last generation of PCHs.

Unfortunately Intel SGX/ME does not provide a mechanism for enclaves to determine whether they are the first/only instance. To protect against forking-attacks,

we must make sure that only a single instance of a state-continuous enclave is running. Similarly to the Fides/TPM platform, we could use a PCR register to detect the presence of other enclaves. On systems that lack a discrete, hardware TPM chip, similar functionality is provided by the ME engine.

This approach has the obvious disadvantage that two enclaves need to store their state on disk for every state update. Benchmarks of the Fides/TPM architecture (Section 6.1.3) show that this results in a non-negligible performance impact. This additional overhead could easily be avoided when a (volatile) in-use bit would be kept with the ME monotonic counters. When the enclave state is being recovered, Ariadne should check this bit: when the counter is not in use, the enclave should set this bit – using an atomic `test_and_set` operation – and continue its recovery. When the bit is already set, another instance of the same enclave may still be running and the newly created instance of the enclave should be destroyed to prevent forking attacks. The Theseus module described in Section B uses the same approach.

Benchmarks In the previous section we determined that on the Fides/TPM architecture at least 99.76% of Ariadne’s execution time was spent on TPM and disk accesses. We are thus especially interested in the cost of ME monotonic counter increments. We performed microbenchmarks on a recent Dell Inspiron 13 7359 equipped with a Skylake Core i7-6500U processor running Windows 10. As with TPM benchmarks, we discarded the first 50 calls to account for warm-up time for each test. Calling an enclave that returned a static integer value 1,050 times took 0.013ms (stdev 0.003). When the enclave established a single PSE session and incremented a monotonic counter upon each call, performance decreased to 97.38ms (stdev 21.04) with outliers ranging between 71.34 and 251.66ms. Time required to increment an ME monotonic counter is thus comparable to incrementing a monotonic counter in our TPM chip (95.99ms, see Figure 4). When the ME counter was only read, not incremented, performance increased significantly to 35.21ms (stdev 1.17). This leads us to expect that the slow operation of counter increments may be attributed to a throttling mechanism to avoid wearing out ME non-volatile memory.

7 Related Work

Many security architectures have been proposed in recent years. Some rely on a huge TCB making state continuity a much easier problem to solve. Other architectures have ignored the problem altogether and are susceptible to rollback attacks and/or cannot guarantee that the sys-

tem will always be able to advance after power is lost. State-continuity is a problem that has not gained a lot of research attention. Only Parno et al. [32] and we in earlier work [46] proposed solutions to the problem. Others provided more application-specific approaches.

7.1 Systems with a Large TCB

Many systems require state-continuity guarantees in one way or another. These include early designs of protected-module architectures such as Terra [15], AppCores [41] and Proxos [51], but also more conventional systems. Cloud providers must also ensure that the entire state of a virtual machine [16, 58] cannot be rolled back. Similarly, applications on modern operating systems must be restarted from their most recent state.

State-continuity on such platforms can be easily provided as the kernel and/or hypervisor is trusted to isolate disk accesses. It is assumed that an attacker cannot gain access to previously stored states and thus also cannot roll back the state. Since this assumption relies on the correct implementation of the access control logic, this is hard to guarantee in practice. Interestingly, the same applies to many formally verified systems such as seL4 [21], HyperV [24] and XMHF [54]. While the most privileged layer is verified, the file system’s implementation usually is not and these systems are still susceptible to attack. Obviously, such designs can also not defend against hardware-level attacks where an attacker is able to physically access the disk to copy and restore stale states.

7.2 Hardware Modifications

Systems such as XOM [26] try to defend against attackers snooping on memory buses by confidentiality and integrity protecting data before it is stored in main memory. Suh et al. [50] show that without anti-replay protection, stale memory contents could be presented as being fresh. Their Aegis architecture and subsequent platforms [9, 29] defend against such attacks by including a freshness tag.

Defense mechanisms against memory replay attacks, do not have to take unexpected loss of power into consideration, nor do they have to consider limitations of non-volatile memory. This enables very different approaches.

7.3 Protected-Module Architectures

Many protected-module architectures have been proposed over the recent years. [9, 22, 27, 28, 30, 31, 38, 41, 48] Interestingly, many do not address the state-continuity problem. To the best of our knowledge only two papers directly addressed the problem. Parno et al. [32] were the first to highlight the problem. They proposed

two mechanisms to provide state-continuity guarantees. Memoir-Basic uses a cryptographic hash to keep track of the fresh state. Unfortunately storing this freshness tag in TPM NVRAM would wear out its memory too quickly to be of any practical use. The authors acknowledge this limitation and propose a solution. Memoir-Opt uses a similar freshness tag, but it relies on TPM PCR registers to protect the most recent value while the system is up and running. When power is lost unexpectedly, an uninterruptible power source ensures that it is written to TPM NVRAM.

In earlier work we proposed ICE [46, 47], an alternative design that assumes “guarded memory”: volatile memory within the CPU package that is written to untrusted, non-volatile memory when power is lost. By avoiding TPM/ME accesses for each state update altogether, we achieve better performance results.

Both Memoir and ICE avoid the significantly constrained TPM NVRAM and rely on some kind of uninterruptible power source to provide state-continuity guarantees. While this leads to better performance, these solutions cannot be readily applied in practice. In contrast Ariadne can be used to protect stateful enclaves against rollback attacks on commodity devices.

7.4 Special-Purpose Applications

Many applications have been proposed that provide special-purpose solutions. We can easily provide similar guarantees, but in a much more general way.

Chun et al. proposed a construct called append-only memory [10] to prevent nodes in a distributed network from making conflicting claims to different nodes. A practical implementation was left as future work. In subsequent work Levin et al. [25] provided similar guarantees by only relying on a trusted incrementer (TrInc) that is able to locally store attestation request of monotonic counters.

Schellekens et al. [39] addressed the problem of limited TPM NVRAM. They show that sensitive data can be stored in non-volatile memory off-chip. A light-weight authentication protocol ensures a secure channel between the trusted module and untrusted, non-volatile memory. However, a monotonic counter needs to be incremented for each write instruction and stored in the modified TPM chip. How this counter can be stored efficiently, is not discussed. We achieve similar results without requiring any modification to the TPM chip.

Kotla et al. [23] propose a system to enable offline use of sensitive data. Once sensitive data is accessed, it cannot be denied by the user. Alternatively, if the user attests that the data was never accessed, she will no longer be able to do so in the future. Interestingly, only a very limited TCB needs to be trusted.

The Intel SGX SDK Manual for Windows [19] also discusses how enclaves can be used to implement limited-use policies. Their approach is similar to the inc-then-store discussed in Section A.1. While their approach guarantees that enclave states cannot be rolled back, they fail to guarantee continuous execution of an enclave and liveness of the system. We provide stronger guarantees in a more general way.

8 Conclusion

Protected module architectures enable protected module writers to guarantee formally provable security properties of their code while the system is up and running. But without support for state-continuity, stateful modules are prone to rollback attacks.

Existing solutions relied on the irreversibility property of hash functions and required an uninterruptible power source or risked wearing out non-volatile TPM NVRAM.

We presented Ariadne, the first solution that achieves state continuity based on a counter. By relying on balanced Gray codes to encode this counter, we achieved the theoretical lower limit of requiring only a single bit flip per state update.

Embedded devices can use Ariadne to minimize their total bill of materials. On SGX-enabled x86 platforms Ariadne can be readily applied by relying on the TPM’s monotonic counters, TPM NVRAM or the management engine’s monotonic counters. We showed that the choice depends on the specific TPM chip on the platform, attack model and use case.

A State-Continuity Based on a Monotonic Counter: Strawman Attempts

State continuity is a hard problem. Solutions borrowed directly from anti-replay defenses fail to provide the required security guarantees. We discuss three approaches.

A.1 Inc, then Store

Listing 3 displays a first – but flawed – implementation. Its implementation is straightforward. Recall the PIN-protected module from Section 3.3. When a user tries to retrieve the module’s secret, she calls the `get_secret` entry point and supplies a PIN. Before this

```

1 #include <libariadne/interface.h>
2
3 void store_state( Blob *blob, String f_format ){
4     hwnctr.inc();
5     hdd.write( create_pkg(blob, hwnctr.value()), f_format );
6 }
7
8 Blob *retrieve_state( String f_format ){
9     Package *pkg = hdd.read( f_format, hwnctr.value() );
10
11    if ( pkg == NULL || !auth( pkg, get_mac_key() ) )
12        return NULL;
13
14    if ( pkg->cntr != hwnctr.value() )
15        return NULL;
16
17    return decrypt( pkg, get_enc_key() );
18 }
19
20 void purge_state( Blob * init_blob, String f_format ){...}

```

Listing 3: Incrementing the counter before writing the package to disk will fail to guarantee liveness.

PIN is checked, the module collects the state of the module and passes it together with the provided PIN and called function, to the `store_state` library function. There the (hardware) monotonic counter is incremented first (listing 3, line 4). Afterwards a new package is created containing the incremented counter value and written to disk.

When the system is rebooted and the module needs to be reloaded in memory, the `on_load` function is called implicitly (listing 1, line 7) which in turn calls the `retrieve_state` library function. Next, the library searches for the filename of the last package written to disk. When this package is read and its integrity verified, the counter value enclosed in the package is compared to the hardware monotonic counter (listing 3, line 9 - 14). If both counter values match, the package is determined fresh. After decryption, it is returned to the `on_load` module function where the module’s state is restored and the execution of the called function is restarted (listing 1, line 11). If the read package from disk is not fresh or its integrity check failed, `NULL` is returned and the module is `reset` losing the stored secret indefinitely.

Attack 1: Breaking Liveness

Unfortunately, the provided scheme is flawed. Imagine an unexpected loss of power immediately after the monotonic counter was incremented (i.e., after listing 3, line 4). When the module is reloaded, the `retrieve_state` library function will only accept packages containing a counter value equal to the hardware counter as being fresh. But this package was never stored and the sys-

```

1 #include <libariadne/interface.h>
2
3 void store_state( Blob *blob, String f_format ){
4     hdd.write( create_pkg( blob, hwcntr.value() + 1 ),
5                 f_format );
6     hwcntr.inc();
7 }
8
8 Blob *retrieve_state( String f_format ){
9     Package *pkg = hdd.read( f_format, hwcntr.value() );
10
11    if ( pkg == NULL || !auth( pkg, get_mac_key() ) )
12        return NULL;
13
14    if ( pkg->cnt != hwcntr.value() )
15        return NULL;
16
17    return decrypt( pkg, get_enc_key() );
18 }
19
20 void purge_state( Blob * init_blob, String f_format ){...}

```

Listing 4: Writing a package to disk before incrementing the monotonic counter will leave the system susceptible to dictionary-style attacks.

tem ends up in a state from where it can never advance. As this situation may also occur even when the system is not under attack, this breaks our liveness requirement. ■

A.2 Store, then Inc

One may be tempted to quickly fix the design flaw of the scheme presented in the previous section by ensuring that packages are written to disk *before* the hardware monotonic counter is incremented. We will show that also this design does not guarantee the required security properties.

Listing 4 displays the updated scheme. When the module requests the libariadne module to store a new state, the `store_state` function will first create a new package with the next counter value and write it to disk (line 4-5) before she increments the hardware counter. The `retrieve_state` function is unchanged.

With these changes in place, a package has always been written to disk that matches the value of the monotonic counter. Therefore the module is always able to recover its state under benign conditions and liveness of this scheme is ensured. Unfortunately, this mitigation enables an attacker to execute a dictionary-style attack.

Attack 2: Dictionary Attack

Let's reuse the module from Section 3.3 as an example. Assume that the attack starts when the module still grants

the attacker with three attempts to guess the correct PIN, and that the monotonic counter has value c . Let's call this state s_0 .

In the preliminary step of the attack, the attacker iterates over all entries of her dictionary. For each PIN, she calls the `get_secret` entry point of the module, but crashes the system after the new package – enclosed counter value $c + 1$ – has been written to disk (listing 4, line 4). Since the module could not yet commit to the new input by incrementing the monotonic counter, the module will recover its previous state and once again wait for user input from state s_0 . At that point, the attacker continues the same process with the next entry in her dictionary.

When the attacker has reached the end of her dictionary, she finally allows the module to commit to the provided input by incrementing the monotonic value to $c + 1$. Afterwards she crashes the system again.

This marks the start of the second step of her attack. When the module is reloaded in memory, it needs to retrieve its state from disk. Its integrity and freshness is verified before it is used to resume its state. But for every dictionary entry, the attacker possesses a package that will be accepted as being authentic and fresh. She completes her dictionary attack by selecting any package and let the module recover its state based on the enclosed guessed PIN. When she learns the PIN is incorrect, she crashes the system, and selects another “fresh” package. ■

A.3 Inc once during recovery

In order to defend against dictionary attacks, one must ensure that no other packages with the same fresh counter value exist when the module is being resumed. Incrementing the counter once during recovery does *not* provide this guarantee. We show an attack against such an implementation.

For completeness we show in Listing 5 the (vulnerable) implementation of the state-continuity security measure. The implementation is identical to that of listing 4, but lines 23 to 25 were added. The main issue is that an attacker is able to abuse the creation and storage of packages during recovery (lines 23 and 24) to keep stale packages fresh. This enables attacks similar to the dictionary attack of Section A.2. Since the attack is much harder to grasp completely, we show a simpler version: an attacker is able to provide a guess of the PIN without it being (permanently) recorded, breaking rollback prevention.

Attack 3: Oblivious Steps

For simplicity say that the PIN-protected module is in a state s_0 with 3 PIN-guesses left and the monotonic

counter is at value 42. The attack is executed in 4 steps. In step I an authentic package is created. This means that an attacker provides a guess ‘‘guess’’, but crashes the module immediately after it wrote the package $\text{pkg}(43 \parallel \text{get_secret} \parallel \text{‘‘guess’'} \parallel s_0)$ to disk (listing 5, line 5). As the module only increments the monotonic counter after the state is stored successfully, it still remains at value 42.

Next in step II, the module is recovered to its previous state, leading to a new package $\text{pkg}(43 \parallel \dots)$ ⁵ and an incremented counter (listing 5 lines 23 to 25). At this moment in time two different packages with enclosed counter value 43 exist.

In step III the implementation of the `retrieve_state` is abused to create a (soon-to-be-fresh) package $\text{pkg}(44 \parallel \dots)$ as follows: First, the module is crashed. During recovery the package $\text{pkg}(43 \parallel \dots)$ is provided and accepted as being fresh. As the `retrieve_state` first writes a new package with an incremented counter value (line 24) the required package is created. Immediately after the package is written to disk, the module is crashed before the monotonic counter can be incremented.

In step IV the module is resumed based on the fresh package $\text{pkg}(43 \parallel \text{get_secret} \parallel \text{‘‘guess’'} \parallel s_0)$ and the monotonic counter is incremented to 44. At this moment the attacker learns the outcome of her guess. If she guessed wrongly, she can choose to crash the system and let the module recover its state from “fresh” package $\text{pkg}(44 \parallel \dots)$. As the module didn’t record her guess, state-continuity is broken. ■

B State-continuous storage for n modules

libariadne as described in Section 4 provides state-continuous storage, at the cost of secure, non-volatile memory. Storing freshness information for every possible protected module in limited-sized, secure non-volatile memory (e.g., TPM NVRAM), is practically infeasible. We resolve the situation using an indirection.

A protected-module “Theseus” is introduced to the system and uses – as the only module in the system – the secure non-volatile memory to store its state. It provides virtual, monotonic counters to other modules executing on the system. Its interface is shown in listing 6.

The `new_counter` entry point to the module, creates a new monotonic counter and protects it with the provided key. It returns the index of the monotonic counter. To

⁵We use the notation $\text{pkg}(43 \parallel \dots)$ here for clarity. We should have introduced a previous state s_{-1} , entrypoint f and input i such that $f(s_{-1}, i) = s_0$. Providing such input to the module will have created the package $\text{pkg}(43 \parallel f \parallel i \parallel s_{-1})$. As f, i and s_{-1} are irrelevant for the attack, we omit these arguments.

```

1 #include <libariadne/interface.h>
2
3 void store_state( Blob *blob, String f_format ){
4     Package *pkg = create_pkg( blob, hwcntr.value() + 1 )
5     hdd.write( pkg, f_format, hwcntr.value() + 1 );
6     hwcntr.inc();
7 }
8
9 Blob *retrieve_state( String f_format ){
10    Package *pkg;
11    Blob *blob;
12
13    pkg = hdd.read( f_format, hwcntr.value() );
14
15    if ( pkg == NULL || !auth( pkg, get_mac_key() ) )
16        return NULL;
17
18    if ( pkg->cntr != hwcntr.value() )
19        return NULL;
20
21    blob = decrypt( pkg, get_enc_key() );
22
23    pkg = create_pkg( blob, hwcntr.value() + 1 );
24    hdd.write( pkg, f_format, hwcntr.value() + 1 );
25    hwcntr.inc();
26
27    return blob;
28 }
29
30 void purge_state( Blob *init_blob, String f_format ){...}

```

Listing 5: When the counter is only incremented once during recovery, an attacker can force the module to keep stale states fresh, enabling rollback attacks.

```

1 int new_counter( uint64_t key );
2 int counter_set_in_use( int idx, uint64_t key, bool in_use );
3 int counter_increment( int idx, uint64_t key );
4 uint64_t counter_value( int idx, uint64_t key );

```

Listing 6: Theseus’ public interface.

protect against inappropriate use, this (index, key)-pair will need to be provided for any subsequent operation on the counter. We assume that communication between the caller and the Theseus module, is confidentiality, integrity and anti-replay protected.

An important feature is the ability to mark a counter to be “in use.” This volatile flag, is used to ensure that only a single instance of a protected module can be resumed after a crash. Hence, `counter_increment` and `counter_value` will return an error code if they are called on a counter that was not previously marked as “in use”.

The Million-Key Question – Investigating the Origins of RSA Public Keys

Petr Švenda, Matúš Nemeč, Peter Sekan, Rudolf Kvašňovský,

David Formánek, David Komárek and Vashek Matyáš

Masaryk University, Czech Republic

Abstract

Can bits of an RSA public key leak information about design and implementation choices such as the prime generation algorithm? We analysed over 60 million freshly generated key pairs from 22 open- and closed-source libraries and from 16 different smartcards, revealing significant leakage. The bias introduced by different choices is sufficiently large to classify a probable library or smartcard with high accuracy based only on the values of public keys. Such a classification can be used to decrease the anonymity set of users of anonymous mailers or operators of linked Tor hidden services, to quickly detect keys from the same vulnerable library or to verify a claim of use of secure hardware by a remote party. The classification of the key origins of more than 10 million RSA-based IPv4 TLS keys and 1.4 million PGP keys also provides an independent estimation of the libraries that are most commonly used to generate the keys found on the Internet.

Our broad inspection provides a sanity check and deep insight regarding which of the recommendations for RSA key pair generation are followed in practice, including closed-source libraries and smartcards¹.

1 Introduction

The RSA key pair generation process is a crucial part of RSA algorithm usage, and there are many existing (and sometimes conflicting) recommendations regarding how to select suitable primes p and q [11, 13, 14, 17, 18] to be later used to compute the private key and public modulus. Once these primes have been selected, modulus computation is very simple: $n = p \cdot q$, with the public exponent usually fixed to the value 65 537. But can the modulus n itself leak information about the design and implementation choices previously used to generate the

primes p and q ? Trivially, the length of the used primes is directly observable. Interestingly, more subtle leakage was also discovered by Mironov [20] for primes generated by the OpenSSL library, which unwantedly avoids small factors of up to 17 863 from $p - 1$ because of a coding omission. Such a property itself is not a security vulnerability (the key space is decreased only negligibly), but it results in sufficiently significant fingerprinting of all generated primes that OpenSSL can be identified as their origin with high confidence. Mironov used this observation to identify the sources of the primes of factorizable keys found by [12]. But can the origins of keys be identified only from the modulus n , even when n cannot be factorized and the values of the corresponding primes are not known?

To answer this question, we generated a large number of RSA key pairs from 22 software libraries (both open-source and closed-source) and 16 different cryptographic smartcards from 6 different manufacturers, exported both the private and public components, and analysed the obtained values in detail. As a result, we identified seven design and implementation decisions that directly fingerprint not only the primes but also the resulting public modulus: 1) Direct manipulation of the primes' highest bits. 2) Use of a specific method to construct strong or provable primes instead of randomly selected or uniformly generated primes. 3) Avoidance of small factors in $p - 1$ and $q - 1$. 4) Requirement for moduli to be Blum integers. 5) Restriction of the primes' bit length. 6) Type of action after candidate prime rejection. 7) Use of another non-traditional algorithm – functionally unknown, but statistically observable.

As different design and implementation choices are made for different libraries and smartcards (cards) with regard to these criteria, a cumulative fingerprint is sufficient to identify a probable key origin even when only the public key modulus is available. The average classification accuracy on the test set was greater than 73% even for a single classified key modulus when a hit within

¹Full details, paper supplementary material, datasets and author contact information can be found at <http://crcs.cz/papers/usenix2016>.

the top 3 matches was accepted². When more keys from the same (unknown) source were classified together, the analysis of as few as ten keys allowed the correct origin to be identified as the top single match in more than 85% of cases. When five keys from the same source were available and a hit within the top 3 matches was accepted, the classification accuracy was over 97%.

We used the proposed probabilistic classifier to classify RSA keys collected from the IPv4 HTTPS/TLS [9], Certificate Transparency [10] and PGP [30] datasets and achieved remarkably close match to the current market share of web servers for TLS dataset.

The optimal and most secure way of generating RSA key pairs is still under discussion. Our wide-scale analysis also provides a sanity check concerning how closely the various recommendations are followed in practice for software libraries and smartcards and what the impact on the resulting prime values is, even when this impact is not observably manifested in the public key value. We identified multiple cases of unnecessarily decreased entropy in the generated keys (although this was not exploitable for practical factorization) and a generic implementation error pattern leading to predictable keys in a small percentage (0.05%) of cases for one type of card.

Surprisingly little has been published regarding how key pairs are generated on cryptographic cards. In the case of open-source libraries such as OpenSSL, one can inspect the source code. However, this option is not available for cards, for which the documentation of the generation algorithm is confidential and neither the source code nor the binary is available for review. To inspect these black-box implementations, we utilized the side channels of time and power consumption (in addition to the exported raw key values). When this side-channel information was combined with the available knowledge and observed characteristics of open-source libraries, the approximate key pair generation process could also be established for these black-box implementations.

This paper is organized as follows: After a brief summary of the RSA cryptosystem, Section 2 describes the methodology used in this study and the dataset of RSA keys collected from software libraries and cryptographic cards. Section 3 provides a discussion of the observed properties of the generated keys. Section 4 describes the modulus classification method and its results on large real-world key sets, the practical impact and mitigation of which are discussed in Section 5. Additional analysis performed for black-box implementations on cards and a discussion of the practical impact of a faulty/biased random number generator are presented in Section 6. Finally, conclusions are offered in Section 7.

²The correct library is listed within the first three most probable groups of distinct sources identified by the classification algorithm.

2 RSA key pairs

To use the RSA algorithm, one must generate a key:

1. Select two distinct large primes³ p and q .
2. Compute $n = p \cdot q$ and $\varphi(n) = (p - 1)(q - 1)$.
3. Choose a public exponent⁴ $e < \varphi(n)$ that is coprime to $\varphi(n)$.
4. Compute the private exponent d as $e^{-1} \bmod \varphi(n)$.

The pair (e, n) is the public key; either (d, n) serves as the secret private key, or (p, q) can be used ((d, n) can be calculated from (p, q, e) and vice versa).

2.1 Attacks against the RSA cryptosystem

The basic form of attack on the RSA cryptosystem is modulus factorization, which is currently computationally unfeasible or at least extremely difficult if p and q are sufficiently large (512 bits or more) and a general algorithm such as the number field sieve (NFS) or the older quadratic sieve (MPQS) is used. However, special properties of the primes enable more efficient factorization, and measures may be taken in the key pair generation process to attempt to prevent the use of such primes.

The primes used to generate the modulus should be of approximately the same size because the factorization time typically depends on the smallest factor. However, if the primes are too close in value, then they will also be close to the square root of n and *Fermat factorization* can be used to factor n efficiently [16].

Pollard's $p - 1$ method outperforms general algorithms if for one of the primes p , $p - 1$ is B -smooth (all factors are $\leq B$) for some small B (which must usually be guessed in advance). The modulus can be factored using *Williams' $p + 1$* method if $p + 1$ has no large factors [27].

Despite the existence of many special-purpose algorithms, the easiest way to factor a modulus created as the product of two randomly generated primes is usually to use the NFS algorithm. Nevertheless, using special primes may potentially thwart such factorization attacks, and some standards, such as ANSI X9.31 [28] and FIPS 186-4 [14], require the use of primes with certain properties (e.g., $p - 1$ and $p + 1$ must have at least one large factor). Other special algorithms, such as *Pollard's rho* method and the *Lenstra elliptic curve* method, are impractical for factoring a product of two large primes.

Although RSA factorization is considered to be an NP-hard problem if keys that fulfil the above conditions are used, practical attacks, often relying on a faulty random

³Generated randomly, but possibly with certain required properties, as we will see later.

⁴Usually with a low Hamming weight for faster encryption.

generator, nevertheless exist. Insufficient entropy, primarily in routers and embedded devices, leads to weak and factorizable keys [12]. A faulty card random number generator has produced weak keys for Taiwanese citizens [3], and supposedly secure cryptographic tokens have been known to produce corrupted or significantly biased keys and random streams [6].

Implementation attacks can also compromise private keys based on leakage in side channels of timing [8] or power [15]. Active attacks based on fault induction [26] or exploits aimed at message formatting [2, 5] enable the recovery of private key values. We largely excluded these classes of attacks from the scope of our analysis, focusing only on key generation.

2.2 Analysis methodology

Our purpose was to verify whether the RSA key pairs generated from software libraries and on cards provide the desired quality and security with respect to the expectations of randomness and resilience to common attacks. We attempted to identify the characteristics of the generated keys and deduce the process responsible for introducing them. The impact of the techniques used on the properties of the produced public keys was also investigated. We used the following methodology:

1. Establish the characteristics of keys generated from open-source cryptographic libraries with known implementations.
2. Gather a large number of RSA key pairs from cryptographic software libraries and cards (one million from each).
3. Compare the keys originating from open-source libraries and black-box implementations and discuss the causes of any observed similarities and differences (e.g., the distribution of the prime factors of $p - 1$).
4. Analyse the generated keys using multiple statistical techniques (e.g., calculate the distribution of the most significant bytes of the primes).

Throughout this paper, we will use the term *source* (of keys) when referring to both software libraries and cards.

2.3 Source code and literature

We examined the source codes of 19 open-source cryptographic libraries variants⁵ and match it to the relevant algorithms for primality testing, prime generation and

⁵We inspected multiple versions of libraries (though not all exhaustively) to detect code changes relevant to the key generation process. If such a change was detected, both versions were included in the analysis.

RSA key generation from standards and literature. We then examined how the different methods affected the distributions of the primes and moduli. Summary results together for all sources are available in Table 1.

2.3.1 Prime generation

Probable primes. Random numbers (or numbers from a sequence) are tested for primality using probabilistic primality (compositeness) tests. Different libraries use different combinations of the Fermat, Miller-Rabin, Solovay-Strassen and Lucas tests. None of the tests rejects prime numbers if implemented correctly; hence, they do not affect the distribution of the generated primes. GNU Crypto uses a flawed implementation of the Miller-Rabin test. As a result, it permits only Blum primes⁶. No other library generates such primes exclusively (however, some cards do).

In the *random sampling* method, large integers (candidates) are generated until a prime is found. If the candidates are chosen uniformly, the distribution is not biased (case of GNU Crypto 2.0.1, LibTomCrypt 1.17 and WolfSSL 3.9.0). An *incremental search* algorithm selects a random candidate and then increments it until a prime is found (Botan 1.11.29, Bouncy Castle 1.54, Cryptix 20050328, cryptlib 3.4.3, Crypto++ 5.6.3, FlexiProvider 1.7p7, mbedTLS 2.2.1, SunRsaSign – OpenJDK 1.8.0, OpenSSL 1.0.2g, and PGPSDK4). Primes preceded by larger “gaps” will be selected with slightly higher probability; however, this bias is not observable from the distribution of the primes.

Large random integers are likely to have some small prime divisors. Before time-consuming primality tests are performed, compositeness can be revealed through trial division with small primes or the computation of the greatest common divisor (GCD) with a product of a few hundred primes. In the case of incremental search, the sieve of Eratosthenes or a table of remainders that is updated when the candidate is incremented can be used. If implemented correctly, these efficiency improvements do not affect the distribution of the prime generator.

OpenSSL creates a table of remainders by dividing a candidate by small primes. When a composite candidate is incremented, this table is efficiently updated using only operations with small integers. Interestingly, candidates for p for which $p - 1$ is divisible by a small prime up to 17 863 (except 2) are also rejected. Such a computational step is useful to speed up the search for a *safe prime*; however, $(p - 1)/2$ is not required (as would be for *safe prime*) to be prime by the library. This strange behaviour was first reported by Mironov [20] and can be used to classify the source if the primes are known.

⁶A prime p is a Blum prime if $p \equiv 3 \pmod{4}$. When both p and q are Blum primes, the modulus n is a Blum integer $n \equiv 1 \pmod{4}$.

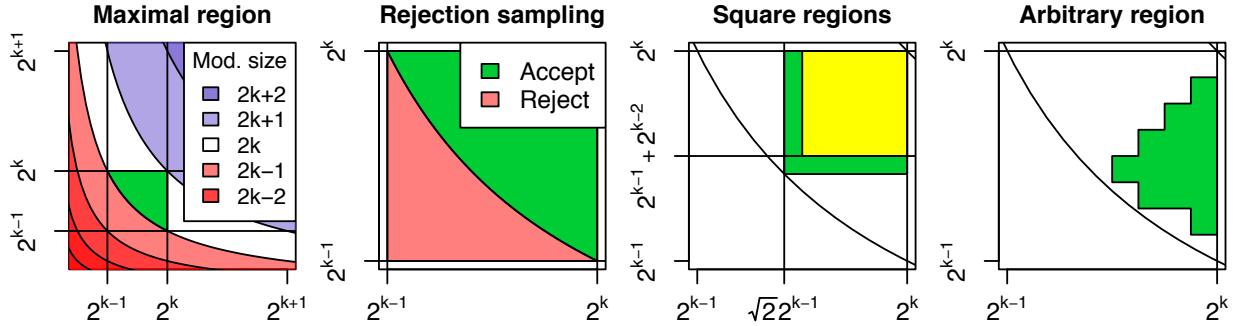

Figure 1: RSA key generation. The maximal region for the generated primes is defined by the precise length of the modulus and equal lengths of the primes. Such keys can be generated through rejection sampling. To avoid generating short moduli (which must be discarded), alternative square regions may be used. Several implementations, such as that of the NXP J2A080 card, generate primes from arbitrary combinations of square regions.

Provable primes. Primes are constructed recursively from smaller primes, such that their primality can be deduced mathematically (using Pocklington’s theorem or related facts). This process is randomized; hence, a different prime is obtained each time. An algorithm for constructing provable primes was first proposed by Maurer [18] (used by Nettle 3.2). For each prime p , $p - 1$ must have a large factor ($\geq \sqrt{p}$ for Maurer’s algorithm or $\geq \sqrt[3]{p}$ for an improved version thereof). Factors of $p + 1$ are not affected.

Strong primes. A prime p is *strong* if both $p - 1$ and $p + 1$ have a large prime factor (used by libgcrypt 1.65 in FIPS mode and by the OpenSSL 2.0.12 FIPS module). We also refer to these primes as *FIPS-compliant*, as FIPS 186-4 requires such primes for 1024-bit keys (larger keys may use probable primes). Differing definitions of strong primes are given in the literature; often, the large factor of $p - 1$ itself (minus one) should also have a large prime factor (PGPSDK4 in FIPS mode). Large random primes are not “weak” by comparison, as their prime factors are sufficiently large, with sufficient probability, to be safe from relevant attacks.

Strong primes are constructed from large prime factors. They can be generated uniformly (as in ANSI X9.31, FIPS 186-4, and IEEE 1363-2000) or with a visibly biased distribution (as in a version of Gordon’s algorithm [11] used in PGPSDK4).

2.3.2 Key generation – prime pairs

The key size is the bit length of the modulus. Typically, an algorithm generates keys of an exact bit length (the only exception being PGPSDK4 in FIPS mode). The primes are thus generated with a size equal to half of the modulus length. These two measures define the *maximal region* for RSA primes. The product of two k -bit primes is either $2k$ or $2k - 1$ bits long. There are two princi-

pal methods of solving the problem of short $(2k - 1)$ -bit moduli, as illustrated in Figure 1.

Rejection sampling. In this method, pairs of k -bit primes are generated until their product has the correct length. To produce an unbiased distribution, two new primes should be generated each time (Cryptix 20050328, FlexiProvider 1.7p7, and mbedTLS 2.2.1). If the greater prime is kept and only one new prime is generated, some bias can be observed in the resulting distribution of RSA moduli (Bouncy Castle up to version 1.53 and SunRsaSign in OpenJDK 1.8.0). If the first prime is kept (without regard to its size) and the second prime is re-generated, small moduli will be much more probable than large values (GNU Crypto 2.0.1).

“Square” regions. This technique avoids the generation of moduli of incorrect length that must be discarded by generating only larger primes such that their product has the correct length. Typically, both primes are selected from identical intervals. When the prime pairs are plotted in two dimensions, this produces a square region.

The smallest k -bit numbers that produce a $2k$ -bit modulus are close to $\sqrt{2} \cdot 2^{k-1}$. Because random numbers can easily be uniformly generated from intervals bounded by powers of two, the distribution must be additionally transformed to fit such an interval. We refer to prime pairs generated from the interval $[\sqrt{2} \cdot 2^{k-1}, 2^k - 1]$ as being generated from the *maximal square region* (Bouncy Castle since version 1.54, Crypto++ 5.6.3, and the Microsoft cryptography providers used in CryptoAPI, CNG and .NET). Crypto++ approximates this interval by generating the most significant byte of primes from 182 to 255.

A more *practical square region*, which works well for candidates generated uniformly from intervals bounded by powers of two, is achieved by fixing the two most significant bits of a candidate to 11₂ (Botan 1.11.29, cryptlib

3.4.3, libgcrypt 1.6.5, LibTomCrypt 1.17, OpenSSL 1.0.2g, PGPSDK4, and WolfSSL 3.9.0). Additionally, the provable primes generated in Nettle 3.2 and the strong primes generated in libgcrypt 1.6.5 (in FIPS mode) and in the OpenSSL 2.0.12 FIPS module are produced from this region.

2.4 Analysis of black-box implementations

To obtain representative results of the key generation procedures used in cards (for which we could not inspect the source codes), we investigated 16 different types of cards from 6 different established card manufacturers ($2 \times$ Gemalto, $6 \times$ NXP, $1 \times$ Infineon, $3 \times$ Giesecke & Devrient (G&D), $2 \times$ Feitian and $2 \times$ Oberthur) developed using the widely used JavaCard platform. The key pair generation process itself is implemented at a lower level, with JavaCard merely providing an interface for calling relevant methods. For each type of card (e.g., NXP J2D081), three physical cards were tested to detect any potential differences among physical cards of the same type (throughout the entire analysis, no such difference was ever detected). Each card was programmed with an application enabling the generation and export of an RSA key pair (using the `KeyPair.generateKey()` method) and truly random data (using the `RandomData.generate()` method).

We focused primarily on the analysis of RSA keys of three different lengths – 512, 1024 and 2048 bits. Each card was repeatedly asked to generate new RSA 512-bit key pairs until one million key pairs had been generated or the card stopped responding. The time required to create these key pairs was measured, and both the public (the modulus n and the exponent e) and private (the primes p and q and the private exponent d) components were exported from the card for subsequent analyses. No card reset was performed between key pair generations. In the ideal case, three times one million key pairs were extracted for every card type. The same process was repeated for RSA key pairs with 1024-bit moduli but for only 50 000 key pairs, as the key generation process takes progressively longer for longer keys. The patterns observed from the analyses performed on the 512-bit keys was used to verify the key set with longer keys⁷.

Surprisingly, we found substantial differences in the intervals from which primes were chosen. In some cases, non-uniform distributions of the primes hinted that the prime generation algorithms are also different to those used in the software libraries. Several methods adopted in software libraries, such as incremental search, seem to be suitable even for limited-resource systems. This

⁷For example, one can quickly verify whether a smaller number of factorized values of $p - 1$ from 1024-bit RSA keys fit the distribution extrapolated from 512-bit keys.

argument is supported by a patent application [21] by G&D, one of the manufacturers of the examined cards. All tested cards from this manufacturer produced Blum integers, as described in the patent, and these integers were distributed uniformly, as expected from the incremental search method.

A duration of approximately 2-3 weeks was typically required to generate one million key pairs from a single card, and we used up to 20 card readers gathering keys in parallel. Not all cards were able to generate all required keys or random data, stopping with a non-specific error (0x6F00) or becoming permanently non-responsive after a certain period. In total, we gathered more than 30 million card-generated RSA key pairs⁸. Power consumption traces were captured for a small number of instances of the key pair generation process.

In addition, 100 MB streams of truly random data were extracted from each card for tests of statistical randomness. When a problem was detected (i.e., the data failed one or more statistical tests), a 1 GB stream was generated for fine-grained verification tests.

3 Analysis of the generated RSA key pairs

The key pairs extracted from both the software libraries and the cards were examined using a similar set of analytical techniques. The goal was to identify sources with the same behaviour, investigate the impact on the public key values and infer the probable key generation algorithm used based on similarities and differences in the observed properties.

3.1 Distributions of the primes

To visualize the regions from which pairs of primes were chosen, we plotted the most significant byte (MSB) of each prime on a heat map. It is possible to observe the *intervals for prime generation*, as discussed in Section 2.3.

Figure 2 shows a small subset of the observed non-uniform distributions. Surprisingly, the MSB patterns were significantly different for the cards and the software implementations. The patterns were identical among different physical cards of the same type and were also shared between some (but not all) types of cards from the same manufacturer (probably because of a shared code base). We did not encounter any library that produced outputs comparable to those of the first two cards from the examples shown in Figure 2. The third example could be reproduced by generating primes alternately and uniformly from 14 different regions, each characterized by a pattern in the top four bits of the primes. By comparison, it was rarer for a bias to be introduced by a library.

⁸The entire dataset is available for further research at [31].

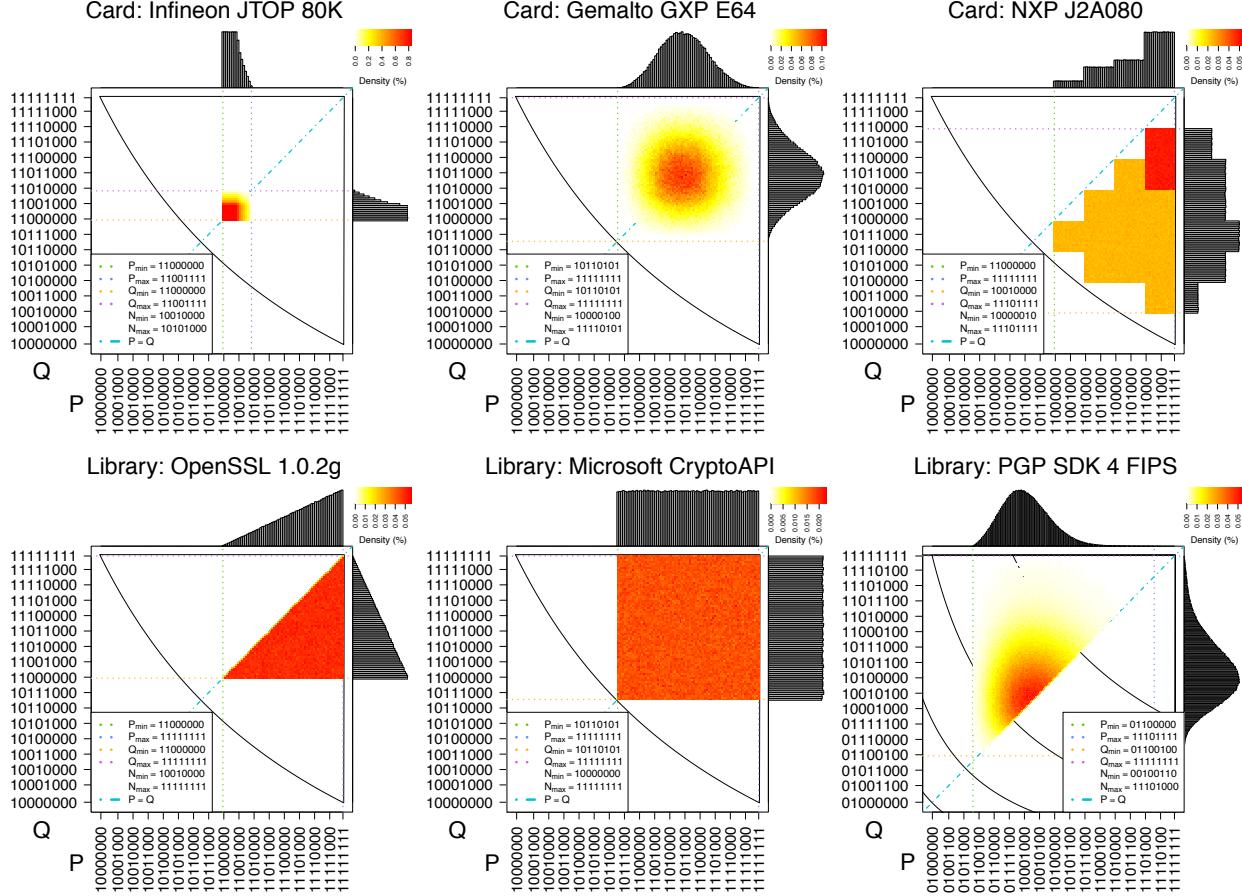

Figure 2: Example distributions of the most significant byte of the prime p and the corresponding prime q from 8 million RSA key pairs generated by three software libraries and three types of cards. The histograms on the top and the side of the graph represent the marginal distributions of p and q , respectively. The colour scheme expresses the likelihood that primes of a randomly generated key will have specific high order bytes, ranging from white (not likely) over orange to red (more likely). For distributions of all sources from the dataset, see our technical report [25].

The relation between the values of p and q reveals additional conditions placed on the primes, such as a minimal size of the difference $p - q$ (PGPSDK4, NXP J2D081, and NXP J2E145G).

It is possible to verify whether small factors of $p - 1$ are being avoided (e.g., OpenSSL or NXP J2D081) or whether the primes generally do not exhibit same distribution as randomly generated numbers (Infineon JT0P 80K) by computing the distributions of the primes, modulo small primes. It follows from Dirichlet's theorem that the remainders should be distributed uniformly among the $\phi(n)$ congruence classes in \mathbb{Z}_n^* [19, Fact 4.2].

The patterns observed for the 512-bit keys were found to be identical to those for the stronger keys of 1024 and 2048 bits. For the software implementations, we checked the source codes to confirm that there were no differences in the algorithms used to generate keys of different lengths. For the cards, we assume the same and gen-

eralize the results obtained for 512-bit RSA keys to the longer (and much more common) keys.

3.2 Distributions of the moduli

The MSB of a modulus is directly dependent on the MSBs of the corresponding primes p and q . As seen in Figure 3, if an observable pattern exists in the distributions of the MSBs of primes p and q , a noticeable pattern also appears in the MSB of the modulus. The preservation of shared patterns was observed for all tested types of software libraries and cards. The algorithm used for prime pair selection can often be observed from the distribution of the moduli. If a source uses an atypical algorithm, it is possible to detect it with greater precision, even if we do not know the actual method used.

Non-randomness with respect to small factors of $p - 1$ can also be observed from the modulus, especially for

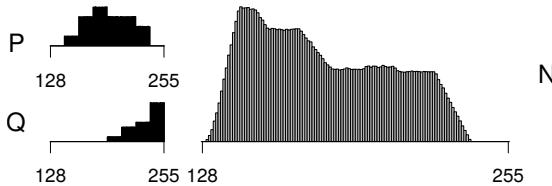

Figure 3: The visible preservation of the MSB distributions of the primes p and q in the MSB distribution of the modulus $n = p \cdot q$. This example is from the NXP J2A081 card.

small divisors. Whereas random primes are equiprobably congruent to 1 and 2 modulo 3, OpenSSL primes are always congruent to 2. As a result, an OpenSSL modulus is always congruent to 1 modulo 3. This property is progressively more difficult to detect for larger prime divisors. The moduli are more probably congruent to 1 modulo all small primes, which are avoided from $p - 1$ by OpenSSL. However, the bias is barely noticeable for prime factors of 19 and more, even in an analysis of a million keys. OpenSSL primes are congruent to 1 modulo 5 with probability 1/3 (as opposed to 1/4 for random primes), to 1 modulo 7 with probability 1/5 (as opposed to 1/6), and to 1 modulo 11 with probability 1/9 (as opposed to 1/10). For the practical classification of only a few keys (see Section 4), we use only the remainder of division by 3.

The use of *Blum integers* can also be detected from the moduli with a high precision, as random moduli are equiprobably congruent to 1 and 3 modulo 4, whereas Blum integers are always congruent to 1 modulo 4. The probability that k random moduli will be Blum integers is 2^{-k} .

Neither libraries nor cards attempt to achieve a uniform distribution of moduli. Existing algorithms [13, 17] have the disadvantage that sometimes a prime will be one bit larger than half of the modulus length. All sources sacrifice uniformity in the most significant bits of the modulus to benefit from more efficient methods of prime and key generation.

We verified that the distribution of the other bytes of the moduli is otherwise uniform. The second least significant bit is biased in the case of Blum integers. Sources that use the same algorithm are not mutually distinguishable from the distributions of their moduli.

3.3 Factorization of $p - 1$ and $p + 1$

It is possible to verify whether *strong primes* are being used. Most algorithms generate strong primes from uniform distributions (ANSI X9.31, FIPS 186-4, IEEE 1363, OpenSSL FIPS, libgcrypt FIPS, Microsoft and Gemalto GCX4 72K), matching the distribution of ran-

dom primes, although PGPSDK4 FIPS produces a highly atypical distribution of primes and moduli, such that this source can be detected even from public keys. Hence, we were obliged to search for the sizes of the prime factors of $p - 1$ and $p + 1$ directly⁹ by factoring them using the YAFU software package [29]. We then extended the results obtained for 512-bit keys to the primes of 1024-bit key pairs (though based on fewer factorized values because of the longer factorization time). Finally, we extrapolated the results to keys of 2048 bits and longer based on the known patterns for shorter keys.

As confirmed by the source code, large factors of $p \pm 1$ generated in OpenSSL FIPS and by libgcrypt in FIPS mode always have 101 bits; this value is hardcoded. PGPSDK4 in FIPS mode also generates prime factors of fixed length; however, their size depends on the size of the prime.

Additionally, we detected strong primes in some of our black-box sources. Gemalto GCX4 72K generates strong primes uniformly, but the large prime factors always have 101 bits. The strong primes of Gemalto GXP E64, which have 112 bits, are not drawn from a uniform distribution. The libraries that use Microsoft cryptography providers (CryptoAPI, CNG, and .NET) produce prime factors of randomized length, ranging from 101 bits to 120 bits, as required by ANSI X9.31.

For large primes, $p \pm 1$ has a large prime factor with high probability. A random integer p will not have a factor larger than $p^{1/u}$ with a probability of approximately u^{-u} [19]. Approximately 10% of 256-bit primes do not have factors larger than 100 bits, but 512-bit keys are not widely used. For 512-bit primes, the probability is less than 0.05%. Therefore, the requirement of a large factor does not seem to considerably decrease the number of possible primes. However, many sources construct strong primes with factors of exact length (e.g., 101 bits). Using the approximation of the prime-counting function $\pi(n) \approx \frac{n}{\ln(n)}$ [19], we estimate that the interval required by ANSI X9.31 (prime factors from 101 to 120 bits) contains approximately 2^{20} times more primes than the number of 101-bit primes. Hence, there is a loss of entropy when strong primes are generated in this way, although we are not aware of an attack that would exploit this fact. For every choice of an auxiliary prime, 2^{93} possible values are considered instead of 2^{113} , which implies the loss of almost 20 bits of entropy. If the primes are to be (p^-, p^+) -safe, then 2 auxiliary primes must be generated. Because we require two primes p and q for every RSA key, we double the estimated loss of entropy compared with ANSI-compliant keys to 80 bits for 1024-bit keys.

When $p - 1$ is guaranteed to have a large prime factor but $p + 1$ is not, the source is most likely using *provable*

⁹By $p - 1$, we always refer to both $p - 1$ and $q - 1$, as we found no relevant difference between p and q in the factorization results.

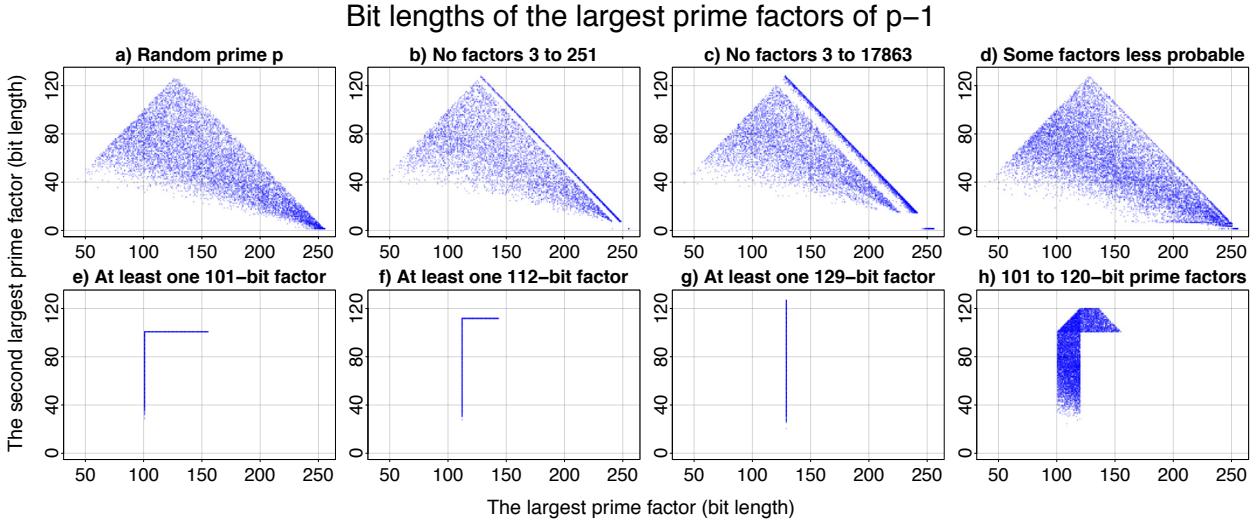

Figure 4: Scatter graphs with all combinations of two biggest factors of $p - 1$ for 512-bit RSA. The tested sources fall into following categories: **a)** Botan 1.11.29, Bouncy Castle 1.53 & 1.54, Cryptix JCE 20050328, cryptlib 3.4.3, Crypto++ 5.6.3, FlexiProvider 1.7p7, GNU Crypto 2.0.1, (GPG) libgcrypt 1.6.5, LibTomCrypt 1.17, mbedTLS 2.2.1, PGPSDK4, SunRsaSign (OpenJDK 1.8), G&D SmartCafe 3.2, Feitian JavaCOS A22, Feitian JavaCOS A40, NXP J2A080, NXP J2A081, NXP J3A081, NXP JCOP 41 V2.2.1, Oberthur Cosmo Dual 72K; **b)** NXP J2D081, NXP J2E145G; **c)** OpenSSL 1.0.2g; **d)** Infineon JT0P 80K; **e)** (GPG) libgcrypt 1.6.5 FIPS, OpenSSL FIPS 2.0.12, Gemalto GCX4 72K; **f)** Gemalto GXP E64; **g)** Nettle 3.2; **h)** MS CNG, MS CryptoAPI, MS .NET.

primes, as in the case of the Nettle library. Techniques for generating provable primes construct p using a large prime factor of $p - 1$ (at least \sqrt{p} for Maurer's algorithm or $\sqrt[3]{p}$ for an improved version thereof). The size of the prime factors of $p + 1$ is not affected by Maurer's algorithm.

Factorization also completes the picture with regard to the avoidance of small factors in $p - 1$. Sources that avoid small factors in $p - 1$ achieve a smaller number of factors on average (and therefore also a higher average length of the largest factor). No small factors are present in keys from NXP J2D081 and J2E145G (values from 3 to 251 are avoided), from OpenSSL (values from 3 to 17 863 are avoided) and from G&D Smartcafe 4.x and G&D Smartcafe 6.0 (values 3 and 5 are avoided). Small factors in $p + 1$ are not avoided by any source.

Concerning the *distribution of factors*, most of the software libraries (14) and card types (8) yield distributions comparable to that of randomly generated numbers of a given length (see Figure 4). The Infineon JT0P 80K card produces significantly more small factors than usual (compared with both random numbers and other sources). This decreases the probability of having a large factor.

We estimated the percentage of 512-bit RSA keys that are susceptible to Pollard $p - 1$ factorization within 2^{80} operations. This percentage ranges from 0% (FIPS-compliant sources) to 4.35% (Infineon JCOP 80K), with

an average of 3.38%. Although the NFS algorithm would still be faster in most cases of keys of 512 bits and larger, we found a card-generated key (with a small maximal factor of $p - 1$) that was factorized via Pollard $p - 1$ method in 19 minutes, whereas the NFS algorithm would require more than 2 000 CPU hours. Note that for 1024-bit keys, the probability of such a key being produced is negligible.

3.4 Sanity check

Based on the exported private and public components of the generated RSA keys obtained from all sources, we can summarize their basic properties as follows (see also Table 1):

- All values p and q are primes and are not close enough for Fermat factorization to be practical.
- All card-generated keys use a public exponent equal to 0x10001 (65 537), and all software libraries either use this value as the default or support a user-supplied exponent.
- Most modulus values are of an exactly required length (e.g., 1024 bits). The only exception is PGPSDK4 in FIPS mode, which also generates moduli that are shorter than the specified length by one or two bits.

- Neither libraries nor cards ensure that p is a safe prime ($p = 2 \cdot q + 1$, where q is also prime).
- Some sources construct strong primes according to the stricter definition or at least comply with the requirements defined in the FIPS 186-4 and ANSI X9.31 standards, such that $p - 1$ and $p + 1$ both have a large prime factor. Other libraries are not FIPS-compliant; however, keys of 1024 bits and larger resist $p - 1$ and $p + 1$ attacks for practical values of the smoothness bound.
- Some libraries (5) and most card types (12) order the primes such that $p > q$, which seems to be a convention for CRT RSA keys. PGPSDK4 (in both regular and FIPS modes) and libgcrypt (used by GnuPG) in both modes order the primes in the opposite manner, $q > p$. In some sources, the ordering is a side effect of the primes having fixed (and different) most significant bits (e.g., 4 bits of p and q are fixed to 1111 and 1001, respectively, by all G&D cards).
- All generated primes were unique for all libraries and all types of cards except one (Oberthur Cosmo Dual 72K).
- All G&D and NXP cards, the Oberthur Cosmo Dual 72K card and the GNU Crypto library generate Blum integers. As seen from a bug in the implementation of the Miller-Rabin test in GNU Crypto, a simpler version of the test suffices for testing Blum primes. However, we hypothesize that the card manufacturers have a different motivation for using such primes.

4 Key source detection

The distinct distributions of specific bits of primes and moduli enable probabilistic estimation of the source library or card from which a given public RSA key was generated. Intuitively, classification works as follows: 1) Bits of moduli known to carry bias are identified with additional bits derived from the modulus value (a *mask*, 6 + 3 bits in our method). 2) The frequencies of all possible *mask* combinations (2^9) for a given source in the learning set are computed. 3) For classification of an unknown public key, the bits selected by the *mask* are extracted as a particular value v . The source with the highest computed frequency of value v (step 2) is identified as the most probable source. When more keys from the same source are available (multiple values v_i), a higher classification accuracy can be achieved through element-wise multiplication of the probabilities of the individual keys.

We first describe the creation of a classification matrix and report the classification success rate as evaluated on our test set [31]. Later, classification is applied to three real-world datasets: the IPv4 HTTPS handshakes set [9], Certificate Transparency set [10] and the PGP key set [30].

4.1 The classification process

The classification process is reasonably straightforward. For the full details of the algorithm, please refer to our technical report [25].

1. All modulus bits identified through previous analysis as non-uniform for at least one source are included in a *mask*. We included the $2^{nd} - 7^{th}$ most significant bits influenced by the prime manipulations described in Section 3.1, the second least significant bit (which is zero for sources that use Blum integers), the result of the modulus modulo 3 (which is influenced by the avoidance of factor 3) and the overall modulus length (which indicates whether an exact length is enforced).
2. A large number of keys (learning set) from known generating sources are used to create a *classification matrix*. For every possible *mask* value (of which there are 2^9 in our case) and every source, the relative frequency of the given mask value in the learning set for the given source is computed.
3. During the classification phase for key K with modulus m , the value v obtained after the application of *mask* to modulus m is extracted. The row (*probability vector*) of the *classification matrix* that corresponds to the value v contains, as its i^{th} element, the probability of K being produced by source i .
4. When a batch of multiple keys that are known to have been produced by the same (unknown) source is classified, the *probability vectors* for every key obtained in step 3 are multiplied element-wise and normalized to obtain the source probabilities p_b for the entire batch, and the source with the highest probability is selected.

Note that the described algorithm cannot distinguish between sources with very similar characteristics, e.g., between the NXP J2D081 and NXP J2E145G cards, which likely share the same implementation. For this reason, if two sources have the same or very similar profiles, they are placed in the same *group*. Figure 5 shows the clustering and (dis-)similarity of all sources considered in this study. If the particular source of one or more key(s) is missing from our analysis (relevant for the classification

Table 1: Comparison of cryptographic libraries and smartcards. The algorithms are explained in Section 2.3. **Prime search method:** incremental search (Incr.); random sampling (Rand.); FIPS 186-4 Appendix B.3.6 or equivalent algorithm for strong primes (FIPS); Maurer’s algorithm for provable primes (Maurer); PGP strong primes (PGP); Gemalto strong primes (Gem.); Infineon algorithm (Inf.); unknown prime generator with almost uniform distribution, possibly incremental or random search (Incr./Rand.). **Prime pair selection:** practical square region (11_2); rejection sampling (RS); maximal square region ($\sqrt{2}$); the primes p and q have a fixed pattern in their top four bits, 1111_2 and 1001_2 , respectively ($FX \times 9X$); Gemalto non-uniform strong primes (Gem.); Infineon algorithm (Inf.); NXP regions – 14 distinct square regions characterized by patterns in the top four bits of p and q (NXP). **Blum integers:** the modulus n is always a Blum integer $n \equiv 1 \pmod{4}$ (✓); the modulus is $n \equiv 1 \pmod{4}$ and $n \equiv 3 \pmod{4}$ with equal probability (×). **Small factors of $p - 1$:** $p - 1$ contains small prime factors (✓); some prime factors are avoided in $p - 1$ (×). **Large factors of $p - 1$:** $p - 1$ is guaranteed to have a large prime factor – provable and strong primes (✓); size of the prime factors of $p - 1$ is random (×). **Large factors of $p + 1$:** similar as for $p - 1$, typically strong primes are (✓); random and provable primes are (×). **$|p - q|$ check:** p and q differ somewhere in their top bits (✓); the property is not guaranteed (×); the check may be performed, but the negative case occurs with a negligible probability (?). **$|d|$ check:** sufficient bit length of the private exponent d is guaranteed (✓); not guaranteed (×); possibly guaranteed, but not detectable (?).

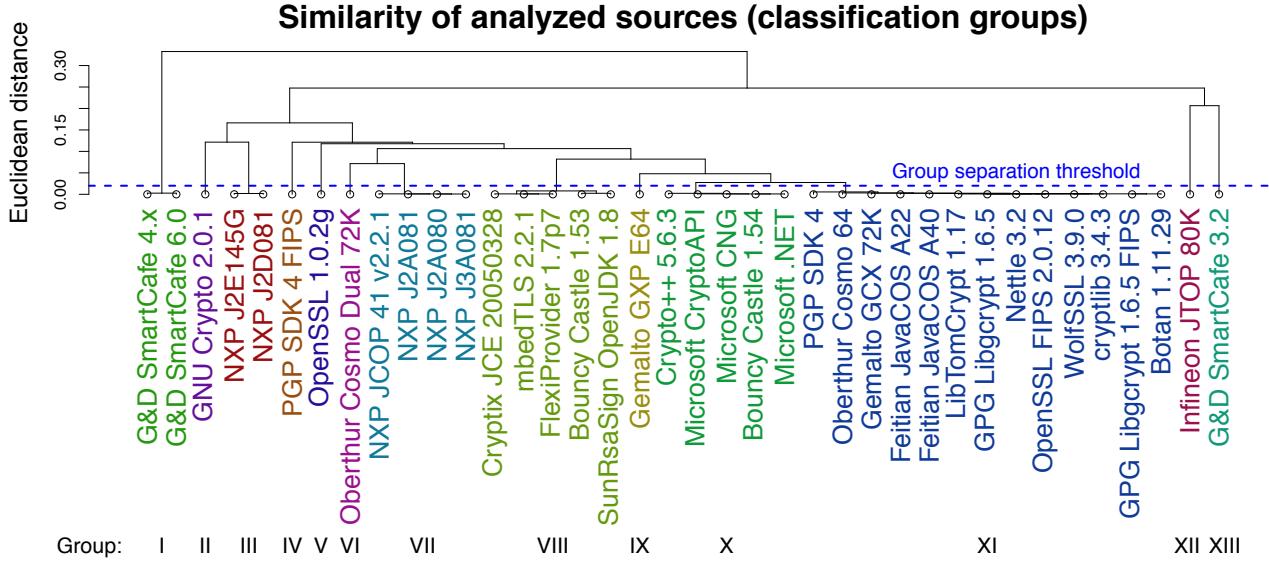

Figure 5: Clustering of all inspected sources based on the 9 bits of the mask. The separation line shows which sources were put by us into the same classification category. Finer separation is still possible (e.g., SunRsaSign vs mbedTLS), but the number of the keys from same source needs to be high enough to distinguish these very similar sources.

Table 2: The classification success rate of 13 groups created from all 38 analyzed sources using test set with same prior probability of sources (see Figure 5 for libraries and cards in particular group). Columns corresponds to different number of keys (1, 2, 5, 10 and 100) classified together from same (unknown) source.

of real-world datasets), any such key will be misclassified as belonging to a group with a similar mask *probability vector*.

Both the construction of the classification matrix and the actual classification are then performed using these *groups* instead of the original single sources. The observed similarities split the examined sources into 13 different groups (labelled I to XIII and listed in Figure 5). The resulting classification matrix¹⁰ has dimensions of 13×512 .

¹⁰Because of its large size, the resulting matrix is available in our technical report [25] and at <http://crcs.cz/papers/usenix2016>.

4.1.1 Evaluation of the classification accuracy

To evaluate the classification success of our method, we randomly selected 10 000 keys from the collected dataset (that were not used to construct the classification matrix) for every source, thereby endowing the test set with equal prior probability for every source.

A single organization may use the same source library to generate multiple keys for its web servers. The classification accuracy was therefore evaluated not only for one key (step 3 of the algorithm) but also for five, ten and one hundred keys (step 4) originating from the same (unknown) source. We evaluated not only the ability to

achieve the “best match” with the correct source group but also the ability to identify the correct source group within the top two and top three most probable matches (top- n match).

As shown in Table 2, the average accuracy on the test set of the most probable source group was over 40% for single keys and improved to greater than 93% when we used batches of 100 keys from the same source for classification. When 10 keys from the same source were classified in a batch, the most probable classified group was correct in more than 85% of cases and was almost always (99%) included in the top three most probable sources.

A significant variability in classification success was observed among the different groups. Groups I (G&D cards) and IV (PGPSDK4 FIPS) could be correctly identified from even a single key because of their distinct distributions of possible mask values. By contrast, group X (Microsoft providers) was frequently misclassified when only a single key was used because of the wider range of possible mask values, resulting in a lower probability of each individual mask value.

We conclude that our classification method is moderately successful even for a single key and very accurate when a batch of at least 10 keys from the same source is classified simultaneously.

Further leakage in other bits of public moduli might be found by applying machine learning methods to the learning set, potentially leading to an improvement of the classification accuracy. Moreover, although we have already tested a wide range of software libraries and cards, more sources could also be incorporated, such as additional commercial libraries, various hardware security modules and additional types of cards and security tokens.

4.2 Classifying real-world keys

One can attempt to classify keys from suitable public datasets using the described method. However, the classification of keys observed in the real world may differ from the classification scenario evaluated above in two respects:

1. The prior probabilities of real-world sources can differ significantly (e.g., OpenSSL is a more probable source for TLS keys than is any card), and the resulting posterior probabilities from the classification matrix will then also be different.
2. Our classification matrix does not include all existing sources (e.g., we have not tested high-speed hardware security modules), and such sources will therefore always be misclassified.

The classification success rate can be significantly improved if the prior distribution of possible sources can be

estimated. Such an estimate can be performed based on meta information such as statistics concerning the popularity of various software libraries or sales figures for a particular card model. Note that the prior distributions may also significantly differ for different application areas, e.g., PGP keys are generated by a narrower set of libraries and devices than are TLS keys. In this work, we did *not* perform any prior probability estimations.

4.2.1 Sources of Internet TLS keys

We used IPv4 HTTPS handshakes collected from the Internet-Wide Scan Data Repository [9] as our source of real-world TLS keys. The complete set contains approximately 50 million handshakes; the relevant subset, which consists of handshakes using RSA keys with a public exponent of 65 537, contains 33.5M handshakes. This set reduces to 10.7M unique keys based on the modulus values. The keys in this set can be further divided into *batches* with the same subject and issue date (as extracted from their certificates), where the same underlying library is assumed to be responsible for the generation of all keys in a given *batch*. As the classification accuracy improves with the inclusion of more keys in a *batch*, we obtained classification results separately for batches consisting of a single key only (users with a single HTTPS server), 2-9 keys, 10-99 keys (users with a moderate number of servers) and 100 and more keys (users with a large number of servers).

Intuitively, batches with 100+ keys will yield very accurate classification results but will capture only the behaviour of users with a large number of HTTPS servers. Conversely, batches consisting of only a single key will result in low accuracy but can capture the behaviours of different types of users.

The frequency of a given source in a dataset (for a particular range of batch sizes) is computed as follows: 1) The classification probability vector p_b for a given batch is computed according to the algorithm from Section 4.1. 2) The element-wise sum of $p_b \cdot n_b$ over all batches b (weighted by the actual number of keys n_b in the given batch) is computed and normalized to obtain the relative proportion vector, which can be found as a row in Table 3.

As shown in Section 4.1.1, a batch of 10 keys originating from the same source should provide an average classification accuracy of greater than 85% – sufficiently high to enable reasonable conclusions to be drawn regarding the observed distribution. Using batches of 10-99 keys, the highest proportion of keys generated for TLS IPv4 (82%) were classified as belonging to group V, which contains a single library – OpenSSL. This proportion increased to almost 90% for batches with 100+ keys. The second largest proportion of these keys (ap-

Dataset (size of included batches)	#keys	Group of sources												
		I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII	XIII
Multiple keys classified in single batch, likely accurate results (see discussion in Section 4.1.1)														
TLS IPv4 (10-99 keys) [9]	518K	-	0.00%	-	0.01%	82.84%	-	-	1.09%	0.28%	10.18%	5.61%	-	-

PGP keyset (2-9 keys) [30]	83K	0.02%	1.47%	1.40%	2.07%	14.36%	7.90%	3.91%	7.74%	16.10%	18.80%	25.86%	0.35%	0.03%
Classification based on single key only, likely low accuracy results														
TLS IPv4 (1 key) [9]	8.8M	0.98%	4.02%	6.47%	1.94%	21.01%	8.63%	6.13%	8.65%	12.22%	11.95%	13.48%	3.49%	1.03%
Cert. Transparency (1 key) [10]	12.7M	0.88%	3.75%	6.90%	1.49%	23.10%	8.69%	6.04%	7.99%	12.08%	11.78%	13.50%	3.04%	0.77%
PGP keyset (1 key) [30]	1.35M	0.44%	4.24%	4.09%	2.17%	13.91%	10.55%	7.18%	8.83%	14.34%	14.22%	16.79%	2.64%	0.59%

Table 3: *The ratio of resulting source groups identified by the classification method described in Section 4. Datasets are split into subsets based on the number of keys that can be attributed to a single source (batch). ‘-’ means no key was classified for the target group. ‘0.00%’ means that some keys were classified, but less than 0.005%.*

proximately 10.2%) was assigned to group X, which contains the Microsoft providers (CAPI, CNG, and .NET).

These estimates can be compared against the estimated distribution of commonly used web servers. Apache, Nginx, LiteSpeed, and Google servers with the OpenSSL library as the default option have a cumulative market share of 86% [32]. This value exhibits a remarkably close match to the classification rate obtained for OpenSSL (group V). MS Internet Information Services (IIS) is included with Microsoft’s cryptographic providers (group X) and has a market share of approximately 12%. Again, a close match is observed with the classification value of 10.2% obtained for users with 10-99 certificates certified within the same day (batch).

Users with 100 and more keys certified within the same day show an even stronger preference for OpenSSL library (89.9%; group V) and also for group VIII (4.6%; this group contains popular libraries such as OpenJDK’s SunRsaSign, Bouncy Castle and mbedTLS) at the expense of groups X and XI.

The classification accuracy for users with only single-key batches or a small number of keys per batch is significantly less certain, but the general trends observed for larger batches persist. Group V (OpenSSL) is most popular, with group X (Microsoft providers) being the second most common. Although we cannot obtain the exact proportions of keys generated using particular sources/groups, we can easily determine the proportion of keys that *certainly could not* have been generated by a given source by means of the occurrence of impossible values produced by the bit mask, i.e., values that are never produced by the given source. Using this method,

we can conclude for certain that 19%, 25%, 17% and 10% of keys for users with 1, 2-9, 10-99 and 100+ keys per batch, respectively, could not have been generated by the OpenSSL library (see [25] for details).

Another dataset of TLS keys was collected from Google’s Pilot Certificate Transparency server [10]. The dataset processing was the same as that for the previous TLS dataset [9]. For users with small numbers of keys (1 and 2-9), the general trends observed from the TLS IPv4 dataset were preserved. Interestingly, however, Certificate Transparency dataset indicates that group X (Microsoft) is significantly more popular (47%) than group V (OpenSSL) for users with 10-99 keys.

4.2.2 Sources of PGP keys

A different set of real-world keys can be obtained from PGP key servers [30]. We used a dump containing nearly 4.2 million keys, of which approximately 1.4 million were RSA keys suitable for classification using the same processing as for the TLS datasets. In contrast to the TLS handshakes, significantly fewer PGP keys could be attributed to the same batch (i.e., could be identified as originating from the same unknown source) based on the subject name and certification date. Still, 84 thousand unique keys were extracted in batches of 2-9 keys and 1 732 for batches of 10-99 keys.

The most prolific source group is group XI (which contains both libgcrypt from the GnuPG software distribution and the PGPSDK4 library), as seen in Table 3. This is intuitively expected because of the widespread use of these two software libraries. Group

VIII, consisting of the Bouncy Castle library (containing the *org.bouncycastle.openpgp* package), is also very common (36%) for batches of 10-99 keys.

Because of the lower accuracy of classification for users with smaller numbers of keys (1 and 2-9), it is feasible only to consider the general properties of these key batches and their comparison with the TLS case rather than being concerned with the exact percentage values in these settings. The results for the PGP dataset indicate a significant drop in the proportion of keys generated using the OpenSSL library. According to an analysis of the keys that *certainly could not* have been obtained from a given source, at least 47% of the single-key batches were certainly *not* generated by OpenSSL, and this percentage increases to 72% for batches of 2-9 keys. PGPSDK4 in FIPS mode (group IV) was found to be significantly more common than in the TLS datasets.

Note that an exported public PGP key usually contains a *Version* string that identifies the software used. Unfortunately, however, this might be not the software used to generate the original key pair but merely the software that was used to export the public key. If the public key was obtained via a PGP keyserver (as was the case for our dataset), then the *Version* string indicates the version of the keyserver software itself (e.g., *Version: SKS 1.1.5*) and cannot be used to identify the ratios of the different libraries used to generate the keys¹¹.

5 Practical impact of origin detection

The possibility of accurately identifying the originating library or card for an RSA key is not solely of theoretical or statistical interest. If some library or card is found to produce weak keys, then an attacker can quickly scan for other keys from the same vulnerable source. The possibility of detection is especially helpful when a successful attack against a weak key requires a large but practically achievable amount of computational resources. Preselecting potentially vulnerable keys saves an attacker from spending resources on all public keys.

The identification of the implementations responsible for the weak keys found in [3, 12] was a difficult problem. In such cases, origin classification can quickly provide one or a few of the most probable sources for further manual inspection. Additionally, a set of already identified weak keys can be used to construct a new classification group, which either will match an already known one (for which the underlying sources are known) or can be used to search for other keys that belong to this new group in the remainder of a larger dataset (even when the source is unknown).

¹¹A dataset with the original *Version* strings could be used to test these predictions.

Another practical impact is the decreased anonymity set of the users of a service that utilizes the RSA algorithm whose users are not intended to be distinguishable (such as the Tor network). Using different sources of generated keys will separate users into smaller anonymity groups, effectively decreasing their anonymity sets. The resulting anonymity sets will be especially small when individual users decides to use cryptographic hardware to generate and protect their private keys (if selected device does not fall into into group with widely used libraries). Note that most users of the Tor project use the default client, and hence the same implementation, for the generation of the keys they use. However, the preservation of indistinguishability should be considered in the development of future alternative clients.

Tor hidden services sometimes utilize ordinary HTTPS certificates for TLS [1], which can be then linked (via classification of their public keys) with other services of the same (unknown) operator.

Mixnets such as mixmaster and mixminion use RSA public keys to encrypt messages for target recipient and/or intermediate mix. If key ID is preserved, one may try to obtain corresponding public key from PGP keyserver and search for keys with the same source to narrow that user's anonymity set in addition to analysis like one already performed on alt.anonymous.messages [22]. Same as for Tor network, multiple seemingly independent mixes can be linked together if uncommon source is used to generate their's RSA keys.

A related use is in a forensic investigation in which a public key needs to be matched to a suspect key-generating application. Again, secure hardware will more strongly fingerprint its user because of its relative rarity.

An interesting use is to verify the claims of remote providers of Cryptography as a Service [4] regarding whether a particular secure hardware is used as claimed. As the secure hardware (cards) used in our analysis mostly exhibit distinct properties of their generated keys, the use of such hardware can be distinguished from the use of a common software library such as OpenSSL.

5.1 How to mitigate origin classification

The impact of successful classification can be mitigated on two fronts: by library maintainers and by library users. The root cause lies with the different design and implementation choices for key generation that influence the statistical distributions of the resulting public keys. A maintainer can modify the code of a library to eliminate differences with respect to the approach used by all other sources (or at least the most common one, which is OpenSSL in most cases). However, although this might

work for one specific library (mimicking OpenSSL), it is not likely to be effective on a wider scale. Changes to all major libraries by its maintainers are unlikely to occur, and many users will continue to use older versions of libraries for legacy reasons.

More pragmatic and immediate mitigation can be achieved by the users of these libraries. A user may repeatedly generate candidate key pairs from his or her library or device of choice and reject it if its classification is too successful. Expected number of trials differs based on the library used and the prior probability of sources within the targeted domain. For example, if TLS is the targeted domain, five or less key generation trials are expected for most libraries to produce “indecisive” key.

The weakness of the second approach lies in the unknown extent of public modulus leakage. Although we have described seven different causes of leakage, others might yet remain unknown – allowing for potential future classification of keys even after they have been optimized for maximal indecisiveness against these seven known causes.

This strategy can be extended when more keys are to be generated. All previously generated keys should be included in a trial classification together with the new candidate key. The selection process should also be randomized to some extent; otherwise, a new classification group of “suspiciously indecisive” keys might be formed.

6 Key generation process on cards

The algorithms used in open-source libraries can be inspected and directly correlated to the biases detected in their outputs. To similarly attribute the biased keys produced by cards to their unknown underlying algorithms, we first verified whether the random number generator might instead be responsible for the observed bias. We also examined the time- and power-consumption side channels of the cards to gain insight into the processes responsible for key generation.

Truly random data generated on-card are a crucial input for the primes used in RSA key pair generation. A bias in these data would influence the predictability of the primes. If a highly biased or malfunctioning generator is used, factorization is not necessary (only a small number of fixed values can be taken as primes) or is feasible even for RSA keys with lengths otherwise deemed to be secure [3, 6, 12].

6.1 Biased random number generator

The output of an on-card truly random number generator (TRNG) can be tested using statistical batteries, and deviances are occasionally detected in commercial security tokens [6]. We generated a 100 MB stream of ran-

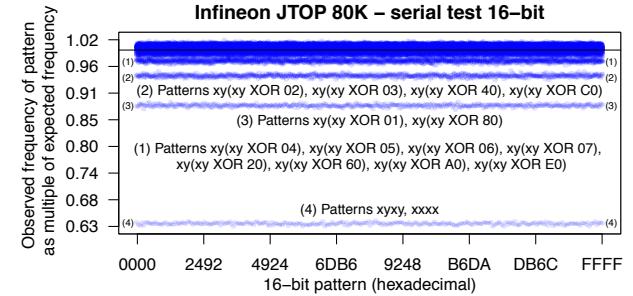

Figure 6: *The frequencies of different patterns with the length of 16 bits computed from 1 GB random data stream generated by the Infineon JTOP 80K card. At least five distinct patterns can be identified where all patterns should exhibit an uniform distribution instead.*

dom data from one card of each type and tested these data streams using the common default settings of the NIST STS and the Dieharder battery of statistical tests [7, 23] as well as our alternative EACirc distinguisher [24]. All types of cards except two (Infineon JTOP 80K and Oberthur Cosmo Dual 72K) passed the tests with the expected number of failures at a confidence level of 1%.

The Infineon JTOP 80K failed the NIST STS Approximate Entropy test (85/100, expected entropy contained in the data) at a significant level and also failed the group of Serial tests from the Dieharder suite (39/100, frequency of overlapping n -bit patterns). Interestingly, the serial tests began to fail only for patterns with lengths of 9 bits and longer (lengths of up to 16 bits were tested), suggesting a correlation between two consecutive random bytes generated by the TRNG. As shown in Figure 6, for 16-bit patterns, all bytes in the form of $xyxy$ (where x and y denote 4-bit values) were 37% less likely to occur than other combinations. At least three more distinct groups of inputs with smaller-than-average probabilities were also identified. Note that deviating distributions were observed in all three physical Infineon JTOP 80K cards that were tested and thus were probably caused by a systematic defect in the entire family of cards rather than a single malfunctioning device. The detected bias is probably not sufficient to enable faster factorization by guessing potential primes according to the slightly biased distribution. However, it may be used to identify this type of card as the source of a sufficiently large (e.g., 1KB) random data stream (i.e., to fingerprint such a random stream).

The Oberthur Cosmo Dual 72K failed more visibly, as two cards were blocked after the generation of only several MB of random data. The statistical tests then frequently failed because of the significant bias in the data. Several specific byte values were never produced in the “random” stream.

We also generated data streams directly from the concatenated exported primes with the two most significant bytes and the least two bits dropped, as the previous analysis had revealed a non-uniform distribution in these bits. Interestingly, both the Infineon JTOP 80K and the Oberthur Cosmo Dual 72K failed only for their random data streams (as described above) but successfully passed¹² for the streams generated from the concatenated primes, hinting at the possibility that either random data are generated differently during prime generation or (unlikely) the prime selection process is able to mask the bias observed in the raw random data.

6.1.1 Malfunctioning generator

All primes for the card-generated 512- and 1024-bit keys were tested for uniqueness. All tested card types except one generated unique primes. In the exceptional case of the Oberthur Cosmo Dual 72K cards, approximately 0.05% of the generated keys shared a specific value of prime q . The flaw was discovered in all three tested physical cards for both 512-bit and 1024-bit keys. The repeated prime value was equal to 0xC000...0077 for 512-bit RSA keys and 0xC000...00E9B for 1024-bit RSA keys. These prime values correspond to the first Blum prime generated when starting from the value 0xC000...000 in each case.

The probable cause of such an error is the following sequence of events during prime generation: 1) The random number generator of the card was called but failed to produce a random number, either by returning a value with all bits set to zero or by returning nothing into the output memory, which had previously been zeroed. 2) The candidate prime value q (equal to 0 at the time) had its highest four bits fixed to 1100₂ (to obtain a modulus of the required length¹³ when multiplied by the prime p), resulting in a value of 0xC0 in the most significant byte. 3) The candidate prime value was tested for primality and increased until the first prime with the required properties (a Blum prime in the case of the Oberthur Cosmo Dual 72K) was found (0xC000...0077 in the case of 512-bit RSA).

The faulty process described above that leads to the observed predictable primes may also occur for other cards or software libraries as a result of multiple causes (e.g., an ignored exception in random number generation or a programming error). We therefore inspected our key pair dataset, the TLS IPv4 dataset [9] and the PGP dataset [30] for the appearance of such primes relevant to key lengths of 512, 1024 and 2048 bits. Interestingly, no such corrupt keys were detected except for those already described.

¹²Except for the Oberthur nearly zero keys (see Section 6.1.1).

¹³As was observed for the dataset analysed in Section 3.

Note that a random search for a prime is much less likely to fail in this mode. Even if some of the top bits and the lowest bit are set to one, the resulting value is not a prime for common MSB masks. New values will be generated if the starting value contains only zeroes.

6.2 Power analysis of key generation

Analysis of power consumption traces is a frequently used technique for card inspection. The baseline power trace expected should cover at least the generation of random numbers of potential primes, primality testing, computation of the private exponent and storage of generated values into a persistent key pair object. We utilized the simple power analysis to reveal significant features like random number generation, RSA encryption, and RSA decryption operation, separately. By programming a card to call only the desired operation (generate random data, encrypt, decrypt), the feature pattern for the given operation is obtained. These basic operations were identified in all tested types of cards. Once identified, the operations can be searched for inside a more complex operations like the RSA key pair generation.

A typical trace of the RSA key pair generation process (although feature patterns may differ with card hardware) contains: 1) Power consumption increases after the generating key pair method is called (cryptographic RSA coprocessor turned on). 2) Candidate values for primes p and q are generated (usage of a TRNG can be observed from the power trace) and tested. 3) The modulus and the private exponent are generated (assumed, not distinguishable from the power trace). 4) Operation with a private key is executed (decryption, in 7 out of 16 types of cards) to verify key usability. 5) Operation with a public key is executed (encryption, 3 types of cards only).

Note that even when the key generation process is correctly guessed, it is not possible to simply implement it again and compare the resulting power traces – as only the card’s main CPU is available for user-defined operations, instead of a coprocessor used by the original process. Additional side-channel and fault induction protection techniques may be also applied. Therefore, one cannot obtain an exactly matching power trace from a given card due to unavailability of low-level programming interfaces and additionally executed operations for verification of key generation hypothesis.

Whereas some steps of the key generation, such as the randomness generation, take an equal time across multiple runs of the process, the time required to generate a prime differs greatly as can be also seen from the example given in Figure 7, where timing is extracted from the power trace. The variability can be attributed to the randomized process of the prime generation. Incremental search will find the first prime greater than a random

number selected as the base of the search. Since both primes p and q are distributed as distances from a random point to a prime number, the resulting time distribution will be affected by a mixture of these two distributions.

In samples collected from 12 out of 16 types of cards, the distribution of time is concentrated at evenly spaced points¹⁴ as seen in Figure 7. The distance between a pair of points is interpreted as the duration of a single primality test, whereas their amount corresponds to the number of candidates that were ruled out by the test as a composite. Then it is possible to obtain a histogram of number of tested candidates, e.g., by binning the distribution with breaks placed in the midpoints of the empty intervals.

6.3 Time distribution

We experimentally obtained distributions for a number of needed primality tests for different parameters of trial division. Then we were able to match them with distributions from several cards, obtaining a likely estimate for the number of primes used by the card in the trial division (sieving) phase. For some types of cards, a single parameter did not match distributions of neither 512-bit nor 1024-bit keys. There may exist a different optimal value of trial division tests and primality tests for different key lengths. Notably, in some cases of card-generated 512-bit keys, the number of primality tests would have to be halved to exactly match a referential distribution. However, we are not aware of a mechanism that would perform two primality tests in parallel or at least in the same time, as is required for testing a candidate of double bit length.

The exact time distribution for software implementations is of less concern since the key generation process tends to be much faster on an ordinary CPU. The source code can be modified to accommodate for counting the number of tests directly (as shown in the inlay in Figure 7) without relying on time measurement that may be influenced by other factors specific to the implementation.

7 Conclusions

This paper presents a thorough analysis of key pairs generated and extracted from 38 different sources encompassing open-source and proprietary software libraries and cryptographic cards. This broad analysis allowed us to assess current trends in RSA key pair generation even when the source codes for key generation were not available, as in the case of proprietary libraries and cards. The

¹⁴Due to small differences in duration of key generation and rounding caused by precision of the measurement, the times belonging to the same group will not be identical to one millisecond. The peaks were highlighted by summing adjoining milliseconds, but only in the case when large (almost) empty spaces exist in the distribution.

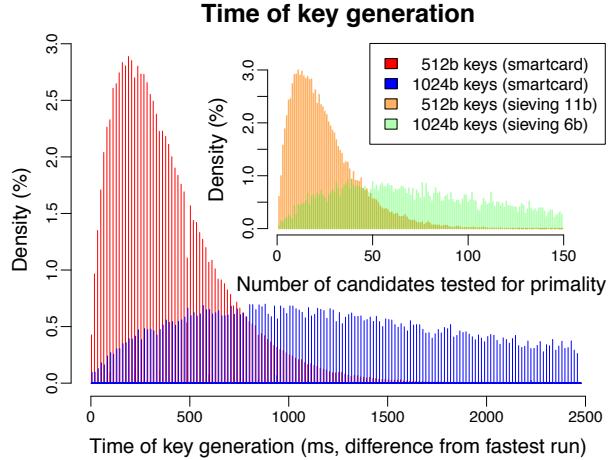

Figure 7: An example of the histogram of times necessary to generate a large number of 512 and 1024-bit RSA keys generated from an NXP J2D081 card. Left – the distribution of key generation times is concentrated around evenly spaced points, with the distance representing the duration of a single primality test. The times were normalized to begin at zero, therefore they represent difference from the fastest run. Inlay – the distribution of number of candidates tested by primality tests obtained from a software implementation. 512-bit keys are generated with trial division up to 11-bit primes, 1024-bit keys used 6-bit primes. The results show a clear correlation between the generation time and an expected number of primality tests.

range of approaches identified indicates that the question of how to generate an optimal RSA key has not yet been settled.

The tested keys were generally found to contain a high level of entropy, sufficient to protect against known factorization attacks. However, the source-specific prime selection algorithms, postprocessing techniques and enforcement of specific properties (e.g., Blum primes) make the resulting primes slightly biased, and these biases serve as fingerprints of the sources. Our paper therefore shows that public moduli leak significantly more information than previously assumed. We identified seven properties of the generated primes that are propagated into the public moduli of the generated keys. As a result, accurate identification of originating library or smartcard is possible based only on knowledge of the public keys. Such an unexpected property can be used to decrease the anonymity set of RSA keys users, to search for keys generated by vulnerable libraries, to assess claims regarding the utilization of secure hardware by remote parties, and for other practical uses. We classified the probable origins of keys in two large datasets consisting of 10 and

15 million (mostly) TLS RSA keys and 1.4 million PGP RSA keys to obtain an estimate of the sources used in real-world applications.

The random number generator is a crucial component for the generation of strong keys. We identified a generic failure scenario that produces weak keys and occasionally detected such keys in our dataset obtained from the tested cards. Luckily, no such weak key was identified in the datasets of publicly used RSA keys.

Fingerprinting Electronic Control Units for Vehicle Intrusion Detection

Kyong-Tak Cho and Kang G. Shin

The University of Michigan

{*ktcho, kgshin*}@umich.edu

Abstract

As more software modules and external interfaces are getting added on vehicles, new attacks and vulnerabilities are emerging. Researchers have demonstrated how to compromise in-vehicle Electronic Control Units (ECUs) and control the vehicle maneuver. To counter these vulnerabilities, various types of defense mechanisms have been proposed, but they have not been able to meet the need of strong protection for safety-critical ECUs against in-vehicle network attacks. To mitigate this deficiency, we propose an anomaly-based intrusion detection system (IDS), called *Clock-based IDS* (CIDS). It measures and then exploits the intervals of periodic in-vehicle messages for fingerprinting ECUs. The thus-derived fingerprints are then used for constructing a baseline of ECUs' clock behaviors with the Recursive Least Squares (RLS) algorithm. Based on this baseline, CIDS uses Cumulative Sum (CUSUM) to detect any abnormal shifts in the identification errors — a clear sign of intrusion. This allows quick identification of in-vehicle network intrusions with a low false-positive rate of 0.055%. Unlike state-of-the-art IDSs, if an attack is detected, CIDS's fingerprinting of ECUs also facilitates a root-cause analysis; identifying which ECU mounted the attack. Our experiments on a CAN bus prototype and on real vehicles have shown CIDS to be able to detect a wide range of in-vehicle network attacks.

1 Introduction

Security has now become an important and real concern to connected and/or automated vehicles. The authors of [9] systematically analyzed different attack vectors in vehicles (e.g., Bluetooth, Cellular), and showed that in-vehicle Electronic Control Units (ECUs) can be compromised for remote attacks. Through a compromised ECU, the adversary can control the vehicle by injecting packets in the in-vehicle network [20, 23]. Researchers have

also been able to compromise and remotely stop a Jeep Cherokee running on a highway [7, 25], which triggered a recall of 1.4 million vehicles. Such a reality of vehicle attacks has made automotive security one of the most critical issues.

As a countermeasure against such attacks on in-vehicle networks, two main lines of defense have been pursued: *message authentication* and *intrusion detection*. Although message authentication provides a certain level of security and is shown to be efficient for Internet security, its adoption in in-vehicle networks is hindered by (i) the limited space available for appending a Message Authentication Code (MAC) in in-vehicle messages and (ii) its requirements of real-time processing and communication.

Various types of Intrusion Detection Systems (IDS) have been proposed [16, 23, 30, 31]. The essence of state-of-the-art IDSs is to monitor the contents and the periodicity of in-vehicle messages and verify whether there are any significant changes in them. Since they are either constant or predictable in in-vehicle networks, such approaches can be feasible in most circumstances. However, there still remain critical attacks which existing IDSs can neither detect nor prevent, for two main reasons: 1) in-vehicle messages do not carry information on their transmitters, and thus one cannot tell whether they originate from genuine transmitters; and 2) lack of the transmitters' information makes it very difficult or impossible for state-of-the-art IDSs to identify which ECU has mounted an attack.

To overcome these limitations and defend against various vehicle attacks, we propose a new anomaly-based IDS, called *Clock-based IDS* (CIDS). The need of CIDS for vehicles is motivated through an analysis of three representative in-vehicle network attacks — fabrication, suspension, and masquerade attacks. Our analysis shows that state-of-the-art IDSs are insufficient, especially in detecting the masquerade attack due to the absence of the transmitters' information in messages. CIDS over-

comes these limitations of existing IDSs by fingerprinting in-vehicle ECUs. Researchers have proposed various schemes for fingerprinting network devices by estimating their clock skews through the timestamps carried in their control packet headers [17, 19, 34, 42]. However, since such embedded timestamps are not available for in-vehicle networks making them inapplicable, CIDS fingerprints in-vehicle ECUs in a very different way.

CIDS monitors the intervals of (commonly seen) periodic in-vehicle messages, and then exploits them to estimate the clock skews of their transmitters which are then used to fingerprint the transmitters. That is, instead of assuming or requiring timestamps to be carried in messages for fingerprinting, CIDS exploits the periodic feature (seen at receivers) of in-vehicle network messages for fingerprinting transmitter ECUs. This makes CIDS invulnerable to attackers who use faked timestamps and thus clock skews — a problem that timestamp-based fingerprinting schemes cannot handle. Based on the thus-obtained fingerprints, CIDS constructs a norm model of ECUs’ clock behaviors using the Recursive Least Squares (RLS) algorithm and detects intrusions with a Cumulative Sum (CUSUM) analysis. This enables CIDS to detect not only attacks that have already been demonstrated or discussed in literature, but also those that are more acute and cannot be detected by state-of-the-art IDSs. Our experimental evaluations show that CIDS detects various types of in-vehicle network intrusions with a low false-positive rate of 0.055%. Unlike state-of-the-art IDSs, if an intrusion is detected in CIDS, its fingerprinting capability facilitates identification of the (compromised) ECU that mounted the attack. We validate these capabilities of CIDS through experimental evaluations on a CAN bus prototype and on real vehicles.

We focus on building CIDS for Control Area Network (CAN), which is the *de facto* standard in-vehicle network. Its applicability to other in-vehicle network protocols is also discussed in Section 6. Considering the ubiquity of CAN and its direct relationship with the drivers/passengers’ safety, it is critically important to build as capable a CAN bus IDS as possible.

This paper makes the following contributions:

- Development of a novel scheme of fingerprinting ECUs by exploiting message periodicity;
- Proposal of CIDS, which models the norm behavior of in-vehicle ECUs’ clocks based on fingerprints and then detects in-vehicle network intrusions;
- Implementation and validation of CIDS on a CAN bus prototype as well as on 3 real vehicles.

The rest of the paper is organized as follows. Section 2 provides the necessary background of CAN and IDS-related work, and Section 3 details the attack model

Figure 1: Format of a CAN data frame.

we consider. Section 4 details the design of CIDS, which is evaluated in Section 5 on a CAN bus prototype as well as on three real vehicles. Section 6 discusses CIDS further, such as its overhead and extension to emerging in-vehicle networks. Finally, we conclude the paper in Section 7.

2 Background

For completeness, we first provide necessary background on the CAN protocol, and then discuss the related work on security solutions for in-vehicle networks.

2.1 Primer on CAN Protocol

CAN frame. CAN is the most widely deployed in-vehicle communication protocol, which interconnects ECUs/nodes through a multi-master, message broadcast bus system [4]. To maintain data consistency and make control decisions, data is exchanged between ECUs via CAN frames, the format of which is shown in Fig. 1. A CAN frame contains fields such as ID, Data Length Code (DLC), Data, and CRC. Since CAN is message-oriented, instead of containing the transmitter/receiver address, a CAN frame contains a unique ID which represents its priority and meaning. For example, a frame with ID=0x20 may contain wheel speed values whereas a frame with ID=0x55 may contain temperature values.

Arbitration. Once the CAN bus is detected idle, nodes with buffered messages to transmit, attempt to access the bus. Multiple nodes could attempt to access the bus simultaneously, i.e., contention occurs for access. Such a contention is resolved via bus arbitration as follows. Each node first transmits the ID value of its CAN frame one bit at a time, starting with the most significant bit. Since CAN is designed to logically behave as a wired-AND gate, some contending nodes see an output of 0 from the bus, although they had transmitted 1. Such nodes withdraw from bus contention and switch to the receive mode. As a result, among the contending nodes, the ECU sending the message with the lowest ID value wins arbitration, and gains exclusive access for message transmission. Those which have lost arbitration re-attempt to transmit once the bus becomes idle again.

Synchronization. For proper bitwise message transmission and reception, hard and soft *bit* synchronizations are achieved, respectively, by using the Start-of-Frame (SOF) signal and bit stuffing in CAN frames [4]. Al-

though these provide alignment of bit edges for message exchange, they do not synchronize the *clocks* of ECUs, i.e., CAN lacks clock synchronization. Thus, since time instants for ECUs are provided by their own quartz crystal clocks, these clocks, in reality, run at different frequencies, resulting in random drifting of clocks: a drift of 2400ms over a period of 24 hours is possible [27].

2.2 Related Work

To defend against various types of vehicle cyber attacks, there have been two main streams of security solutions: *message authentication* and *intrusion detection*.

Message authentication. In the area of Internet security, cryptographic message authentication provides strong protection against forgery. Thus, researchers have attempted to borrow such approaches from the domain of Internet security to address in-vehicle network security problems. However, since the maximum payload length allowed in the CAN data field is only 8 bytes, the available space for appending a cryptographically secure Message Authentication Code (MAC) is very limited, i.e., the protocol specification limits its maximum cryptographic strength. To overcome this difficulty, rather than appending a MAC in one CAN frame’s data field, the authors of [38] proposed to truncate it across multiple frames. Instead of the data field, the authors of [33] proposed to use multiple CRC fields to include 64 bits of CBC-MAC. The authors of [15] suggested to exploit an out-of-band channel for message authentication.

Although such preventive measures provide some degree of security, they alone cannot guarantee complete security due to their inability to handle certain critical attacks, e.g., Denial-of-Service (DoS). Moreover, their operations not only require a significant amount of processing power but also increase message latencies and bus utilization. Since in-vehicle networks must operate in real time and ECUs are resource-limited for cost reasons, unlike in the Internet, these “costs” of preventive measures hinder their adoption [30]. More importantly, when an adversary has full access to any data stored in RAM and/or FLASH, including data used for implementing security mechanisms (e.g., shared secret keys), some cryptographic solutions become incapable [24].

Intrusion detection. To overcome such limitations of preventive measures, different Intrusion Detection Systems (IDSs) have been proposed. Some state-of-the-art IDSs exploit the fact that most CAN messages are periodic, i.e., sent at fixed time intervals. The authors of [30] proposed an IDS which monitors the intervals of periodic messages, measures their entropies, and exploits them for intrusion detection. Similarly, a method of modeling the distribution of message intervals, and utilizing it for intrusion detection was proposed in [23]. In addition

to message frequency, researchers also proposed to verify the message contents. The authors of [31] exploited in-vehicle sensors to verify message range, correlation, etc. Abnormal measurements on brake-related sensors were detected by using the tire-friction model [10].

Although existing IDSs are capable of detecting most attacks through the above approaches, they fail to cover some critical attacks which are more acute, and thus are not sufficient to provide security. We will elaborate on such shortcomings of state-of-the-art IDSs while analyzing the attack scenarios under consideration in Section 3.3.

3 Attack Model

We first discuss the adversary model under consideration, and then the three representative attack scenarios.

3.1 Adversary Model

Adversaries can physically/remotely compromise more than one in-vehicle ECU via numerous attack surfaces and means [9]. We consider an adversary who wants to manipulate or impair in-vehicle functions. The adversary can achieve this by either injecting arbitrary messages with a spoofed ID into the in-vehicle network, which we refer to as *attack messages*, or by stopping/suspending message transmissions of the compromised ECU.

Strong and weak attackers. Depending on their hardware, software, and attack surfaces, ECUs of different vehicles have different degrees of vulnerabilities, thus providing attackers different capabilities. So, we consider two different types of compromised ECUs: *fully* and *weakly* compromised ECUs.

Through a *weakly* compromised ECU, the attacker is assumed to be able to stop/suspend the ECU from transmitting certain messages or keep the ECU in listen-only mode, but cannot inject any fabricated messages. We call such an attacker with limited capabilities a *weak attacker*, and will use this term interchangeably with “weakly compromised ECU”.

In contrast, with a *fully* compromised ECU, the attacker is assumed to have full control of it and access to memory data. Thus, in addition to what a weak attacker can do, the attacker controlling a fully compromised ECU can mount attacks by injecting arbitrary attack messages. We call such an attacker with more attack capabilities a *strong attacker*, and will use this term interchangeably with a “fully compromised ECU”. Even when preventive security mechanisms (e.g., MAC) are built into the ECUs, since the strong attacker has full access to any data stored in their memory, including data used for implementing security mechanisms (e.g., shared secret keys), it can disable them [24]. On the other hand,

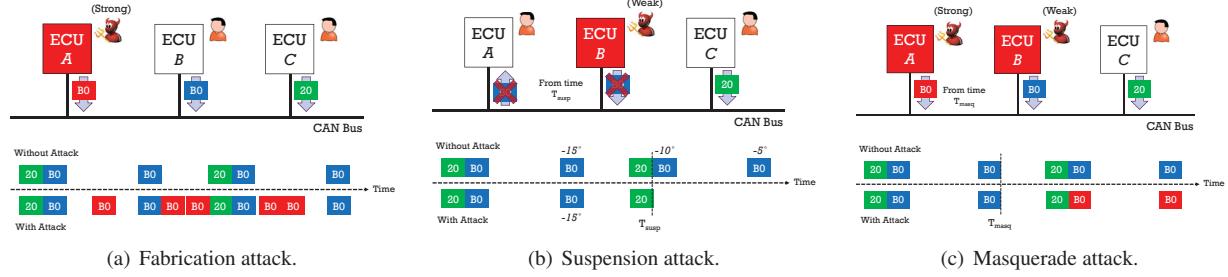

Figure 2: Three representative attack scenarios on in-vehicle networks.

a weak attacker can only stop, or listen to message transmissions, but cannot start a new one.

Foster *et al.* [13] have recently proved the possible existence of these two types of attackers in in-vehicle networks. They have shown that the firmware versions of telematics units can affect/limit the attacker's capabilities in injecting and monitoring in-vehicle network messages. Specifically, for a certain firmware version of the telematics unit, an attacker having control of that ECU was shown to be able to receive CAN messages but unable to send the messages. On the other hand, for some other firmware versions, the attacker was capable of both sending and receiving CAN messages to and from the in-vehicle network. In other words, the firmware version of an ECU determines which type of an attacker — strong or weak — it can become, if compromised.

To further comprehend how and why these two different types of attackers can exist, let's consider one of the most common CAN controllers, Microchip MCP2515 [1]. For ECUs with such a controller, various operation modes like configuration, normal, and listen-only can be selected by user instructions through the Serial Peripheral Interface (SPI). Thus, user-level features for configuring the CAN controller allow attackers to easily enter different modes (e.g., listen-only mode for a weak attacker). In contrast, there are no such features allowing attackers to easily inject forged messages. In other words, the specification of the ECU hardware/software, if compromised, can *restrict* the adversary to become a weak attacker only. Note that the required functionalities of a strong attacker subsume those of a weak attacker. It is thus easier for an adversary to become a weak attacker than a strong attacker, let alone researchers have already demonstrated how to create such a strong attacker [9, 20, 23, 24].

3.2 Attack Scenarios

Based on the adversary model discussed so far, we consider the following attack scenarios that can severely impair in-vehicle functions: *fabrication*, *suspension*, and

*masquerade.*¹

Fabrication attack. Through an in-vehicle ECU compromised to be a strong attacker, the adversary fabricates and injects messages with forged ID, DLC, and data. The objective of this attack is to override any periodic messages sent by a legitimate safety-critical ECU so that their receiver ECUs get distracted or become inoperable. For example, as shown in Fig. 2(a), the strong attacker \mathbb{A} injects several attack messages with ID=0xB0, which is usually sent by a legitimate ECU \mathbb{B} , at a high frequency. Thus, other nodes which normally receive message 0xB0 are forced to receive the fabricated attack messages more often than the legitimate ones. We refer to such a case as \mathbb{A} mounting a fabrication attack on message 0xB0 or its genuine transmitter \mathbb{B} . Demonstrated attacks such as controlling vehicle maneuver [20] and monopolizing the CAN bus with highest priority messages [16] exemplify a fabrication attack.

Suspension attack. To mount a suspension attack, the adversary needs only one weakly compromised ECU, i.e., become a weak attacker. As one type of Denial-of-Service (DoS) attack, the objective of this attack is to stop/suspend the weakly compromised ECU’s message transmissions, thus preventing the delivery/propagation of information it acquired, to other ECUs. For some ECUs, they must receive certain information from other ECUs to function properly. Therefore, the suspension attack can harm not only the (weakly) compromised ECU itself but also other receiver ECUs. An example of this attack is shown in Fig. 2(b) where the weak attacker having control of the Electric Power Steering ECU \mathbb{B} stops transmitting its measured steering wheel angle value. So, the Electronic Stability Control (ESC) ECU \mathbb{A} , which requires the steering wheel angle value from \mathbb{B} for detecting and reducing the loss of traction, no longer receives its updates and thus malfunctions.

Masquerade attack. To mount a masquerade attack, the adversary needs to compromise two ECUs, one as a strong attacker and the other as a weak attacker. The

¹In this paper, we focus on only these three attack scenarios and do not consider others as they may be less feasible or harmful, or be detectable by existing IDSs.

objective of this attack is to manipulate an ECU, while shielding the fact that an ECU is compromised. Fig. 2(c) shows an example where the adversary controls a strong attacker \mathbb{A} and a weak attacker \mathbb{B} . Until time T_{masq} , the adversary monitors and learns which messages are sent at what frequency by its weaker attacker, e.g., \mathbb{B} sends message 0xB0 every 20ms. Since most in-vehicle network messages are periodic and broadcast over CAN, it is easy to learn their IDs and intervals. Once it has learned the ID and frequency of a message, at time T_{masq} , the adversary stops the transmission of its weak attacker and utilizes its strong attacker \mathbb{A} to fabricate and inject attack messages with ID=0xB0. Stopping \mathbb{B} 's transmission and exploiting \mathbb{A} for transmission of attack messages are to overcome the weak attacker's inability of injecting messages. After T_{masq} , the original transmitter of 0xB0, \mathbb{B} , does not send that message any longer, whereas \mathbb{A} sends it *instead* at its original frequency. So, when the CAN bus traffic is observed, the frequency of message 0xB0 remains the same, whereas its transmitter has changed. We refer to such a case as \mathbb{A} mounting a masquerade attack on message 0xB0 or its original transmitter \mathbb{B} .

In fact, in order to attack and remotely stop a Jeep Cherokee running on a highway, Miller *et al.* [25] had to control its ABS collision prevention system by mounting a *masquerade* (not fabrication) attack. In contrast to other vehicles which they had previously examined (e.g., Toyota Prius), the Jeep Cherokee's brake was not controllable via the fabrication attack as its ABS collision prevention system, which was the attack vector for engaging brakes, was switched off when the fabrication attack was mounted. On the other hand, when mounting the masquerade attack, the system was not switched off, thus allowing them to control the Jeep Cherokee's braking maneuver.

Using masquerade attacks, the adversary can not only inject attack messages from the compromised/impersonating ECU but also cause other severe problems, significantly degrading the in-vehicle network performance. The impersonating ECU sending a message instead of another ECU implies that it would generate more messages to periodically transmit than before, making its transmit buffer more likely overloaded. This may, in turn, lead to severe consequences, such as non-abortable transmission requests [12], deadline violation [18], and significant priority inversion [32]. Moreover, the original sequence of messages may also change, thus failing to meet the requirement of some in-vehicle messages to be sent sequentially in a correct order for proper vehicle operations. These network problems from a masquerade attack occur while not deviating much from the norm network behavior (e.g., message frequency remains the same). This is in sharp contrast to the cases of mounting a fabrication attack

or a suspension attack, which may also incur similar problems. Such problems have been identified to be critical since they degrade the real-time performance of CAN significantly, and thus undermine vehicle safety [12, 18, 32]. The masquerade attack can thus cause more problems to the in-vehicle network than just injecting attack messages.

3.3 Defense Against the Attacks

When the fabrication or suspension attack is mounted, the frequency of certain messages significantly and abnormally increases or decreases, respectively. Thus, if state-of-the-art IDSs [16, 23, 30, 31], which monitor the message frequencies, were to be used, the attacks can be detected.

When mounting the masquerade attack, however, the adversary does not change the original frequency of messages. Thus, the adversary may use this attack to evade state-of-the-art IDSs. Moreover, if the adversary does not change the content of messages as well, it can behave like a legitimate ECU. However, the adversary may later mount other types of attacks (e.g., a fabrication attack) through the impersonating ECU. Hence, defending against the masquerade attack implies not only detecting the attack reactively, but also preventing other attacks *proactively*.

4 Clock-Based Detection

Although state-of-the-art IDSs are capable of detecting some basic attacks such as fabrication attack and suspension attack, they fail to detect more sophisticated ones such as the masquerade attack for the following reasons.

- *No authenticity* — CAN messages lack information on their transmitters. So, existing IDSs do not know whether or not the messages on the CAN bus were sent by the genuine transmitter, and hence cannot detect any changes of the message transmitter.
- *Inability of identifying a compromised ECU* — Lack of the transmitter's information makes it very difficult or impossible for state-of-the-art IDSs to identify which of compromised ECUs mounted an attack.

If CAN frames do not carry any information on their transmitters, how could an IDS identify them and detect intrusions such as the masquerade attacks? Which behavior of CAN should the IDS model for detection of such intrusions? We answer these questions by developing a novel IDS, CIDS, which exploits message frequency to fingerprint the transmitter ECUs, and models a norm behavior based on their fingerprints for intrusion

detection. We focus on detecting intrusions in *periodic* messages as most in-vehicle messages are sent periodically [32, 36].

4.1 Fingerprinting ECUs

For each in-vehicle ECU in CAN, the time instants of periodic message transmissions are determined by its quartz crystal clock [27]. We follow the nomenclature of clocks of the NTP specification [26] and Paxson [35]. Let C_{true} be a “true” clock which reports the true time at any moment and C_i be some other non-true clock. We define the terms “clock offset, frequency, and skew” as follows.

- **offset:** difference in the time reported by clock C_i and the true clock C_{true} . We define *relative offset* as the offset between two non-true clocks.
- **frequency:** the rate at which clock C_i advances. Thus, the frequency at time t is $C'_i(t) \equiv dC_i(t)/dt$.
- **skew:** difference between the frequencies of clock C_i and the true clock C_{true} . We define *relative skew* as the difference in skews of two non-true clocks.

If two clocks have relative offset and skew of 0, then they are said to be *synchronized*. Otherwise, we consider they are *unsynchronized*. Since CAN lacks clock synchronization, it is considered to be unsynchronized.

Clock skew as a fingerprint. The clock offsets and skews of unsynchronized nodes depend solely on their local clocks, thus being distinct from others. As others have also concluded [17, 19, 42], clock skews and offsets can therefore be considered as fingerprints of nodes. Various studies have exploited this fact to fingerprint physical devices [17, 19, 34, 42]. However, they are not applicable to our problem as they exclusively rely on the timestamps carried in the packet headers, which are, as discussed before, not available in in-vehicle networks. Kohno *et al.* [19] considered an alternative to embedded timestamps: using Fourier Transform for clock skew estimation. However, as their approach relies on the unique characteristics of the Internet (e.g., multi-hop delays, large network topology), it cannot be directly applied to in-vehicle networks.

To build an effective IDS, which can detect various types of attack including the masquerade attack, it should be capable of verifying the transmitter of each message. However, since such information is not present in CAN messages, we must fingerprint ECUs with other “leaked” information. Unlike the existing approaches that exploit embedded timestamps, we exploit *message periodicity* to extract and estimate the transmitters’ clock skews, which are then used to fingerprint the transmitter ECUs.

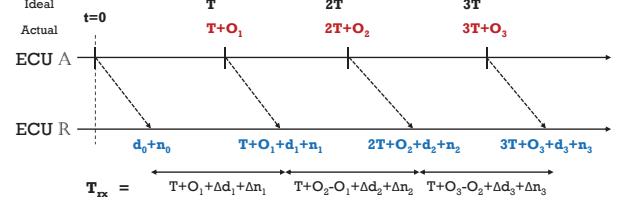

Figure 3: Timing analysis of message arrivals.

Clock skew estimation. Consider an ECU \mathbb{A} which broadcasts a message every T ms and an ECU \mathbb{R} which periodically receives that message. From the perspective of \mathbb{R} , since only its timestamp is available, we consider its clock as the true clock. As shown in Fig. 3, due to the clock skew, periodic messages are sent at times with small offsets from the ideal values (e.g., T , $2T$, $3T$, \dots). Let $t = 0$ be the time when the first message was sent from \mathbb{A} , and O_i be the clock offset of \mathbb{A} when it sends the i -th message since $t = 0$. Then, after a network delay of d_i , ECU \mathbb{R} would receive that message and put an arrival timestamp of $iT + O_i + d_i + n_i$, where n_i denotes the noise in \mathbb{R} ’s timestamp quantization [42]. Thus, the intervals between each arrival timestamp, $T_{rx,i} = T + \Delta O_i + \Delta d_i + \Delta n_i$, where ΔX_i denotes the difference of X between step i and $i - 1$, and $O_0 = 0$. Since the change in O_i within one time step is negligible and n_i is a zero-mean Gaussian noise term [2], the expected value of the timestamp intervals, $\mu_{T_{rx}} = E[T_{rx,i}]$, can be expressed as:

$$\begin{aligned} \mu_{T_{rx}} &= E[T + \Delta O_i + \Delta d_i + \Delta n_i] \\ &= T + E[\Delta O_i + \Delta d_i + \Delta n_i] \\ &\approx T, \end{aligned} \quad (1)$$

where the second equality holds since T is a pre-determined constant. Since the data lengths of CAN periodic messages, i.e., DLCs, are constant over time, for now, we consider $E[\Delta d_i] = 0$. Later in Section 4.4, we will discuss the case when d_i is not constant, and how it may affect the performance of CIDS.

Based on the arrival timestamp of the first message, $d_0 + n_0$, and the average of timestamp intervals, $\mu_{T_{rx}}$, we extrapolate and determine the *estimated* arrival time of the i -th message as $i\mu_{T_{rx}} + d_0 + n_0$, whereas the actual *measured* arrival time is $iT + O_i + d_i + n_i$. As we are estimating subsequent arrival times, $\mu_{T_{rx}}$ is determined by past measurements. Since T is constant over time and thus again $\mu_{T_{rx}} \approx T$, the average difference between the estimated and measured times is:

$$E[\mathbb{D}] = E[i(T - \mu_{T_{rx}}) + O_i + \Delta d + \Delta n] \approx E[O_i]. \quad (2)$$

That is, from message periodicity, we can estimate the *average clock offset*, $E[O_i]$, which will indeed be distinct for different transmitters. Since clock offset is

slowly varying and non-zero [17, 42], $E[O_i] \neq 0$, whereas $E[\Delta O_i] = 0$.

If ECU \mathbb{R} were to determine the average clock offset for every N received messages, since it is derived in reference to the first message (of N messages), it represents only the average of *newly* incurred offsets. Thus, to obtain the total amount of incurred offset, which we call the *accumulated clock offset*, the absolute values of the average clock offsets have to be summed up. By definition, the slope of the accumulated clock offset would thus represent the clock skew, which is constant as we will show and as others have also concluded [19, 29, 35, 40]. This enables CIDS to estimate the clock skew from arrival timestamps and thus fingerprint the message transmitter for intrusion detection. We will later show, via experimental evaluations on a CAN bus prototype and on 3 real vehicles, that the thus-derived clock skew is indeed a fingerprint of an in-vehicle ECU.

4.2 CIDS — Per-message Detection

By determining the clock skew from observation of message intervals, transmitter ECUs can be fingerprinted. We exploit this in designing CIDS, a clock-based IDS for in-vehicle networks which detects intrusions in two different ways: *per-message* detection and *message-*

pairwise detection, where the latter supplements the former in reducing false positive/negative results. Next, we first discuss per-message detection and then pairwise detection.

Modeling. For a given message ID, CIDS derives the accumulated clock offset inherent in the arrival timestamps. Since clock skew is constant, the accumulated clock offset is linear in time, and hence CIDS describes it as a linear regression model. A linear parameter identification problem is thus formulated as:

$$O_{acc}[k] = S[k] \cdot t[k] + e[k], \quad (3)$$

where at step k , $O_{acc}[k]$ is the accumulated clock offset, $S[k]$ the regression parameter, $t[k]$ the elapsed time, and $e[k]$ the identification error. The regression parameter S represents the slope of the linear model and thus the *estimated clock skew*. The identification error, e , represents the residual which is not explained by the model. In CIDS, O_{acc} , S , t , and e are updated every N messages, i.e., KN messages are examined up to step k .

To determine the unknown parameter S , we use the Recursive Least Squares (RLS) algorithm [14], which uses the residual as an objective function to minimize the sum of squares of the modeling errors. Hence, in RLS, the identification error skews towards 0, i.e., has 0 mean. We will discuss the computational overhead of RLS as well as other possible solutions in Section 6.

Algorithm 1 describes how the clock skew is estimated using RLS. First, CIDS measures the arrival times and their intervals of N messages for a given ID. If the intended message has not been received for a long time — possibly due to suspension attack — as in line 13–14, CIDS sets the remaining timestamp and interval values significantly higher. Once N values are measured, CIDS determines the accumulated clock offset and accordingly, the identification error. Based on the thus-derived value, the gain, G , and the covariance, P , are updated with RLS for identifying the regression parameter S , i.e., estimate clock skew. This procedure of clock skew estimation continues iteratively during the operation of CIDS and, if uncompromised, outputs an identification error skewed towards 0 and a constant clock skew. This way, the *norm clock behavior* of the transmitter can be described as a linear model with the clock skew being the slope. In RLS, a forgetting factor, λ , is used to give exponentially less weights to older samples and thus provide freshness. In CIDS, we set $\lambda=0.9995$.

Detection. For a given message ID, CIDS runs RLS for clock skew estimation, constructs a norm model on clock behavior, and verifies whether there are any abnormal measurements deviating from it, i.e., intrusions.

Consider a fabrication attack in which the adversary injects an attack message with ID=0x01, which is originally sent every 10ms by some ECU. The fabrication

attack significantly increases the absolute average difference between the estimated and measured arrival times of 0x01. As a result, due to a sudden increase in the rate at which the accumulated clock offset changes, a high identification error results. Similarly, when the suspension attack is mounted, the absolute average difference also increases and thus a high error is also incurred. When a masquerade attack is mounted, since the adversary sends the message through a different ECU than its original one, the increase rate of accumulated clock offset, i.e., clock skew, suddenly changes and also results in a high identification error. In summary, unlike when the mean of identification error should usually skew towards 0, which is the norm clock behavior, its mean suddenly shifts towards a high non-zero value when there is an intrusion.

CIDS exploits the Cumulative Sum (CUSUM) method, which derives the cumulative sums of the deviations from a target value to detect sudden shifts. Since it is cumulative, even minor drifting from the target value leads to steadily increasing or decreasing cumulative values. It is therefore optimal in detecting small persistent changes and is widely used for change-point detection [8]. CIDS detects intrusions via CUSUM as follows. At each step of clock skew estimation, CIDS updates the mean and variance of the identification errors (e), μ_e and σ_e^2 , respectively. In CIDS, these values represent the CUSUM target values of e (i.e., norm clock behavior), and thus require proper tracking. Hence, as a precaution of abnormal values incurring from an attack to be reflected into the target values, μ_e and σ_e^2 are updated only if $|\frac{e-\mu_e}{\sigma_e}| < 3$. Then, per derived identification error e , the upper and lower control limits of CUSUM, L^+ and L^- are updated as [41]:

$$\begin{aligned} L^+ &\leftarrow \max [0, L^+ + (e - \mu_e)/\sigma_e - \kappa] \\ L^- &\leftarrow \max [0, L^- - (e - \mu_e)/\sigma_e - \kappa] \end{aligned} \quad (4)$$

where κ is a parameter reflecting the number of standard deviations CIDS intends to detect. Note that κ can be learned offline, or by monitoring normal in-vehicle traffic. If either of the control limits, L^+ or L^- , exceeds a threshold Γ_L , a sudden positive or negative shift in value has been detected, respectively, and thus CIDS declares it as an intrusion. As the general rule of thumb for CUSUM is to have a threshold of 4 or 5 [28], we set $\Gamma_L = 5$.

4.3 CIDS — Message-pairwise Detection

In addition to per-message detection, CIDS also alarms intrusions via message-pairwise detection, which examines the *correlation* between the average clock offsets in two periodic messages. Consider two messages M_1 and M_2 periodically sent by an ECU A. Since these messages

originate from the same transmitter, their instantaneous average clock offsets are likely equivalent. Thus, the correlation coefficient, ρ , between their average clock offsets (derived per step) would show a high value close to 1, i.e., correlated. On the other hand, if the two messages were sent by different ECUs, $\rho \approx 0$, i.e., uncorrelated.

Modeling and detection. If clock offsets in two messages are highly correlated ($\rho > 0.8$), their relationship can be linear. So, CIDS describes them as a linear regression model: $O_{M_2}[k] = \alpha O_{M_1}[k] + e_{corr}[k]$, where O_{M_i} denotes the average clock offset of message M_i at step k , α the regression parameter, and $e_{corr}[k]$ the identification error. As per-message detection, message-pairwise detection is also based on a linear model. Thus, we apply the same detection method, CUSUM. Since message-pairwise detection seeks intrusions from a different perspective than per-message detection, it reduces false positive/negative results. Note, however, that message-pairwise detection is only applicable when two messages' clock offsets are highly correlated, whereas per-message detection is applicable to any periodic message. Moreover, albeit effective, it requires pairwise computations. Therefore, we use message-pairwise detection as an *optional* feature of CIDS. We will later show via experimental evaluations how message-pairwise detection further improves the performance of CIDS.

4.4 Verification

To reduce possible false positives/negatives, CIDS also performs a verification process. Suppose that a possible intrusion was alarmed due to a high identification error when verifying message V_i , the i -th message of V . Although such a high error can be due to an intrusion, it can also be due to an incorrect computation of average clock offset. In Section 4.1, we considered $E[\Delta d_i] = 0$ and could thus extract and determine the average clock offset. Although this is true in most cases, occasionally $E[\Delta d_i] \neq 0$, which affects the accuracy of deriving the true clock offset and thus the detection result. In CAN, $E[\Delta d_i] \neq 0$ only occurs if the transmission of V_i was delayed due to the bus being busy or its transmitter losing arbitration when attempting to send V_i . Note that the latter also results in the bus being busy before the transmission/reception of V_i . Thus, CIDS also checks if the possibility of $E[\Delta d_i] \neq 0$ is the main cause of a (possibly false) alarm of intrusion by verifying whether the CAN bus was busy right before receiving V_i . This way, CIDS enhances its detection accuracy. However, as discussed before, usually $E[\Delta d_i] = 0$ in an actual CAN bus due to its high speed, its messages having short lengths, and low bus load. In other words, the nature of CAN bus communication helps CIDS reduce false positives/negatives.

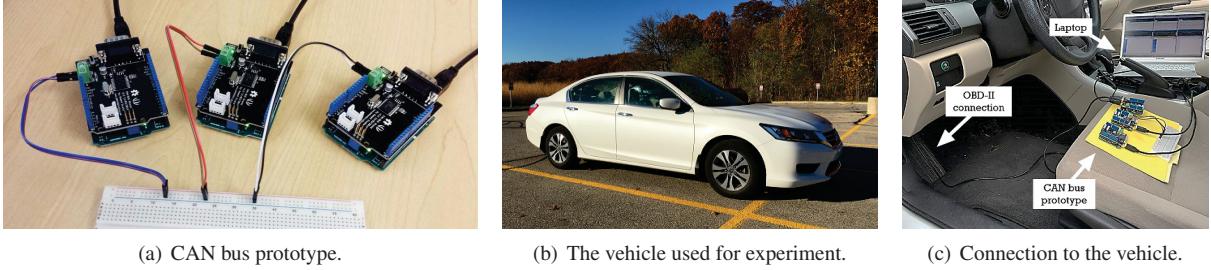

Figure 4: Different evaluation settings: (a) CAN bus prototype; (b) Honda Accord 2013 used for experiments on real vehicle; and (c) three prototype nodes communicating with real ECUs through the OBD-II port.

4.5 Root-cause Analysis

When an intrusion is detected for some message ID, CIDS can also identify which compromised ECU mounted the attack. It can extract the clock skew for that attacked message ID, compare it with other clock skew values extracted from other message IDs, and exploit the comparison result in determining whether they originated from the same transmitter. This way, CIDS can at least reduce the scope of ECUs which may (or may not) have mounted the attack, thus facilitating a root-cause analysis.

5 Evaluation

We now validate that clock skews can be used as fingerprints of transmitter ECUs, and evaluate the performance of CIDS on a CAN bus prototype and real vehicles.

CAN bus prototype: As shown in Fig. 4(a), we built a prototype with 3 CAN nodes, each of which consists of an Arduino UNO board and a SeeedStudio CAN shield. The CAN bus shield consists of a Microchip MCP2515 CAN controller, MCP2551 CAN transceiver, and a 120Ω terminal resistor to provide CAN bus communication capabilities. This prototype was set up to operate at a 500Kbps bus speed as in typical CAN buses. The first node \mathbb{A} was programmed to send messages 0x11 and 0x13 every 50ms, and the second node \mathbb{B} to send message 0x55 at the same frequency. The third node \mathbb{R} was programmed to run CIDS.

Real vehicle: A 2013 Honda Accord (Fig. 4(b)) is also used for our experiments in an isolated and controlled (for safety) environment. As shown in Fig. 4(c), via the On-Board Diagnostic (OBD-II) system port [3], we connected our CAN bus prototype nodes — which function as an adversary or CIDS — to the in-vehicle network. Through the OBD-II port, the three nodes were able to communicate with real ECUs.

CAN log data: To further validate that CIDS’s fingerprinting is applicable to other vehicles, we also refer to CAN traffic data logged from a Toyota Camry

2010 by Ruth *et al.* [36] and data logged from a Dodge Ram Pickup 2010 by Daily [11]. Both data were logged through a Gryphon S3 and Hercules software. In the Toyota Camry 2010, there were 42 distinct messages transmitted on the CAN bus: 39 of them sent periodically at intervals ranging from 10ms to 5 seconds, and 3 of them sent sporadically. In the Dodge Ram Pickup 2010, there were 55 distinct messages which were all sent periodically on the CAN bus.

In order to identify which messages originate from the same real ECU and thus exploit it as a ground truth, we used the naive method discussed in [32]. The messages, which originate from the same ECU and have the same preset message interval, were shown to have the same number of transmissions on the bus, when traced for at least a few minutes. Such a method can be an alternative to fingerprinting, but it requires pairwise comparisons and cannot be completed in real time as required in the design of CIDS, which is essential for intrusion detection in real in-vehicle networks.

While running CIDS, we determined offsets and skews for every 20 received samples, i.e., $N = 20$, and set $\kappa = 5$.

5.1 Clock Skew as a Fingerprint

We first evaluate the validity of CIDS’s fingerprinting of the transmitter ECUs based on the estimated clock skews. We evaluate skew estimates in microseconds per second ($\mu s/s$) or parts per million (ppm).

CAN bus prototype. Fig. 5(a) plots our evaluation results of CIDS’s fingerprinting on the CAN bus prototype: accumulated clock offsets of messages 0x11, 0x13, and 0x55. Note that the slopes in this figure represent the estimated clock skews. All the derived accumulated clock offsets were found to be linear in time, i.e., constant estimated skews. Messages 0x11 and 0x13, both of which were sent from node \mathbb{A} , exhibited the same constant clock skew of 13.4ppm. On the other hand, the message 0x55 sent from a different node \mathbb{B} showed a different clock skew of 27.2ppm. Thus, the clock skews derived by CIDS can be used to differentiate ECUs.

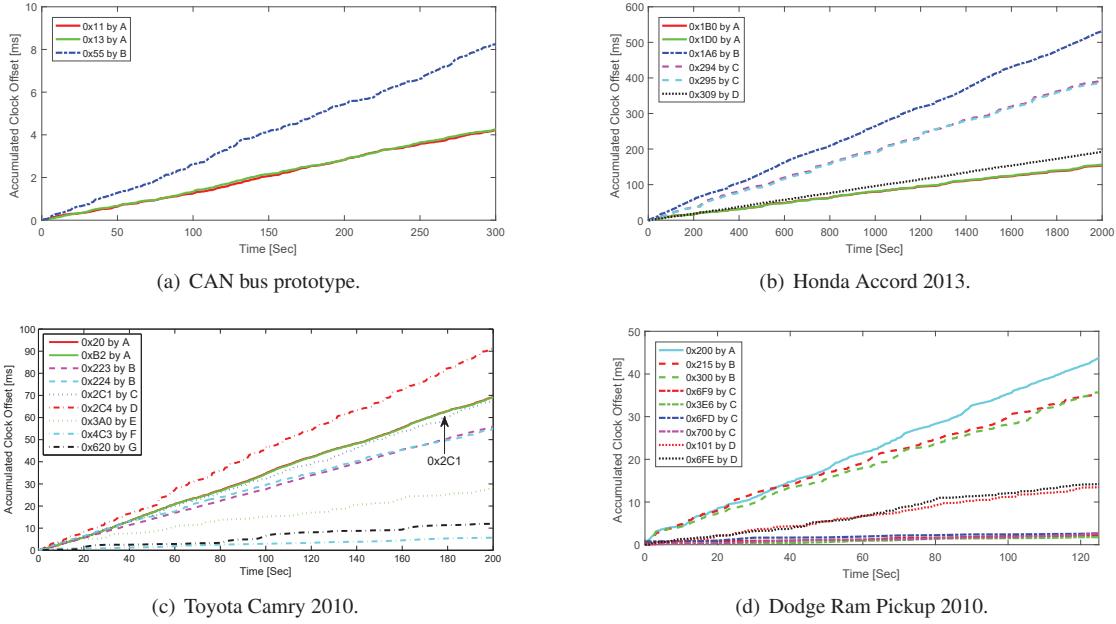

Figure 5: Accumulated clock offsets derived by CIDS in different evaluation settings.

Honda Accord 2013. For CIDS’s evaluation on a real vehicle, the CAN prototype nodes logged the in-vehicle CAN traffic of the Honda Accord 2013, and ran CIDS on messages 0x1B0, 0x1D0, 0x1A6, 0x294, 0x295, and 0x309. The approach in [32] was adopted to verify that messages {0x1B0, 0x1D0} were sent from the same ECU, {0x294, 0x295} both sent from another ECU, whereas others were sent from different ECUs. Utilizing these facts, one can conclude from Fig. 5(b) that the clock offsets and the skews derived in CIDS are equivalent *only* for those messages sent from the same ECU; 0x1B0 and 0x1D0 showed a skew of 78.4ppm, 0x294 and 0x295 showed a skew of 199.8ppm, while messages 0x1A6 and 0x309 showed very different skews of 265.7ppm and 95.78ppm, respectively. This result again shows that clock skews between *different* ECUs are distinct and can thus be used as the fingerprints of the corresponding ECUs.

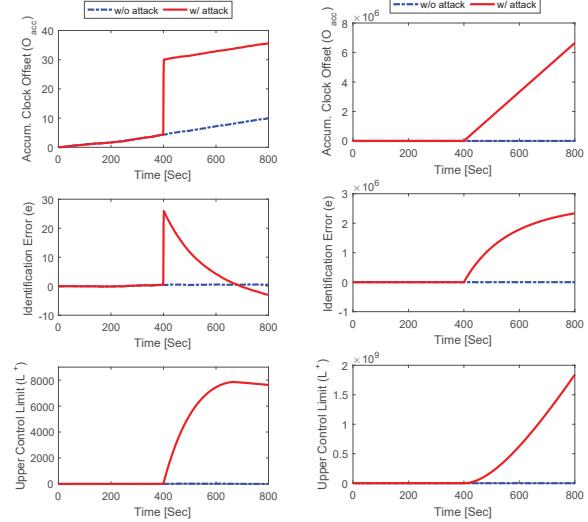

Toyota Camry 2010. To show that the applicability of CIDS’s fingerprinting is not limited to the specific vehicle model used, we also conducted experiments on a different vehicle: running CIDS’s fingerprinting on the Toyota Camry logged data. Similarly to the real vehicle evaluation in Section 5.1, the approach in [32] was used as the ground truth. It was verified that messages {0x20, 0xB2} within the CAN log data were all sent from some ECU A. Also, {0x223, 0x224} were both sent from some ECU B, whereas 0x2C1, 0x2C4, 0x3A0, 0x4C3, and 0x620 were each sent from a different ECU. As shown in Fig. 5(c), messages 0x20 and 0xB2 both showed a

clock skew of approximately 345.3ppm, whereas 0x223 and 0x224 showed a different clock skew of 276.5ppm. 0x2C4, 0x3A0, 0x4C3, and 0x620 showed very different clock skews of 460.1ppm, 142.5ppm, 26.1ppm and 58.7 ppm, respectively.

We made an interesting observation on message 0x2C1, showing a clock skew of 334.1ppm, which was different from the skews of messages {0x20, 0xB2} only by 3%, despite the fact that it was sent by a different ECU. This may confuse CIDS in determining whether they were sent by the same ECU or not. However, in such a case, CIDS can further examine the correlation between clock offsets and can thus fingerprint with a higher accuracy, which we will discuss and evaluate further in Section 5.4.

Dodge Ram Pickup 2010. We also ran CIDS’s fingerprinting on the CAN log data of a Dodge Ram Pickup 2010. For this vehicle, it was verified that message 0x200 was sent from some ECU A, {0x215, 0x300} sent from B, {0x6F9, 0x3E6, 0x6FD, 0x700} sent from C, and {0x101, 0x6FE} sent from D. Fig. 5(d) shows that CIDS determined that 0x200 has a clock skew of 351.7ppm, {0x215, 0x300} to have approximately 295.3ppm, {0x6F9, 0x3E6, 0x6FD, 0x700} to have 24.5ppm, and {0x101, 0x6FE} to have 110.3ppm, thus correctly fingerprinting their transmitters.

These results of a Toyota Camry and a Dodge Ram Pickup CAN log data again affirm the fact that the clock skews derived by CIDS are diverse and can indeed be used as fingerprints of in-vehicle ECUs. Moreover, they

(a) Fabrication attack.

(b) Suspension attack.

Figure 6: CIDS defending fabrication attack (left) and suspension attack (right) in a CAN bus prototype.

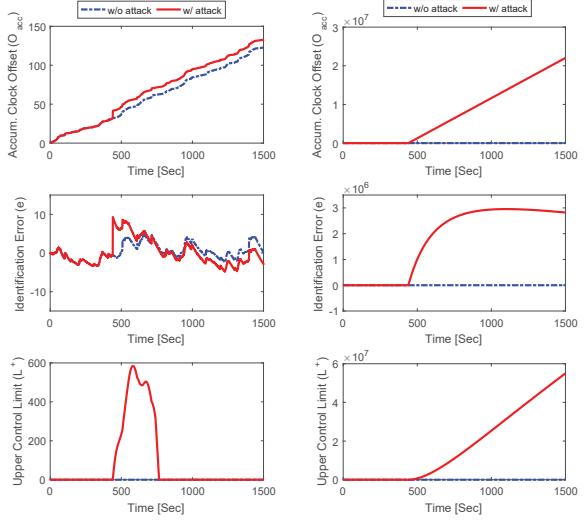

show that CIDS’s fingerprinting is not limited to a specific vehicle model, and can thus be applied to other vehicle models.

5.2 Defending Against Fabrication and Suspension Attacks

On both the CAN bus prototype and the real vehicle setting (Honda Accord 2013), we launch the fabrication and suspension attacks, and evaluate CIDS’s effectiveness in detecting them.² To this end, we consider CIDS to only perform per-message detection, and will later evaluate CIDS with message-pairwise detection.

CAN bus prototype. For evaluation of CIDS defending against fabrication attack on the CAN bus prototype, \mathbb{B} was programmed to inject a fabricated message at $t = 400$ secs with ID=0x11, which is a periodic message usually sent by \mathbb{A} , i.e., \mathbb{B} launches a fabrication attack on \mathbb{A} . ECU \mathbb{R} was running CIDS on message 0x11 and derived accumulated clock offset (O_{acc}), identification error (e), and control limits (L^+, L^-). For the suspension attack, \mathbb{A} was instead programmed to stop transmitting 0x11 at $t = 400$ secs.

Fig. 6(a) shows how such values changed for message 0x11 in the presence and absence of a fabrication attack. As soon as \mathbb{B} mounted a fabrication attack, as discussed in Section 4.2, there was a sudden positive shift in the accumulated clock offset, thus yielding a high iden-

(a) Fabrication attack.

(b) Suspension attack.

Figure 7: CIDS defending fabrication attack (left) and suspension attack (right) in a Honda Accord 2013.

tification error. Due to such a shift, the upper control limit, L^+ , of CUSUM suddenly increased and exceeded its threshold $\Gamma_L = 5$, i.e., detecting an intrusion. Similarly, Fig. 6(b) shows that since the suspension attack also shifted the accumulated clock offset significantly, CIDS was able to detect the attack.

Real vehicle. To evaluate CIDS against the fabrication attack under the real vehicle setting, one CAN prototype node \mathbb{R} was programmed to run CIDS, and another node \mathbb{A} as an adversary mounting the attack on a real ECU. The attack was mounted by injecting a fabricated attack message with ID=0x1B0, which was sent every 20ms by some real in-vehicle ECU, i.e., \mathbb{A} mounted the fabrication attack on a Honda Accord ECU sending 0x1B0. For the suspension attack, the message filter of \mathbb{R} was reset at $t = 420$ secs so as to no longer receive 0x1B0, thus emulating the suspension attack.

Fig. 7(a) shows how accumulated clock offsets (O_{acc}), identification errors (e), and upper control limits (L^+) changed for both cases of with and without a fabrication attack. Again, the attack message injected at around $t = 420$ secs caused a sudden increase in O_{acc} and e , thus increasing L^+ to exceed $\Gamma_L = 5$. As a result, CIDS declares the detection of an attack. After the attack, since 0x1B0 was still periodically sent by the real in-vehicle ECU, the clock skew — i.e., the slope of O_{acc} graph — remains unchanged. Similarly, as shown in Fig. 7(b), the suspension attack increases the offset values, thus causing L^+ to exceed the threshold, i.e., the suspension attack was detected by CIDS.

²As the attacks cannot be emulated using the CAN log data, we do not consider their use for evaluating CIDS against the attacks.

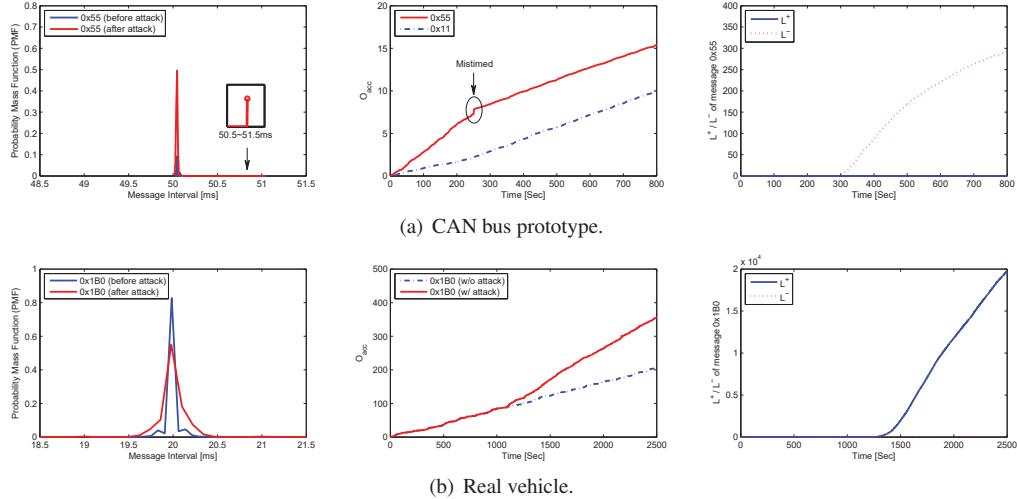

Figure 8: Masquerade attack — Probability mass function of message intervals (left), changes in accumulated clock offsets (middle), and control limits (right) derived in CIDS.

5.3 Defending Against Masquerade Attack

We now evaluate the performance of CIDS in detecting a masquerade attack.

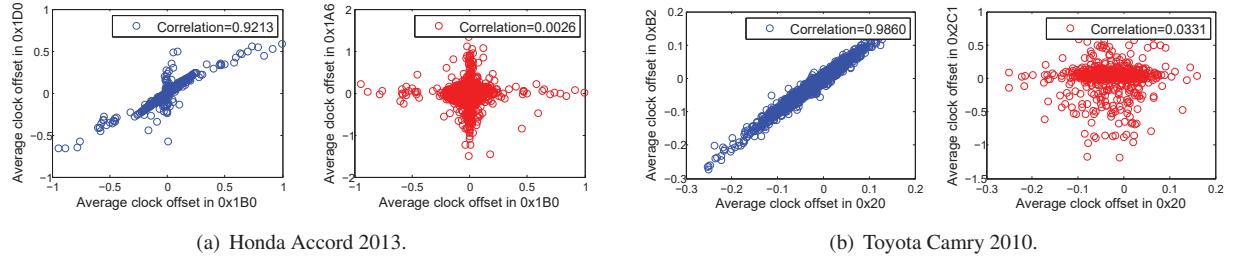

CAN bus prototype. To evaluate CIDS’s defense against the masquerade attack in the CAN bus prototype, nodes \mathbb{A} and \mathbb{B} were considered to have been compromised as strong and weak attackers as in Fig. 2(c), respectively. \mathbb{A} was programmed to mount a masquerade attack on \mathbb{B} , i.e., stop \mathbb{B} transmitting message 0x55 and instead send it through \mathbb{A} onwards, once $T_{masq} = 250$ secs had elapsed. As usual, messages 0x11 and 0x13 were periodically sent by \mathbb{A} , and CIDS was run by \mathbb{R} .

Fig. 8(a) (left) shows the Probability Mass Function (PMF) of the intervals of message 0x55: before and after the attack was mounted. In contrast to the fabrication attack, since the attacker sent the attack message at its original frequency after masquerading, the distribution did not deviate much from that before the attack. However, at T_{masq} , since there was some delay when the transmitter was switched from one node to another, the first masquerade attack message was sent 51.04ms after its previous transmission, whereas it should have been approximately 50ms which is the preset message interval of 0x55. Due to such a slightly *mistimed* masquerade attack, the PMF graph shows a message interval with an abnormal deviation from the mean. We will later evaluate the perfectly *timed* masquerade attack — a much more severe case than a mistimed attack — on a real vehicle, and show the efficacy of CIDS in detecting it.

The resulting changes in O_{acc} , L^+ , and L^- at \mathbb{R} are also shown in Fig. 8(a) (middle and right). The change in the ECU transmitting message 0x55 caused the slope

(i.e., clock skew) in O_{acc} graph to change after the attack was mounted. Since the measurements of O_{acc} after T_{masq} significantly deviated from their expected values, which is determined by the estimated clock skew of $t < T_{masq}$, the CUSUM lower control limit, L^- , in CIDS exceeded the threshold, thus declaring detection of an intrusion. Since the transmitter of 0x55 was changed (to ECU \mathbb{A}), its clock skew after $t = T_{masq}$ was equivalent to the clock skew in 0x11. Accordingly, via root-cause analysis, CIDS identifies the compromised ECU to be ECU \mathbb{A} . Unlike the previous results, since the change in slope was negative, persistent identification error with high negative values caused L^- to exceed the threshold.

Real vehicle. To evaluate CIDS’s defense against the masquerade attack in a real vehicle, we consider a scenario in which real in-vehicle ECUs \mathbb{V}_1 and \mathbb{V}_2 transmitting 0x1A6 and 0x1B0 are compromised as a strong and a weak attacker, respectively. Of the three CAN prototype nodes (\mathbb{A} , \mathbb{B} , and \mathbb{R}), which were connected to the real in-vehicle network via OBD-II, we programmed node \mathbb{R} to run CIDS on in-vehicle message 0x1B0 and another node \mathbb{B} to simply log the CAN traffic. To generate a scenario of real ECU \mathbb{V}_1 mounting a masquerade attack on real ECU \mathbb{V}_2 , \mathbb{R} was programmed further to receive message 0x1A6 instead of 0x1B0, but still record the received messages’ ID to be 0x1B0, once $T_{masq} = 1100$ seconds had elapsed. That is, we let \mathbb{R} interpret 0x1A6 as 0x1B0 for $t > T_{masq}$, i.e., the transmitter of 0x1B0 changes from \mathbb{V}_2 to \mathbb{V}_1 . Such a change in interpretation was achieved by programming \mathbb{R} to modify its message acceptance filter from only accepting 0x1B0 to only accepting 0x1A6. Since 0x1B0 and 0x1A6 were observed to be always transmitted nearly at the same time, such a

(a) Honda Accord 2013.

(b) Toyota Camry 2010.

Figure 9: Correlated and uncorrelated clock offsets.

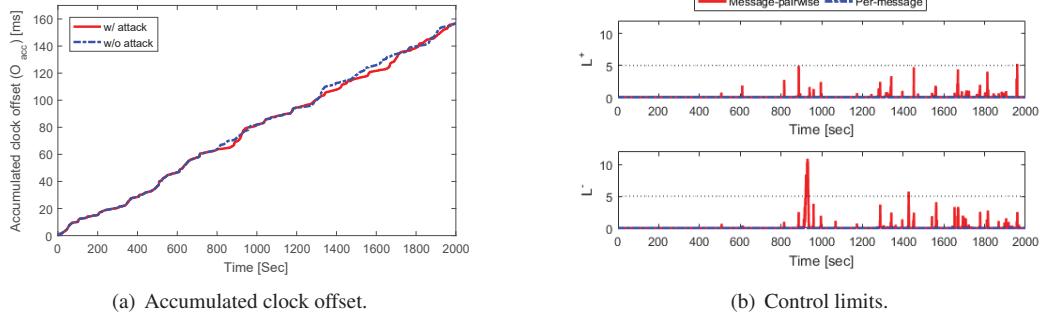

Figure 10: Defense against the worst-case masquerade attack via message-pairwise detection.

setting replicates the *timed* masquerade attack. During such a process, \mathbb{B} continuously logged 0x1B0 so that we can obtain a reference for circumstances when no attacks are mounted.

Fig. 8(b) (left) shows the PMF of the message intervals of 0x1B0 before and after the attack. Since the message periodicity remained the same, the distribution of the messages intervals did not change. Moreover, since we considered a timed masquerade attack, in contrast to the result in Fig. 8(a), there were no such abnormal message intervals. Such a result indicates that state-of-the-art IDSs, which try to find abnormal message frequencies, cannot detect such an attack. Although the distribution of message intervals remained unchanged, due to the change in ECU transmitting 0x1B0 ($V_2 \rightarrow V_1$), the accumulated clock offset suddenly exhibited a different trend in its change, i.e., a different clock skew after the attack. Here, the original trend in offset changes was determined by the data obtained from \mathbb{B} . So, as shown in Fig. 8(b) (right), CIDS was able to detect a sudden shift in its identification error and thus outputted a high level of CUSUM upper control limit, i.e., an intrusion detection. CIDS's capability of detecting various types of masquerade attack is evaluated further in Section 5.5.

In conclusion, through its modeling and detection processes, CIDS can detect not only the fabrication attack but also the masquerade attack, i.e., is capable of doing not only what existing solutions can do, but also more.

5.4 Message-pairwise Detection

We evaluate the feasibility and efficiency of message-pairwise detection in CIDS. To validate its practicability in the real-world, we first examine whether there exists pairs of messages inside real vehicles with correlated clock offsets — the condition for CIDS to run message-pairwise detection.

Fig. 9(a) shows two cases of correlated and uncorrelated clock offsets of in-vehicle messages collected from the Honda Accord 2013. Fig. 9(a) (left) shows that the average clock offsets of messages 0x1B0 and 0x1D0, which were determined to have been sent from the same ECU, showed a high correlation of 0.9213, i.e., linear relationship. In contrast, as shown in Fig. 9(a) (right), average clock offsets of messages 0x1B0 and 0x1A6, which were sent every 20ms from different ECUs, showed a near 0 correlation.

By the Birthday paradox, some ECUs in the vehicle may probably have near-equivalent clock skews — as it was for messages 0x20 and 0x2C1 in the examined Toyota Camry 2010 (see Fig. 5(c)). Although clock skews may be near-equivalent, instantaneous clock offsets of two different ECUs cannot be near-equivalent and are thus uncorrelated as they run different processes. The results in Fig. 9(b) corroborate such a fact by showing that clock offsets of messages 0x20 and 0xB2, which were sent by the same ECU, had a high correlation of 0.9860, whereas offsets of messages 0x20 and 0x2C1 —

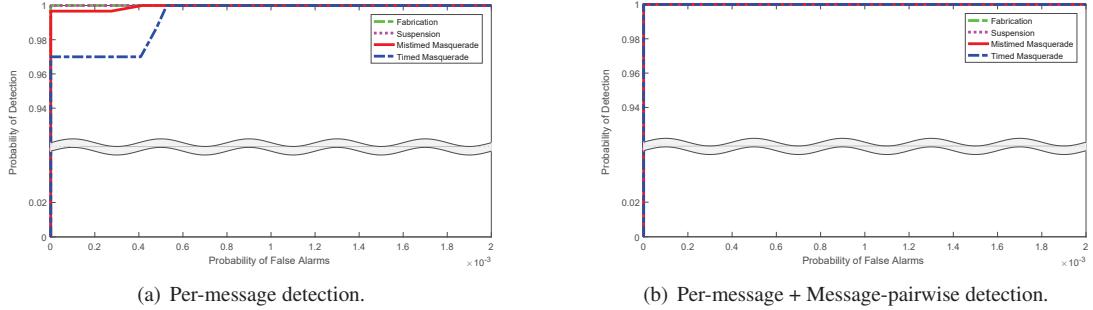

Figure 11: ROC curves of CIDS in the real vehicle.

sent by different ECUs with similar clock skews — had a low correlation of 0.0331. Thus, for messages with near-equivalent clock skews, CIDS can further examine the correlation between their clock offsets, and correctly determine their transmitters.³ These facts and observations indicate the feasibility and efficiency of message-pairwise detection in CIDS.

To show that message-pairwise detection can support per-message detection in decreasing false positives/negatives by examining offset correlations, we consider a scenario in which an attacker \mathbb{V}_1 has mounted a masquerade attack on a Honda Accord ECU \mathbb{V}_2 at $t_{masq} = 800$ secs. We refer to \mathbb{V}_2 as the ECU which originally transmits message 0x1B0. To consider the *worst case* in detecting the masquerade attack, we assume that the clock skews of \mathbb{V}_1 and \mathbb{V}_2 are nearly equivalent, similarly to messages 0x20 and 0x2C1 in the Toyota Camry. We replicated such a worst-case scenario by randomly permuting the acquired offset values of 0x1B0 for $t > t_{masq}$, and considering the permuted values to be output from \mathbb{V}_1 . As shown in Fig. 10(a), this leads to a situation where the clock skew does not change even though the message transmitter has been changed from one ECU to another. Although the clock skew remained equivalent at $t = t_{masq}$, the correlation between offsets of 0x1B0 and 0x1D0 suddenly dropped from 0.9533 to 0.1201, i.e., a linear to non-linear relationship. As a result, as shown in Fig. 10(b), the control limits in CIDS’s message-pairwise detection exceeded the threshold $\Gamma_L = 5$. On the other hand, since the clock skews before and after the attack were equivalent, per-message detection was not able to detect the intrusion.

5.5 False Alarm Rate

We also examined the false alarm rate of CIDS under the real vehicle setting. The results obtained from the CAN

³If the two ECUs’ clock behaviors are still not distinguishable, CIDS can be set up to exclude them for examination so that the risk of false positives significantly decreases. However, this may impact CIDS’s capability of detecting attacks mounted through those ECUs.

bus prototype are omitted due to their insignificance, i.e., not many false alarms occurred due to its less complex bus traffic. Based on data recorded for 30 minutes from the Honda Accord 2013 — approximately 2.25 million messages on the CAN bus — four attack datasets were constructed to each contain 300 different intrusions. The intrusions either had different injection timings, suspension timings, or changes in clock skews: each in the form of fabrication attack, suspension attack, mistimed masquerade attack, and timed masquerade attack. For each dataset, we varied the κ parameter of CIDS to acquire one false positive rate (false-alarm rate) and one false negative rate (1–detection rate).

Fig. 11(a) shows the Receiver Operating Characteristic (ROC) curve of CIDS, which represents its trade-off between false alarm and detection, executing *only* per-message detection on the attack datasets. Clearly, CIDS is shown to be able to detect fabrication, suspension, and masquerade attacks with a high probability. Since the timed masquerade attack is the most difficult to detect, it showed the highest false positive rate among all the attack scenarios considered: a false positive rate of 0.055% while not missing any anomalies (100% true positives). Even for false positives $< 0.055\%$, 97% of the anomalies were detected by CIDS. However, these false positives can be of great concern for in-vehicle networks. Therefore, to eliminate such false positives, CIDS can additionally run message-pairwise detection. Fig. 11(b) shows the ROC curve of CIDS executing not only per-message detection but also message-pairwise detection for further verification. Accordingly, CIDS was able to detect all types of attacks considered without having any false positives, which is in contrast to CIDS with only per-message detection, i.e., all false positives were eliminated via message-pairwise detection.

6 Discussion

Discussed below are the overhead, deployment, limitations, and applications of CIDS.

Identification algorithm. To estimate clock skew, one can also use other algorithms than RLS, such as Total Least Squares (TLS) and Damped Least Squares (DLS), which perform orthogonal linear and non-linear regression, respectively. Although they might identify the clock skew with a higher accuracy than RLS, their gains are offset by the accompanying high complexity. TLS requires Singular Value Decomposition (SVD), which is computationally expensive, and DLS requires a large number of iterations for curve fitting. RLS is known to have a computation complexity of $\mathcal{O}(N^2)$ per iteration, where N is the size of the data matrix. However, in CIDS, only a scalar clock offset is exploited for identification, and thus the computational complexity is relatively low.

Defeating CIDS. There may be several ways the adversary may attempt to defeat CIDS. First, the adversary may try to compromise the ECU running CIDS and disable it. However, if *cross-validation* for CIDS was to be exploited, such an attempt can be nullified. For the detection of intrusions, CIDS only requires an ECU to record the timestamps of message arrivals. Such a low overhead makes it feasible for CIDS to be installed distributively across several in-vehicle ECUs for cross-validation. Suppose using CIDS, ECU A monitors attacks on messages $\{M_1, M_2\}$, ECU B monitors $\{M_2, M_3\}$, and ECU C monitors $\{M_1, M_3\}$. Since CIDS regards the *receiver's* time clock as the true clock, cross-validation provides multiple perspectives of clock behaviors for each message ID, e.g., two different perspectives of M_2 from A and B. Thus, even when an ECU running CIDS gets compromised, cross-validation via CIDS can handle such a problem.

Another way the adversary may try to defeat CIDS is to adapt to how its algorithm is running and thus deceive it. The adversary may figure out the clock skew of the target ECU and then heat up or cool down the compromised ECU so that its clock skew changes to match that of the target. In such a case, the clock skew can be matched and thus may bypass CIDS's per-message detection. However, as discussed in Section 5.4, unless the adversary also matches the instantaneous clock offset, which is affected by the ECU's *momentary* workload and temperature, CIDS can detect the intrusion via message-pairwise detection.

Upon intrusion detection. False alarms for intrusion detection systems, especially in in-vehicle networks, are critical. Thus, CIDS should also deal with them as accurately as possible. To meet this requirement, if an intrusion has been determined, even after going through the verification process, CIDS can follow the following steps for further examination:

1. If an intrusion was detected while using only per-message detection, examine it further via message-pairwise detection.

2. If still alarmed as an intrusion and the attacked ECU is a safety-critical ECU, go straight to step 4.
3. If not, communicate with other ECUs for cross-validation as they would provide different perspectives of the clock skew results. If communicating with other ECUs incurs too much overhead (in terms of bus load, processing overhead, etc.), send traffic data for a remote diagnosis.
4. Request re-patching of firmware and advise the driver to stop the vehicle.

Limitation of CIDS. CIDS is shown to be effective in detecting various types of in-vehicle network intrusions. One limitation of CIDS might be that since it can only extract clock skews from periodic messages, it would be difficult to fingerprint ECUs which are sending aperiodic messages. That is, if the attacker injects messages aperiodically, although CIDS can still detect the intrusion, it would not be able to pinpoint where the attack message came from, i.e., finding the root-cause of attacks launched with or on aperiodic messages. Recall that CIDS can achieve this only for periodic messages. In future, we would like to find new features other than clock skew, which can fingerprint ECUs, regardless of whether they send messages periodically or aperiodically.

Applicability to other in-vehicle networks. Although most modern in-vehicle networks are based on CAN, some may be equipped with other protocols, such as CAN-FD, TTCAN and FlexRay, for more complex operations. CAN-FD is an enhanced version of CAN, providing flexible and higher data rates [5]. Since its basic components conform to CAN and thus also lacks synchronization, CIDS can be applied to CAN-FD. For protocols such as TTCAN [21] and FlexRay [22], nodes are periodically synchronized for determinative timing of message exchanges. The interval between two consecutive synchronizations depends on how each protocol is deployed [32]. For TTCAN, it can be up to $2^{16} = 65536$ bits long, i.e., 131ms in a 500Kbps bus [37]. This lets some messages be sent multiple times between consecutive synchronizations. So, if the time interval is long, CIDS would still be able to extract clock skews from messages which are sent multiple times, whereas, if the period is short, CIDS may not be feasible. However, the fact that TTCAN and FlexRay have high implementation cost, whereas for CAN-FD it is minimal, makes CAN-FD a favorite candidate for next-generation in-vehicle networks [6, 39]. This means that CIDS can be applicable to not only current but also future in-vehicle networks.

7 Conclusion

New security breaches in vehicles have made vehicle security one of the most critical issues. To defend against

vehicle attacks, several security mechanisms have been proposed in the literature. They can cope with some attacks but cannot cover other safety-critical attacks, such as the masquerade attack. To remedy this problem, we have proposed a new IDS called CIDS, which extracts clock skews from message intervals, fingerprints the transmitter ECUs, and models their clock behaviors using RLS. Then, based on the thus-constructed model, CIDS detects intrusions via CUSUM analysis. Based on our experiments on a CAN bus prototype and on real vehicles, CIDS is shown to be capable of detecting various types of in-vehicle network intrusions. CIDS can address all attacks that existing IDSs can and cannot handle as well as facilitates root-cause analysis. Thus, it has potential for significantly enhancing vehicle security and safety.

Abstract

While most automotive immobilizer systems have been shown to be insecure in the last few years, the security of remote keyless entry systems (to lock and unlock a car) based on rolling codes has received less attention. In this paper, we close this gap and present vulnerabilities in keyless entry schemes used by major manufacturers. In our first case study, we show that the security of the keyless entry systems of most VW Group vehicles manufactured between 1995 and today relies on a few, global master keys. We show that by recovering the cryptographic algorithms and keys from electronic control units, an adversary is able to clone a VW Group remote control and gain unauthorized access to a vehicle by eavesdropping a single signal sent by the original remote. Secondly, we describe the Hitag2 rolling code scheme (used in vehicles made by Alfa Romeo, Chevrolet, Peugeot, Lancia, Opel, Renault, and Ford among others) in full detail. We present a novel correlation-based attack on Hitag2, which allows recovery of the cryptographic key and thus cloning of the remote control with four to eight rolling codes and a few minutes of computation on a laptop. Our findings affect millions of vehicles worldwide and could explain unsolved insurance cases of theft from allegedly locked vehicles.

1 Car Keys

For several decades, car keys have been used to physically secure vehicles. Initially, simple mechanical keys were introduced to open the doors, unlock the steering, and operate the ignition lock to start the engine. Given physical access to a mechanical key, or at hand of a detailed photograph, it is possible

to create a duplicate. In addition, mechanical tumbler locks and disc locks are known to be vulnerable to techniques such as lock-picking and bumping that allow to operate a lock without the respective key. Finally, for most types of car locks, locksmith tools exist that allow to decode the lock and create a matching key.

1.1 Electronics in a Car Key

With electronic accessories becoming available, additional features were integrated into the locking and starting systems of cars: some of them to improve the comfort, others to increase security. On the side of the car key, this implies some electronic circuitry integrated in its plastic shell, as illustrated in Figure 1. Note that the link between Remote Keyless Entry (RKE) and immobilizer is optional. In the Hitag2 system (Section 4), the immobilizer interface can be used to re-synchronize the counter used for RKE, while VW Group vehicles (Section 3) completely separate RKE and immobilizer. In vehicles with Passive Keyless Entry and Start (PKES) (Section 1.1.2), the low-frequency immobilizer link is used to trigger the transmission of a door opening signal over the high-frequency RKE interface.

1.1.1 Immobilizer Transponders

One of the most notable events in the history of car security was the introduction of the immobilizer, which significantly reduced the number of stolen cars and so-called joyrides conducted by teenagers. An electronic immobilizer improves the security of the car key with respect to starting the engine. Technically, most immobilizers rely on Radio Frequency IDentification (RFID) technology: An RFID transponder is embedded in the plastic shell of the car key and contains a secret that is required to

¹These authors contributed the research on Hitag2.

²These authors contributed the research on VW Group.

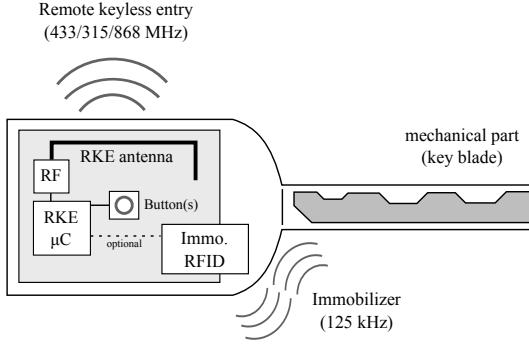

Figure 1: Main components of a car key: RKE and immobilizer systems are separate and use different RF frequencies.

switch on the ignition and start the engine. An antenna coil around the ignition lock establishes a bidirectional communication link and provides the energy for the transponder in order to verify its authenticity with a range of a few centimeters. All modern immobilizers use cryptography for authentication between transponder and vehicle, typically based on a challenge-response protocol.

For many years, only weak, proprietary cryptography was implemented in immobilizer transponders worldwide. This may have been caused by the limited energy available on RFID-powered devices, technological limitations, and cost considerations. The first type of immobilizer transponder to be broken was the widespread DST40 cipher used in Texas Instrument’s Digital Signature Transponder (DST), which was reverse-engineered and broken at Usenix Security 2005 [8]: The 40-bit secret key of the cipher can be revealed in a short time by means of exhaustive search. This paper was at the same time one of the first published attacks on a commercial device in the literature. A few years later, at Usenix Security 2012, researchers published several cryptanalytic attacks on NXP’s Hitag2 transponders [30, 32], the most widely used car immobilizer at that time. The authors showed that an attacker can obtain the 48-bit secret key required to bypass the electronic protection in less than 360 seconds. One year later, in a paper submitted to Usenix Security 2013 (and finally published in 2015), the security mechanism of the Megamos Crypto transponder were found to be vulnerable to cryptanalytic attacks [31, 33]. The 96-bit secret key of the cipher is mapped into a 57-bit state of a stream cipher that can be rolled back. A flawed key generation (multiple bits of the secret key are set to zero) additionally found in various transponders decreases the attack time from the order of days to a few seconds

using a Time-Memory Tradeoff (TMTO).

As a result, the majority of RFID immobilizers used in today’s vehicles can be cloned: the secret of the transponder can be obtained by an adversary to circumvent the added security provided by the immobilizer. The cryptography of these immobilizers has to be considered broken as their added protection to prevent criminals from starting the engine of a car is very weak.

1.1.2 Passive Keyless Entry and Start

Today, certain modern cars (especially made by luxury brands) are equipped with PKES systems that rely on a bidirectional challenge-response scheme, with a small operating range of about one meter: When in proximity of the vehicle, the car key generates a cryptographic response to a challenge transmitted by the car. A valid response unlocks the doors, deactivates the alarm system, and enables the engine to start. As a consequence, the only remaining mechanical part in some cars is a door lock for emergencies (usually found behind a plastic cover on the driver’s side), to be used when the battery is depleted.

Unfortunately, PKES does not require user interaction (such as a button press) on the side of the car key to initiate the cryptographic computations and signal transmission. The lack of user interaction makes PKES systems prone to relay attacks, in which the challenge and response signals are relayed via a separate wireless channel: The car key (e.g., in the pocket of the victim) and vehicle (e.g., parked hundreds of meters away) will assume their mutual proximity and successfully authenticate. Since the initial publication of these relay attacks in 2011 [14], tools that automatically perform relay attacks on PKES systems are available on the black market and are potentially used by criminals to open, start, and steal vehicles.

1.1.3 Remote Keyless Entry Systems

RKE systems rely on a unidirectional data transmission from the remote control, which is embedded in the car key, to the vehicle. Upon pressing a button, an active Radio Frequency (RF) transmitter in the remote control usually generates signals in a freely usable frequency band. These include the 315 MHz band in North America and the 433 MHz or 868 MHz band in Europe, with a typical range of several tens to hundreds of meters. Note that a few old cars have been using infrared technology instead of RF. RKE systems enable the user to comfortably lock and un-

lock the vehicle from a distance, and can be used to switch on and off the anti-theft alarm, when present.

The first remote controls for cars used no cryptography at all: The car was unlocked after the successful reception of a constant “fix code” signal. Replay attacks on these systems are straightforward. We encountered a Mercedes Benz vehicle manufactured around 2000 that still relies on such fix code RKE systems.

The next generation of RKE systems are so-called rolling code systems, which employ cryptography and a counter value that is increased on each button press. The counter value (and other inputs) form the plaintext for generating a new, encrypted (or otherwise authenticated) rolling code signal. After decryption/verification on the side of the vehicle, the counter value is checked by comparing it to the last stored counter value that was recognized as valid: An increased counter value is considered new and thus accepted. A rolling code with an old counter value is rejected. This mechanism constitutes an effective protection against replay attacks, since a rolling code is invalidated once it has been received by the vehicle. The cryptographic mechanisms behind rolling code systems are further described in Section 2.

In principle, such unidirectional rolling code schemes can provide a suitable security level for access control. However, as researchers have shown in the case of KEELOQ in 2008, the security guarantees are invalidated if they rely on flawed cryptographic schemes: KEELOQ was broken both by cryptanalysis [7, 15] and, in a more realistic setting, by side-channel attacks on the key derivation scheme executed by the receiver unit [12, 17]. Although it is frequently mentioned that KEELOQ is widely used for vehicle RKE systems, our research indicates that this system is prevalently employed for garage door openers.

Another attack, targeting an outdated automotive RKE scheme of an unspecified vehicle (built between 2000 and 2005), was demonstrated by Cesare in 2014 [9]: An adversary has to eavesdrop three subsequent rolling codes. Then, using phase-space analysis, the next rolling code can be predicted with a high probability. However, apart from this attack the cryptographic security of automotive RKE systems has not been investigated to our knowledge. In particular, a large-scale survey and security analysis of very wide-spread rolling code systems has not been carried out.

A different, simple but effective method used by criminals to break into cars is to jam the RF communication when the victim presses the remote con-

trol to lock the car. The victim may not notice the attack and thus leave the car open. A variant of the attack is “selective jamming”, i.e., a combined eavesdropping-and-jamming approach: The transmitted rolling code signal is monitored and at the same time jammed, with the effect that the car is not locked and the attacker possesses a temporarily valid (one-time) rolling code. Consequently, a car could be found appropriately locked after a burglary. This approach was first mentioned in [17] and later practically demonstrated by [16, 27]. Note that one successful transmission of a new rolling code from the original remote to the car usually invalidates all previously eavesdropped rolling codes, i.e., the time window for the attack is relatively small. Furthermore, it is usually not possible to change the signal contents, for example, convert a “lock” command into an “unlock”. This limitation is often overlooked (e.g. in [16, 27]) and severely limits the practical threat posed by this type of attack.

1.2 Contribution and Outline

In this paper, we study several extremely widespread RKE systems and reveal severe vulnerabilities, affecting millions of vehicles worldwide. Our research was in part motivated by reports of unexplained burglaries of locked vehicles (for example [1, 2]), as well as scientific curiosity regarding the security of our own, personal vehicles.

The remainder of this paper is structured as follows: In Section 2, we briefly summarize the results of our preliminary analysis of different RKE systems solely by analyzing the transmitted RF signals. The main contributions presented subsequently are:

1. In Section 3, we analyze the RKE schemes employed in most VW Group group vehicles between 1995 and today. By reverse-engineering the firmware of the respective Electronic Control Units (ECUs), we discovered that VW Group RKE systems rely on cryptographic schemes with a single, worldwide master key, which allows an adversary to gain unauthorized access to an affected vehicle after eavesdropping a single rolling code.
2. In Section 4, we study an RKE scheme based on the Hitag2 cipher, as used by many different manufacturers. We have reverse-engineered the protocol in a black-box fashion and present a novel, fast correlation attack on Hitag2 applicable in an RKE context. By eavesdropping four to eight rolling codes, an adversary can re-

cover the cryptographic key within minutes and afterwards clone the original remote control.

2 Preliminary Analysis of RKE Systems

To address the research question of this paper: “how secure are modern automotive RKE systems?”, we captured RF signals from the remote controls of a variety of vehicles, including our own cars (VW Passat 3B, Škoda Fabia, Alfa Romeo Giulietta). Today, the required hardware for receiving (and sending) RKE signals is widely available. For our analyses, we used various devices, including Software-Defined Radios (SDRs) (HackRF, USRP, `rtl-sdr` DVB-T USB sticks) and inexpensive RF modules. Figure 2 shows our simple setup which costs $\approx \$40$, is battery-powered, can eavesdrop and record rolling codes, emulate a key, and perform reactive jamming.

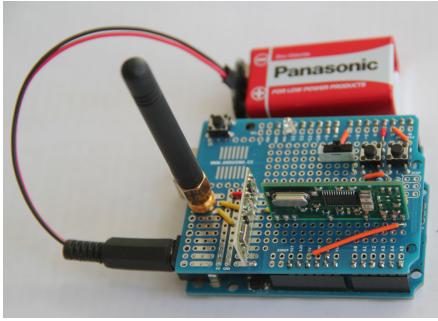

Figure 2: Arduino-based RF transceiver

Studying the raw received signals and guessing the respective modulation and encoding schemes turned out to be straightforward: The majority of the studied RKE systems uses simple Amplitude-Shift Keying (ASK) as modulation scheme, while a smaller percentage employs Frequency Shift Keying (FSK). For the encoding of the actual data bits, the most prevalent methods are Manchester encoding and pulse-width encoding. The utilized bit rates range from less than 1 kBit/s (for older remotes) to 20 kBit/s (for newer remotes).

A typical rolling code packet consists of a preamble (i.e., a regular sequence of 0 and 1), a fixed start pattern (a sequence of one or a few fixed bytes), the actual, cryptographic data payload, and a final checksum, cf. Figure 3. Note that many schemes slightly deviate from this general structure. Also, in virtually all cases, the same packet is sent multiple times, presumably to increase the reliability in presence of environmental disturbances.

The data payload normally contains the Unique

Preamble	Start pattern	Payload	Checksum
----------	---------------	---------	----------

Figure 3: General packet structure of a rolling code. Gray background indicates that the part is either encrypted or authenticated.

Identifier (UID) of the remote control, the rolling counter value, and the pressed button (i.e., “unlock”, “lock”, “open trunk”, in the US also “panic” or “alarm”). Obviously, the data sent by the remote control has to be cryptographically authenticated in some way. There appear to be two major routes that were taken by designers of RKE systems:

Implicit authentication: The complete payload (or part of it) is symmetrically encrypted. The receiver then decrypts the packet, and checks if the content is valid, i.e., if the UID is known to the vehicle and the counter is in its validity window. Examples for this approach can be found in Section 3.

Explicit authentication: Some form of Message Authentication Code (MAC) is computed over the data payload and then appended to the packet. An example of this approach is the Hitag2 scheme described in Section 4.

As a next step, we tried to determine the utilized encryption algorithms. However, a search for publicly available documentation or data sheets yielded little results. For example, the systems employed in VW Group vehicles (VW, Seat, Škoda, and Audi) appear to be a complete black box without any publicly documented security analysis. Since VW Group vehicles are extremely wide-spread, we selected this manufacturer as the target of our first case study (Section 3). Our second case study focuses on the Hitag2 scheme, for which abridged (one-page) data sheets can be found on the Internet [26]. We found Hitag2-based remote controls in vehicles made by a variety of manufacturers, hence, we opted to recover the exact functionality and further analyze the security of this RKE scheme (Section 4).

3 Case Study 1: The VW System

With over 23% market share in Europe (September 2015) and 11.1% worldwide (August 2014), the VW Group is amongst the leading global automotive manufacturers [13]. We had access to a wide variety of VW Group vehicles for our security analysis, from vehicles manufactured in the early 2000s to ones for the model year 2016. In total, the VW Group has sold almost 100 million cars from 2002 until 2015. While not all of these vehicles use the

RKE schemes covered in this section, we have strong indications that the vast majority is vulnerable to the attacks presented in the following. Note that the VW Group also includes certain luxury brands (e.g., Porsche, Bentley, Lamborghini, Bugatti) that we did not analyze in detail. Instead, we focused on more wide-spread vehicles manufactured by VW, Seat, Škoda, and Audi. For a list of cars that we validated our findings with, refer to Section 3.5.1. Eavesdropping and analyzing the signals transmitted by numerous remote controls, we identified at least 7 different RKE schemes, referred to as VW-x ($x = 1 \dots 7$) in the following. Out of these systems, we selected the four schemes covering the largest amount of vehicles:

VW-1: The oldest system, used in model years until approximately 2005. The remote control transmits On-Off-Keying (OOK) modulated signals at 433.92 MHz, using pulse-width coding at a bitrate of 0.667 kBit/s.

VW-2: Used from approximately 2004 onwards. The operating frequency is 434.4 MHz using OOK (same as for VW-3 and VW-4), transmitting Manchester-encoded data at a bitrate of 1 kBit/s.

VW-3: Employed for models from approximately 2006 onwards, using a frequency of 434.4 MHz and Manchester encoding at a bitrate of 1.667 kBit/s. The packet format differs considerably from VW-2.

VW-4: The most recent scheme we analyzed, found in vehicles between approximately 2009 and 2016. The system shares frequency, encoding, and packet format with VW-3, but uses a different encryption algorithm (see below).

The remaining three schemes are used in Audi vehicles from approximately 2005 until 2011 (VW-5), the VW Passat since 2005 (model B6/type 3C and newer, VW-6) and new VW vehicles like the Golf 7 (VW-7). We have not further investigated the security of these systems, but at least for older vehicles, it seems likely that similar design choices as for VW-1–VW-4 were made.

For our initial analyses, we implemented the most likely demodulation and decoding procedure for all of the above systems. We then collected rolling codes of multiple remote controls for each scheme and compared the resulting data. For all schemes VW-1–VW-4, we found that most of the packet content appeared to be encrypted, except for a fixed start pattern and the value of the pressed button sent in plain. We hence assumed that all systems use implicit authentication, i.e., check the correctness of a rolling code after decryption. Demodulation routines for VW-3 and VW-4 were independently

published in 2015 [6] after we had carried our preliminary analysis. Note that this does not cover any of the cryptographic algorithms presented here.

3.1 Analysis of Remote Control and ECU

We obtained various VW Group remote controls and extracted the Printed Circuit Boards (PCBs) for further analysis of the hardware. A typical PCB for a VW Group RKE remote includes a Microcontroller (μ C), an RF transmitter, an antenna (integrated on the PCB) and a coin cell battery as the main components. On many remote control PCBs (e.g., implementing VW-2), we found a μ C marked with Temic/Atmel M44C890E, cf. Figure 4. According to the datasheet available online [3], this μ C is a 4-bit processor, the so-called MARC4. The μ C is mask-programmed, i.e., the program code is placed in Read Only Memory (ROM) and hence fixed at manufacturing. According to Laurie [21], it is possible to re-construct the program code of MARC4 processors by taking microscopic photographs of the ROM memory and applying further image processing to extract the value of each individual bit. However, we did not follow this approach because we did not have access to suitable microscopic equipment.

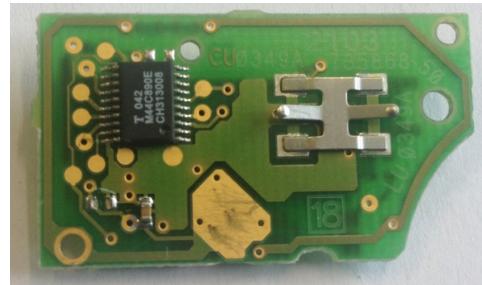

Figure 4: PCB of an older VW Group remote control using a MARC4 μ C

When studying remote controls of newer vehicles, we found different, not easily identifiable μ Cs on the PCB. An example of this is shown in Figure 5: We could not identify the type of μ C from the markings on the main IC (top, towards the right), which complicates the reverse engineering.

It seemed conceivable that some form of key derivation could be present, which would have to be implemented on the receiving ECU's side. Thus, we opted to analyze the RKE ECUs in the vehicle that receive and process the remote control signals. We therefore bought a number of ECUs implementing the respective RKE functionality, and attemp-

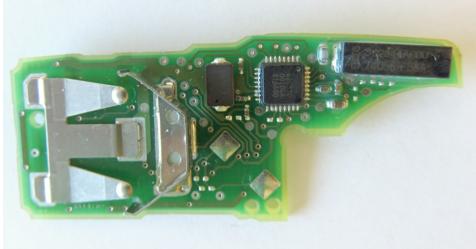

Figure 5: PCB of a newer VW Group remote control using an unidentified μ C

ted to extract the firmware of the μ Cs present on the PCB of the ECU. Note that in contrast to the low-power 4-bit or 8-bit processors usually employed in the remote control, the RKE ECUs often handles numerous additional features of the vehicle and thus utilizes a more powerful, Flash-programmable 16-bit or 32-bit μ C (with documented debug and programming interfaces).

Using widely available, standard programming tools for automotive processors, we were able to obtain firmware dumps for all studied ECUs. We then located and recovered the cryptographic algorithms by performing static analysis of the firmware image, searching amongst others for constants used in common symmetric ciphers and common patterns of such ciphers (e.g., table lookups, sequences of bitwise operations). The results of this process are described in more detail for each scheme VW-1–VW-4 in the following. Note that as part of our negotiations with VW Group, and to protect VW Group customers, we agreed to not fully disclose the part numbers of the analyzed ECUs and the employed μ Cs at this point. We furthermore agreed to omit certain details of the reverse-engineering process, as well as the values of cryptographic keys.

3.2 The VW-1 Scheme

The VW-1 system is the only VW Group scheme discussed in this paper that operates at 433.92 MHz (all newer systems use a frequency of 434.4 MHz). In contrast to newer RKE schemes, the start of a packet is not indicated by a long preamble, but by a single 1-0 pattern (500 μ s high level, 500 μ s low level). After this, the data bits are transmitted LSB-first in pulse-width encoded form: A zero is indicated by a short high level followed by a longer low level, while a one is represented with the opposite pattern (long high, short low). We discovered that the first four bytes hold the UID of the remote in an obfuscated form (several bytes of the packet are XORed). The following three bytes *lfsr* hold the

(byte-permuted) state of a Linear Feedback Shift Register (LFSR) that is clocked a fixed number of ticks for each new rolling code (i.e., the LFSR state has the role of a counter). For reasons of responsible disclosure, we do not provide the full details of the obfuscation function and the LFSR feedback in this paper. One bit of the final nibble *btn* indicates the pressed button. The overall structure of a VW-1 rolling code packet is shown in Figure 6:

UID	lfsr	btn
0	32	56 59

Figure 6: Packet structure of a rolling code for VW-1. Gray background indicates that the part is obfuscated or holds the LFSR state. The start pulse is not shown.

In conclusion, the security of the VW-1 is *solely based on obscurity*. Neither is there a cryptographic key involved in the computation of the rolling code, nor are there any vehicle or remote control specific elements for some form of key diversification. With the knowledge of the details of the obfuscation function and the LFSR, an adversary can generate valid rolling codes to open and close a VW-1 vehicle based on a single eavesdropped signal (to obtain the UID and the current state of the LFSR). Note that we observed similarly insecure LFSR-based schemes in older Audi vehicles built before 2004.

3.3 The VW-2 and VW-3 Schemes

Starting with VW-2, a rolling code packet has the following structure: A preamble (regular 0-1 pattern) is followed by a fixed start sequence *start* (individual per scheme), an encrypted 8-byte payload, and finally a byte *btn* indicating the button that was pressed. The packet structure (not showing the preamble) is depicted in Figure 7.

start	UID	ctr	btn'	btn
0	24	56	80	88 95

Figure 7: Packet structure of a rolling code for VW-2–4. Gray background indicates that the part is encrypted. Note that the fixed start pattern is shorter for VW-2.

The 8-byte payload is generated from the following plaintext: a 4-byte *UID*, a 3-byte counter *ctr*, and one byte *btn'* again indicating the pressed button. This payload is then encrypted using a proprietary block cipher that we recovered from the ECU

firmware as described in Section 3.1. We later found that this cipher appears to be the so-called AUT64 cipher employed in certain immobilizer transponders as well [4]. Hence, we will use the name AUT64 in the following and follow the notation given in the public datasheet.

AUT64 is an iterated cipher, operating on 8-byte blocks. It uses a round structure as depicted in Figure 8: In each round i the state (represented as bytes $a_0 \dots a_7$) is first byte-permuted, using a *key-dependent* permutation σ . This permutation is fully described by a $3 \cdot 2^3 = 24$ bit string. Then, bytes $a_0 \dots a_6$ are left unchanged, while byte a_7 is updated using the round function $g(a_0, \dots, a_7, key_i)$, where key_i is a 32-bit round key. In the case of AUT64 in the VW Group system, the cipher has 12 rounds, while the datasheet [4] only specifies a possible number of rounds between 8 and 24. The

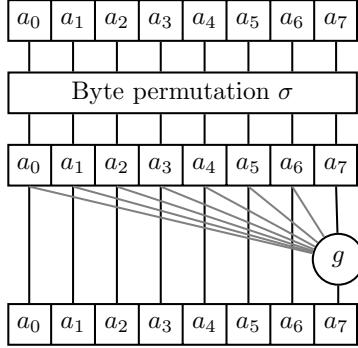

Figure 8: One round i of the AUT64 block cipher as used in VW-2 and VW-3. a_0, \dots, a_7 is the 8-byte state of the cipher, $g(a_0, \dots, a_7, key_i)$ the round function.

internal structure of g is shown in Figure 9: The input bytes a_0, \dots, a_7 are first combined with the 32-bit round key key_i using a sequence of concatenations, table look-ups, and XOR operations denoted as f . Note that the round key is derived from a part (denoted as k_f in the following) of the main key k by a fixed, nibble-wise permutation per round. Each nibble of the 8-bit output of f is then passed through the same 4-to-4 S-Box τ , bit-permuted using the same permutation σ used for the state (but applied on a bit-level), and again passed through a second instance of τ . Note that both σ and τ are *key-dependent* in addition to key_i . Hence, the full key of the AUT64 cipher is the tuple $k = (k_f, \sigma, \tau)$ with an overall key size of $32 + 3 \cdot 2^3 + 4 \cdot 2^4 = 120$ bit.

However, not all choices for τ and σ are permissible in order to have a bijective S-Box and a valid permutation—in total, there are $16!$ bijective

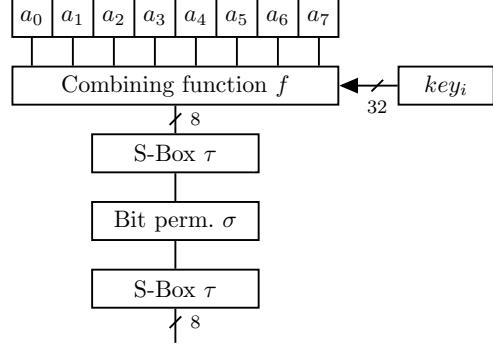

Figure 9: One round function g of the AUT64 block cipher as used in VW-2 and VW-3. a_0, \dots, a_7 is the 8-byte state of the cipher, key_i the round key.

4-to-4 S-Boxes and $8!$ permutations. This results in an effective key size of $32 + \log_2(8!) + \log_2(16!) = 91.55$ bit. Finding an AUT64 key by exhaustive search is therefore beyond current computational capabilities, where a security level of 80 bit is usually deemed acceptable for lightweight ciphers.

We have not further analyzed the mathematical security of the cipher, but believe this to be an interesting research problem, especially due to the unconventional design with several key-dependent operations. For the analysis of the VW-2 and VW-3 RKE systems, however, it turned out that no further cryptanalysis is necessary: Both schemes use a fixed, *global master key* independent of vehicle or remote control. In other words, this means that the same AUT64 key is stored in millions of ECUs and RKE remotes, *without any key diversification* being employed at all. The sole means by which the vehicle determines if a rolling code is valid is hence by white-listing certain UIDs and checking if the counter is within the validity window. Incidentally, this also implies that a VW Group vehicle using a particular scheme receives and decrypts all rolling codes for that scheme transmitted in the vicinity.

Note that the global AUT64 master keys for VW-2 and VW-3 are different, but both can be extracted from the ECU firmware and possibly from the μC in the remote control as well (e.g. with invasive attacks like micro-probing or side-channel analysis).

3.4 The VW-4 Scheme

In newer VW Group vehicles from approximately 2009 onwards, we found an RKE system that has the same encoding and packet structure as VW-3 (although with a different start pattern), but does not employ the AUT64 cipher. For this system VW-4,

the analysis of the respective ECU firmware revealed that the XTEA cipher [24] is used to encrypt a rolling code packet with a format otherwise identical to VW-3 (cf. Figure 7).

XTEA is a block cipher based on a 64-round Feistel structure with 64-bit block size and 128-bit key. Due to the structure of the round function based on Addition, Rotate, XOR (ARX) operations, it is well suited for lightweight software implementations required for low-end and low-power devices like RKE remotes. The best known cryptanalytical attack on XTEA [22] is of theoretical nature (related-key rectangle attack on 36 rounds with $2^{63.83}$ byte of data and $2^{104.33}$ steps) and hence not relevant in the context of RKE systems.

However, again we found that a *single, worldwide key* is used for all vehicles employing the VW-4 system. The same single point of failure of the older systems VW-1–VW-3 is hence also present in recently manufactured vehicles. For example, we found this scheme implemented in an Audi Q3, model year 2016, and could decrypt and generate new valid rolling codes to open and close this vehicle (and numerous other VW Group vehicles, cf. Section 3.5.1).

3.5 Implications and Observations

As the main result of this section, we discovered that the RKE systems of the majority of VW Group vehicles have been secured with only a few cryptographic keys that have been used worldwide over a period of almost 20 years. With the knowledge of these keys, an adversary only has to eavesdrop a single signal from a target remote control. Afterwards, he can decrypt this signal, obtain the current UID and counter value, and create a clone of the original remote control to lock or unlock any door of the target vehicle an arbitrary number of times.

We observed that (mostly) VW-4 vehicles blocked the original remote control if a valid rolling code with a counter more than 2 behind is received. In other words, if ctr is the value expected by the vehicle, any rolling code with $ctr - 2$ or less leads to the blocking. If an adversary sends at least two valid signals with increased counter values (e.g., “unlock” and “lock”), the original remote control of the owner will stop working in the moment when the car receives an outdated signal. In this case, usually automatic re-synchronization procedures described in the respective vehicle’s manual help technically experienced car owners to re-synchronize the remote control to the car. In contrast, if the adversary only sends a single valid signal, the original remote will not be blocked, but only operate on the second button press, be-

cause the counter in vehicle and remote are in sync afterwards. Note that the blocking behaviour could be used for an automatized Denial-of-Service (DoS) attack (aiming to lock out the legitimate car owners of affected vehicles) by intentionally sending an old signal (with a counter value of $ctr - 2$ or less).

In conclusion, while the cryptographic algorithms have improved over the years (from LFSR over AUT64 to XTEA), the crucial problem of key distribution has not been properly solved in the studied schemes VW-1–4. However, according to VW Group, this problem has been addressed in the latest generation of vehicles, where individual cryptographic keys are used. We discuss the consequences and general implications of a successful attack on a RKE system in more detail in Section 5.

3.5.1 Vulnerable Vehicles

Our findings affect amongst others the following VW Group vehicles manufactured between 1995 and 2016. Cars that we have practically tested are highlighted in bold. Note that this list is not exhaustive, as we did not have access to all types and model years of cars, and that it is unfortunately not clear if and when a car model has been upgraded to a newer scheme.

Audi: **A1**, **Q3**, R8, S3, TT, various other types of Audi cars (e.g. remote control part number 4D0 837 231)

VW: **Amarok**, (New) Beetle, Bora, **Caddy**, Crafter, e-Up, Eos, Fox, **Golf 4**, Golf 5, **Golf 6**, Golf Plus, Jetta, Lupo, **Passat**, **Polo**, **T4**, **T5**, Scirocco, **Sharan**, **Tiguan**, Touran, Up

Seat: **Alhambra**, Altea, Arosa, Cordoba, **Ibiza**, Leon, MII, Toledo

Škoda: City Go, Roomster, **Fabia 1**, **Fabia 2**, Octavia, SuperB, Yeti

It is conceivable that all VW Group (except for some Audi) cars manufactured in the past and partially today rely on a “constant-key” scheme and are thus vulnerable to the attacks described in this paper, except for those cars that rely on the latest platform, e.g., the Golf 7 for VW.

Note that identical VW Group cars are sold under different names in other countries, e.g., some Golf versions were sold as “Rabbit” in North America. We have tested some remote controls operating at 315 MHz, e.g., for the US market, and found them to be vulnerable to our attacks as well, i.e., the only difference to their European counterparts is the operating frequency. Furthermore, cars of different brands

may share the same basic technology, e.g., we found some model years of Ford Galaxy that have the same flawed RKE system as their VW Group derivatives VW Sharan and Seat Alhambra.

3.5.2 Temporary Countermeasures

Completely solving the described security problems would require a firmware update or exchange of both the respective ECU and (worse) the vehicle key containing the remote control. Due to the strict testing and certification requirements in the automotive industry and the high cost of replacing or upgrading all affected car keys in the field, it is unlikely that VW Group can roll out such an update in the short term. Hence, we give recommendations for users of affected vehicles in the following.

The well-known advice (see e.g. [25]) to verify that a vehicle was properly locked with the remote control (blinking direction lights, sound) is no longer sufficient. An adversary may have eavesdropped the “lock” signal from a distance of up to 100 m and generate a new, valid “unlock” rolling code any time later. Preventing or detecting the eavesdropping of RF signals is impractical. Hence, the only remaining (yet impractical) countermeasure is to fully deactivate or at least not use the RKE functionality and resort to the mechanical lock of the vehicle. Note that in addition, for many cars, the alarm will trigger after a while if the car doors or the trunk are mechanically opened, unless the immobilizer is disarmed with the original key.

With respect to forensics, there are several potential indicators (due to the nature of rolling code schemes) that the remote control may have been cloned: If the vehicle does not unlock on the first button press, this could imply that an adversary has sent valid rolling codes with counter values greater than the one stored in the original remote control. Note that no traces of the attack are left once the counter in the original remote control has caught up with the increased value stored in the car. Further, a complete blocking of the remote control (see above) may be an indicator (e.g., for insurance-related court cases) that the RKE system was attacked. It should however be taken into account that, according to our practical tests, the remote control will also be blocked if the car receives a counter that is increased by more than 250 compared to the last stored value—this could for example happen if the remote control buttons are pushed many times while not in the range of the vehicle.

4 Case Study 2: The Hitag2 System

The Hitag2 rolling code system is an example of a RKE scheme that is not specific to a single vehicle brand. Instead, it is implemented on the PCF7946 and PCF7947 ICs manufactured by NXP. While these ICs contain an 8-bit general-purpose μ C that (in theory) allows to realize a fully proprietary scheme [26], it appears that numerous vehicle manufacturers have used a similar (though not identical) RKE system, potentially following NXP’s reference implementation. In contrast to the VW Group system described in Section 3, it seems that manufacturers did not use a fixed, global cryptographic key. Hence, to break this system, we developed a novel attack to exploit the cryptographic weaknesses of Hitag2 in the RKE context.

We first describe the Hitag2 cipher, which was previously published in [35]. We have fully reverse-engineered the rolling code scheme used in the Hitag2 remote control ICs PCF7946/7947 as further described in Section 4.2. The analysis was done in a black-box fashion—we used a remote control for which we were able to obtain the Hitag2 key (since it was shared with the immobilizer in this particular case), guessed potential implementations (based on the immobilizer protocol) for the rolling code system, and finally recovered the complete scheme. In contrast to the analysis of the VW Group systems, no firmware extraction and reverse-engineering of program code was necessary.

To this date, the best known practical cryptanalysis of Hitag2 was proposed in [32] in the context of vehicle immobilizers. Their attack requires 136 authentication attempts and 2^{35} encryptions/lookups, which take 5 minutes on a laptop. In the context of RKE systems, gathering 136 rolling code traces is not practical in a realistic scenario, as it requires to wait for the victim to push a button on the remote that many times. We therefore propose a new attack that requires eavesdropping less authentication attempts (usually between 4 and 8) and one minute computation on a laptop. In Section 4.4, we present our novel correlation attack on Hitag2 in a RKE scenario.

We first need to introduce some notation. Let $\mathbb{F}_2 = \{0, 1\}$ the field of two elements (or the set of Booleans). The symbol \oplus denotes exclusive-or (XOR) and 0^n denotes a bitstring of n zero-bits. Given two bitstrings x and y , xy denotes their concatenation. \bar{x} denotes the bitwise complement of x . We write y_i to denote the i -th bit of y . For example, given the bitstring $y = 0x03$, $y_0 = y_1 = 0$ and $y_6 = y_7 = 1$. We denote encryptions by $\{-\}$.

4.1 Hitag2 Cipher

The targeted RKE protocol uses the Hitag2 stream cipher. This cipher has been reverse engineered in [35]. The cipher consists of a 48-bit LFSR and a non-linear filter function f . Each clock cycle, twenty bits of the LFSR are put through the filter function, generating one bit of keystream. Then the LFSR is shifted one bit to the left, using the feedback polynomial to generate a new bit on the right. See Figure 10 for a schematic representation.

Definition 4.1 *The feedback function $L: \mathbb{F}_2^{48} \rightarrow \mathbb{F}_2$ is defined by $L(x_0 \dots x_{47}) := x_0 \oplus x_2 \oplus x_3 \oplus x_6 \oplus x_7 \oplus x_8 \oplus x_{16} \oplus x_{22} \oplus x_{23} \oplus x_{26} \oplus x_{30} \oplus x_{41} \oplus x_{42} \oplus x_{43} \oplus x_{46} \oplus x_{47}$.*

The filter function f consists of three different circuits f_a, f_b and f_c , which output one bit each. The circuits f_a and f_b are employed more than once, using a total of twenty input bits from the LFSR. Their resulting bits are used as input for f_c . The circuits are represented by three Boolean tables that contain the resulting bit for each input.

Definition 4.2 (Filter function) *The filter function $f: \mathbb{F}_2^{48} \rightarrow \mathbb{F}_2$ is defined by*

$$f(x_0 \dots x_{47}) = f_c(f_a(x_2 x_3 x_5 x_6), f_b(x_8 x_{12} x_{14} x_{15}), \\ f_b(x_{17} x_{21} x_{23} x_{26}), f_b(x_{28} x_{29} x_{31} x_{33}), \\ f_a(x_{34} x_{43} x_{44} x_{46})),$$

where $f_a, f_b: \mathbb{F}_2^4 \rightarrow \mathbb{F}_2$ and $f_c: \mathbb{F}_2^5 \rightarrow \mathbb{F}_2$ are

$$f_a(i) = (0xA63C)_i \\ f_b(i) = (0xA770)_i \\ f_c(i) = (0xD949CBB0)_i.$$

Because $f(x_0 \dots x_{47})$ only depends on $x_2, x_3, x_5 \dots x_{46}$ we shall define $f_{20}: \mathbb{F}_2^{20} \rightarrow \mathbb{F}_2$, writing $f(x_0 \dots x_{47})$ as $f_{20}(x_2, x_3, x_5 \dots x_{46})$.

Remark 4.3 (Cipher schematic) *Figure 10 is different from the schematic that was introduced by [35] and later used by [11, 28, 34]. The input bits of the filter function in Figure 10 are shifted by one with respect to those of [35]. The filter function in the old schematic represents a keystream bit at the previous state $f(x_{i-1} \dots x_{i+46})$, while the one in Figure 10 represents a keystream bit of the current state $f(x_i \dots x_{i+47})$. Furthermore, we have adapted the Boolean tables to be consistent with our notation.*

4.2 Rolling Code Scheme

This section describes the rolling code scheme used by remotes based on the chips PCF7946/7947. When a button on the remote control is pressed, it

transmits a message of the form shown in Figure 11. UID is a 32-bit identifier; btn is a 4-bit button identifier; $lctr$ are the 10 least-significant bits of a 28-bit counter ctr ; ks are 32-bits of keystream; and chk is an 8-bit checksum. The checksum is computed by simply XORing each byte, i.e., computing a parity byte.

During the authentication protocol, the internal state of the stream cipher is initialized. The initial state consists of the 32-bits UID concatenated with the first 16 bits of the key k . Next, the counter ctr is incremented and then $iv = ctr \parallel btn$ is XORed with the last 32 bits of the key and shifted into the LFSR. From this point, the next 32 bits of keystream, which are output by the cipher ks , are sent as proof of knowledge of the secret key k .

4.3 Cipher Initialization

The following precisely defines the initialization of the cipher and the generation of the LFSR stream $a_0 a_1 \dots$ and the keystream ks .

Definition 4.4 *Given a key $k = k_0 \dots k_{47} \in \mathbb{F}_2^{48}$, an identifier $id = id_0 \dots id_{31} \in \mathbb{F}_2^{32}$, a counter $ctr = ctr_0 \dots ctr_{27} \in \mathbb{F}_2^{28}$, a button identifier $btn_0 \dots btn_{31} \in \mathbb{F}_2^4$ and keystream $ks = ks_0 \dots ks_{31} \in \mathbb{F}_2^{32}$, we let the initialization vector $iv \in \mathbb{F}_2^{32}$ be defined as*

$$iv = ctr \parallel btn.$$

Furthermore, the internal state of the cipher at time i is $\alpha_i := a_i \dots a_{47+i} \in \mathbb{F}_2^{48}$. Here the $a_i \in \mathbb{F}_2$ are given by

$$a_i := id_i \quad \forall i \in [0, 31] \quad (1)$$

$$a_{32+i} := k_i \quad \forall i \in [0, 15] \quad (2)$$

$$a_{48+i} := k_{16+i} \oplus iv_i \oplus f(a_i \dots a_{i+47}) \quad \forall i \in [0, 31] \quad (3)$$

$$a_{80+i} := L(a_{32+i} \dots a_{79+i}) \quad \forall i \in \mathbb{N}. \quad (4)$$

Furthermore, we define the keystream bit $ks_i \in \mathbb{F}_2$ by

$$ks_i := f(a_{32+i} \dots a_{79+i}) \quad \forall i \in [0, 31]. \quad (5)$$

Note that the a_i , α_i , and ks_i are formally functions of k , id , and iv . Instead of making this explicit by writing, e.g., $a_i(k, id, iv)$, we just write a_i where k , id , and iv are clear from the context.

4.4 A Fast Correlation Attack on Hitag2

This section describes a practical key-recovery correlation attack against Hitag2. This attack requires a minimum of four rolling codes (“traces”), but will be faster and have higher success probability if more are provided. The rolling codes can have an arbitrary counter value, i.e., do not have to be consecutive. In fact, the probability of success is higher

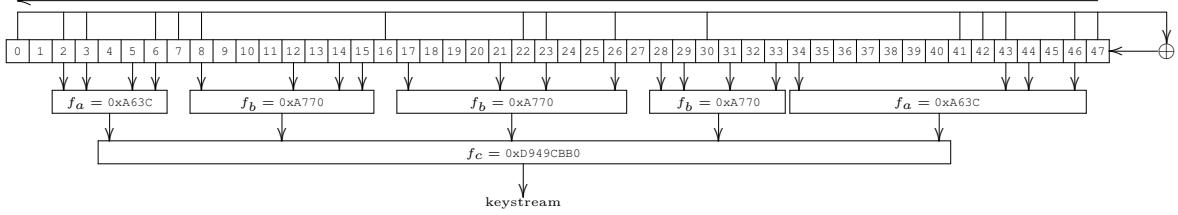

Figure 10: Structure of the Hitag2 stream cipher, based on [35]

0x0001	UID	btn	lctr	ks	0	chk
0	16	48	52	62	94 95	102

Figure 11: Packet structure of a rolling code for Hitag2. Gray background indicates the keystream part produced by the cipher.

when the traces are not consecutive, as consecutive traces often only differ in a few bits from each other, thus providing less correlation information. It also depends on whether the same button was pressed or not. The lower limit of four traces for the key recovery to work was determined experimentally. The number of consecutive traces needed is higher, usually eight. Let $\langle UID, iv^j, ks^j \rangle$, $j = 0 \dots n - 1$ be n authentication traces for $n > 3$. Then, the attacker proceeds as follows:

1. The adversary first guesses a 16-bit window corresponding to LFSR stream bits $a_{32} \dots a_{47}$. Observe that $a_{32} \dots a_{47} = k_0 \dots k_{15}$ and together with the UID, this gives the adversary LFSR bits $a_0 \dots a_{47}$, see Definition 4.4. Also note that $a_0 \dots a_{47}$ is constant over all traces. The adversary can now compute $b_0 = f(a_0 \dots a_{47})$.
2. The adversary will then shift this 16-bit window to the left of the LFSR, until bits $a_{32} \dots a_{47}$ are on the very left of the LFSR. This is the point when the cipher starts outputting ks , see Equation 5.
3. Next, the adversary will compute a correlation score for this guess. The window determines 8 input bits $x_0 \dots x_7$ to the filter function f_{20} (see Figure 10) while the remaining 12 inputs remain unknown. This correlation is taken as the ratio of those 2^{12} input values $x_8 \dots x_{19}$ that produce the correct keystream bit (ks_0). Furthermore, shifting our window further to the left allows the adversary to perform tests on multiple keystream bits ($ks_0 \dots ks_{15}$). Although, with every bit shift, the window becomes smaller as the leftmost bits will fall outside the LFSR, meaning that more input bits are unknown.

Definition 4.5 We define the single-bit correlation score as:

$$bit_score(x_0 \dots x_{n-1}, b) = \frac{\#(b = f_{20}(y_0 \dots y_{19}))}{2^{19-n}}$$

where $y_0 \dots y_{n-1} = x_0 \dots x_{n-1}$, $n < 20$ (at the first iteration of Step 3, $n=8$). We define the multiple-bit correlation score as:

$$score(x_0, ks_0) = bit_score(x_0, ks_0)$$

$$score(x_0 \dots x_{n-1}, ks_0 \dots ks_{n-1}) =$$

$$bit_score(x_0 \dots x_{n-1}, ks_{n-1}) * score(x_0 \dots x_{n-2}, ks_0 \dots ks_{n-2})$$

for $n < 20$.

The adversary will assign this guess the average score over all traces. Note that, so far this scoring computation is independent of the value iv as it happens before iv gets to have any influence on it (i.e. it is only XORed with unknown bits).

4. The adversary will now sort all guesses according to their score and store them in a table of fixed size, discarding the guesses with lowest scores when needed. Experiments show that a table of size 400,000 guesses is usually sufficient.
5. For each guess in the table, the adversary goes back to Step (1) and proceeds as before, except that she will now extend the window size by one (to size 17, ..., 32), guessing the next LFSR stream bit (a_{48}, \dots, a_{51}). The bigger window allows the adversary to test on an additional bit of keystream, giving her more meaningful correlation information each time. Special care needs to be taken at Step (3) while scoring multiple traces, since $a_{48} = k_{16+i} \oplus iv_i \oplus b_0$ (see Eq. 3) and the iv will be different in each trace. This is not a problem since in the previous Step (1) we had computed the corresponding keystream bit b_i , and iv_i is sent in clear. Therefore key bits k_{16+i} can be computed for $i \in [0, 31]$.

The power of this attack comes from using the window on the right of the LFSR to compute the necessary keystream bits to correct the internal state, while combining different traces and using the window on the left of the LFSR to get meaningful correlation information on multiple keystream bits.

4.5 Practical Results and Implications

We implemented the above correlation attack on a standard laptop. When executing this attack in practice, the first obstacle that an adversary faces is the fact that only the 10 Least Significant Bits (LSBs) of the counter ctr are sent over the air (see Figure 11), but the full 28-bit counter is used to initialize the cipher (both car and remote store the full counter). Therefore, the adversary needs to guess the remaining 18 bits. In practice, this is not a problem as it takes $2^{10} = 1024$ key pushes on the remote to have a carry to the Most Significant Bits (MSBs) and therefore this usually happens only a couple of times a year. In the worst case, the adversary has to repeat the above attack with increasing MSBs until she has the correct guess.

On average, our attack implementation recovers the cryptographic key in approximately 1 minute computation, requiring a few eavesdropped rolling codes (between 4 and 8). As mentioned, the adversary needs to repeat this computation for each guess of the 18 MSBs of the counter. For the vehicles we tested, the MSBs of the counter were usually between 0 and 10, which results in a total attack time of less than 10 min. Besides, there was a strong correlation between the vehicle’s age and the counter value, so educated guesses are also possible.

We verified our findings in practice by building a key emulator and then unlocking and locking the vehicles with newly generated rolling codes:

Manufacturer	Model	Year
Alfa Romeo	Giulietta	2010
Chevrolet	Cruze Hatchback	2012
Citroen	Nemo	2009
Dacia	Logan II	2012
Fiat	Punto	2016
Ford	Ka	2009, 2016
Lancia	Delta	2009
Mitsubishi	Colt	2004
Nissan	Micra	2006
Opel	Vectra	2008
Opel	Combo	2016
Peugeot	207	2010
Peugeot	Boxer	2016
Renault	Clio	2011
Renault	Master	2011

The vehicles in the above list are our own and also from colleagues and friends who volunteered. We furthermore found the following list of supported vehicles for an after-market universal remote control [19] that is presumably implementing the

Hitag2 RKE scheme: *Abarth 500, Punto Evo; Alfa Romeo Giulietta, Mito; Citroen Jumper, Nemo; Fiat 500, Bravo, Doblo, Ducato, Fiorino, Grande Punto, Panda, Punto Evo, Qubo; Dacia Duster; Ford Ka; Lancia Delta, Musa; Nissan Pathfinder, Navara, Note, Qashqai, X-Trail; Opel Corsa, Meriva, Zafira, Astra; Peugeot Boxer, Expert; and Renault Clio, Modus, Trafic, Twingo*. This list includes most of our tested vehicles. This would indicate that all vehicles mentioned in the list (although not practically tested by us) are vulnerable to the described attacks as well.

In contrast to the VW Group scheme, the vulnerabilities in the Hitag2 RKE system are caused by the cryptographically weak cipher, not a weak key distribution method. In consequence, even though it must be said that the correlation attack of Section 4.4 is devastating from a cryptographic point of view, the data complexity is slightly higher compared to the VW Group schemes, which can be broken with one single eavesdropped signal. The attack on Hitag2 requires at least four (not necessarily consecutive) rolling codes, i.e., the adversary has to be present for a longer period of time to capture signals for multiple key presses on the victim’s remote control.

However, to quickly obtain the required rolling codes, the adversary could selectively jam the signal during the final checksum byte (which is predictable). In this case, the vehicle ignores the rolling code, but the adversary nevertheless obtains the keystream. The victim would hence notice that the vehicle does not respond, and instinctively press the button repeatedly. After having received the fourth signal, the adversary stops jamming and the remote control operates normally from the victim’s point of view. However, the attacker has then collected the required amount of rolling codes to subsequently extract the cryptographic key. Hence, if the described behaviour is observed by a vehicle owner, it is an indication that an attack may be in progress.

5 Conclusion

Answering the original research question about the security of automotive RKE systems, the results of this paper show that major manufacturers have used insecure schemes over more than 20 years. Due to the widespread use of the analyzed systems, our findings have worldwide impact. Owners of affected vehicles should be aware that unlocking the doors of their car is much simpler than commonly assumed today. Both for the VW Group and the Hitag2 rolling code schemes, it is possible to clone the original remote control and gain unauthorized access to

the vehicle after eavesdropping one or a few rolling codes, respectively. The necessary equipment to receive and send rolling codes, for example SDRs like the USRP or HackRF and off-the-shelf RF modules like the TI Chronos smart watch, are widely available at low cost. The attacks are hence highly scalable and could be potentially carried out by an unskilled adversary. Since they are executed solely via the wireless interface, with at least the range of the original remote control (i.e., a few tens of meters), and leave no physical traces, they pose a severe threat in practice.

Security and Safety Implications The implications of our findings are manifold: Personal belongings left in a locked vehicle (as well as vehicle components like the infotainment system) could be stolen if a thief uses the vulnerabilities of the RKE system to unlock the vehicle after the owner has left. This approach is considerably more stealthy and harder to prevent than the currently known methods of theft (e.g., using physical force or jamming the rolling code). Moreover, since a valid rolling code usually disables the alarm system, the theft is more likely to remain undetected for a longer period of time. Common recommendations like “lock it or lose it” [25] or “verify that the vehicle has been successfully locked and the transmission has not been jammed” (blinking direction lights, sound) are hence no longer sufficient to effectively prevent theft. A successful attack on the RKE and anti-theft system would also enable or facilitate other crimes:

- theft of the vehicle itself by circumventing the immobilizer system (e.g. [32, 33]) or by programming a new key into the car via the OBD port with a suitable tool
- compromising the board computer of a modern vehicle [10, 20], which may even affect personal safety, e.g., by deactivating the brakes while switching on the wiping system in a bend
- inconspicuously placing an object or a person inside the car. The car could be locked again after the act
- on-the-road robbery, affecting the personal safety of the driver or passengers if they (incorrectly) assume that the vehicle is securely locked

Note that due to the long range of RKE systems it is technically feasible to eavesdrop the signals of all cars on a parking lot or at a car dealer by placing an eavesdropping device there overnight. Afterwards, all vulnerable cars could be opened by the adversary. Practical experiments suggest that the

receiving ranges can be substantially increased: The authors of [18] report eavesdropping of a 433 MHz RFID system, with technology comparable to RKE, from up to 1 km using low-cost equipment. Likewise, a large-scale DoS attack targeting VW Group cars would be possible with an automated approach—as a result, the RKE system of the vulnerable vehicle types would be deactivated for the respective remote control and VW Group would face increased demand for customer service, i.e., re-synchronizing remotes.

Legal Implications, Forensics, and Counter-measures It is unclear whether such attacks on the RKE scheme are currently carried out in the wild by criminals. However, there have been various media reports about unexplained theft from locked vehicles in the last years. The security issues described in this paper could explain such incidents. Note that we have analyzed further automotive RKE systems (with similar results regarding their (in)security), but due to the difficulty of responsible disclosure, cannot publish all results at this point.

As of today, even experts in car theft cases expressed the opinion that the alarm and electronic door locking systems of a car cannot be easily circumvented. From now on, they have to consider that special universal remote controls to bypass the security mechanisms might be used by criminals. In contrast to mechanical tools to open vehicles, such a device would leave no physical traces. Insurance companies may thus have to accept that certain car theft scenarios that have so far been regarded as insurance fraud (e.g. theft of personal belongings out of a locked car without physical traces) have, considering the results of this paper, a higher probability to be real. From a forensics point of view, the need to press the button of the remote control more than once in order to unlock the vehicle is an indicator that the car might have been accessed by a criminal. For VW Group vehicles, the “blocking” of a remote control should be regarded as suspicious as well. However, there are other causes for such behaviour, e.g., short range due to an empty battery of the remote control or environmental RF noise.

While the vulnerabilities of the VW Group system are due to worldwide master keys, Hitag2-based systems suffer from weaknesses in the cipher itself. Hence, in conclusion, for a “good” RKE system, both secure cryptographic algorithms (e.g., AES) and secure key distribution are necessary. Techniques to solve the security problems discovered in this paper are widely available [23]. Atmel has created an open RKE protocol design [5], which is pub-

lished in full detail. The security of their design was scrutinized by Tillich et al. in [29]. It is now up to vehicle manufacturers to securely implement such next-generation RKE schemes.

For owners of affected vehicles, as a temporary countermeasure in cases where valuable items are left in the vehicle, we can unfortunately only recommend to stop using or disable/remove the RKE part of the car key and fall back to the mechanical lock: **Lock It or Lose It? Remove It!**

6 Responsible Disclosure

Regarding the vulnerabilities of VW Group systems, we contacted VW Group first in November 2015. We discussed our findings in a meeting with VW Group and an affected sub-contractor in February 2016, before submitting the paper. VW Group received a draft version of this paper and the final version. VW Group acknowledged the vulnerabilities. As mentioned in the paper, we agreed to leave out amongst others the following details: cryptographic keys, part numbers of vulnerable ECUs, and the used programming devices and details about the reverse-engineering process.

For Hitag2, we notified NXP in January 2016. NXP received a version of this paper before submission. We would like to mention that the fact that Hitag2 is cryptographically broken has been publicly known for several years and NXP has already informed their customers back in 2012. We would further like to highlight that for several years, NXP offers newer, AES-based RKE ICs that are not affected by the vulnerabilities described in this paper. Furthermore, many car manufacturers have already started using the more secure chips for new designs.

OBLIVP2P: An Oblivious Peer-to-Peer Content Sharing System

Abstract

Peer-to-peer (P2P) systems are predominantly used to distribute trust, increase availability and improve performance. A number of content-sharing P2P systems, for file-sharing applications (e.g., BitTorrent and Storj) and more recent peer-assisted CDNs (e.g., Akamai Netsession), are finding wide deployment. A major security concern with content-sharing P2P systems is the risk of long-term *traffic analysis* — a widely accepted challenge with few known solutions.

In this paper, we propose a new approach to protecting against persistent, global traffic analysis in P2P content-sharing systems. Our approach advocates for hiding data access patterns, making P2P systems *oblivious*. We propose OBLIVP2P— a construction for a scalable distributed ORAM protocol, usable in a real P2P setting. Our protocol achieves the following results. First, we show that our construction retains the (linear) scalability of the original P2P network w.r.t the number of peers. Second, our experiments simulating about 16,384 peers on 15 Deterlab nodes can process up to 7 requests of 512KB each per second, suggesting usability in moderately latency-sensitive applications as-is. The bottlenecks remaining are purely computational (not bandwidth). Third, our experiments confirm that in our construction, no centralized infrastructure is a bottleneck — essentially, ensuring that the network and computational overheads can be completely offloaded to the P2P network. Finally, our construction is highly parallelizable, which implies that remaining computational bottlenecks can be drastically reduced if OBLIVP2P is deployed on a network with many real machines.

1 Introduction

Content sharing peer-to-peer (P2P) systems, especially P2P file-sharing applications such as BitTorrent [1], Storj [2] and Freenet [3] are popular among users for

sharing files on the Internet. More recently, peer-assisted CDNs such as Akamai Netsession [4] and Squirrel [5] are gaining wide adoption to offload web CDN traffic to clients. The convenient access to various resources attract millions of users to join P2P networks, e.g., BitTorrent has over 150 million active users per month [6] and its file-sharing service contributes 3.35% of all worldwide bandwidth [7]. However, the majority of such P2P applications are susceptible to long-term traffic analysis through global monitoring; especially, analyzing the *pattern* of communication between a sender and a receiver to infer information about the users. For example, many copyright enforcement organizations such as IFPI, RIAA, MPAA, government agencies like NSA and ISP's are reported to globally monitor BitTorrent traffic to identify illegal actors. Monitoring of BitTorrent traffic has shown to reveal the data requested and sent by the peers in the network [8–10]. Unfortunately, while detecting copyright infringements is useful, the same global monitoring is applicable to *any* user of the P2P network, and can therefore collect benign users' data. Thus, users of such P2P systems are at a risk of leaking private information such as the resources they upload or download.

To hide their online traces, users today employ anonymous networks as a solution to conceal their digital identities or data access habits. Currently, anonymous networks include Mix networks [11–13], and Onion routing/Tor-based systems [14–17], as well as other P2P anonymity systems [18–23]. Such systems allow the user to be *anonymous*, so that the user is unidentifiable within a set of users [24].

Although above solutions provide an anonymity guarantee, they are vulnerable to long-term traffic pattern analysis attacks, which is an important threat for P2P systems like BitTorrent [25–30]. Researchers have demonstrated attacks targeting BitTorrent users on top of Tor that reveal information related to the resources uploaded or downloaded [31, 32]. Such attacks raise the question - *is anonymizing users the right defense against traffic*

*Lead authors are alphabetically ordered.

pattern analysis in P2P content sharing systems?

In this paper, we investigate a new approach to solve the problem of persistent analysis of data communication patterns. We advocate that data / resource access pattern hiding is an important and necessary step to thwart leakage of users data in P2P systems. To this end, we present a first candidate solution, OBLIVP2P—an oblivious protocol for peer-to-peer content sharing systems. Hiding data access patterns or making them *oblivious* unlinks user’s identity from her online traces, thereby defending against long-term traffic monitoring.

1.1 Approach

For hiding data access patterns between a trusted CPU and an untrusted memory, Goldreich and Ostrovsky proposed the concept of an Oblivious RAM (ORAM) [33]. We envision providing similar obliviousness guarantees in P2P systems, and therefore select ORAM as a starting point for our solution. To the best of our knowledge, OBLIVP2P is the first work that adapts ORAM to accesses in a P2P setting. However, directly employing ORAM to hide access patterns in a P2P system is challenging. We outline two key challenges in designing an oblivious and a scalable P2P protocol using ORAM.

Obliviousness. The first challenge arises due to the difference in the setting of a standard ORAM as compared to a P2P content sharing system. Classical ORAM solutions consists of a single client which securely accesses an untrusted storage (server), wherein the client is eventually the owner and the only user of the data in the memory. In contrast, P2P systems consist of a set of trusted trackers managing the network, and multiple data owners (peers) in the network. Each peer acts both as a client as well as a server in the network i.e., a peer can either request for a data or respond to other peer’s request with the data stored on its machine. Hence, adversarial peers present in the network can see the plaintext and learn the data requested by other peers, a threat that does not exists in the traditional ORAM model where only encrypted data is seen by the servers.

Scalability. The second challenge lies in seeking an oblivious P2P system that 1) the throughput scales linearly with the number of peers in the network, 2) has no centralized bottleneck and 3) can be parallelized with an overall acceptable throughput. In standard ORAM solutions, the (possibly distributed) server is responsible for serving all the data access requests from a client one-by-one. In contrast, P2P systems operate on a large-scale with multiple peers (clients) requesting resources from each other simultaneously without overloading a particular entity. To retain scalability of P2P systems, it is necessary to ensure that requests can be served by dis-

tributing the communication and computation overhead.

Solution Overview. We start with a toy construction (OBLIVP2P-0) which directly adapts ORAM to a P2P setting, and then present our main contribution which is a more efficient solution (OBLIVP2P-1).

Centralized Protocol (OBLIVP2P-0): Our centralized protocol or OBLIVP2P-0, is a direct adaptation of ORAM in a P2P system. The peers in the network behave both like distributed storage servers as well as clients. They request a centralized, trusted tracker to access a particular resource. The tracker performs all the ORAM operations to fetch the resource from the network and returns it to the requesting peer. However, this variant of OBLIVP2P protocol has limited scalability as it assigns heavy computation to the tracker, making it a bottleneck.

Distributed Protocol (OBLIVP2P-1): As our main contribution, we present OBLIVP2P-1 which provides both obliviousness and scalability properties in a tracker-based P2P system. To attain scalability, the key idea is to avoid any single entity (say the tracker) as a bottleneck. This requires distributing all the ORAM operations for fetching and sharing of resources among the peers in the network, while still maintaining obliviousness guarantees. To realize such a distributed protocol, our main building block, which we call *Oblivious Selection* (OblivSel), is a novel combination of private information retrieval with recent advances in ORAM. Oblivious Selection gives us a scalable way to securely distribute the load of the tracker. Our construction is proven secure in the honest-but-curious adversary model. Constructions and proofs for arbitrarily malicious fraction of peers is slated for future work.

1.2 System and Results

We provide a prototype implementation of both OBLIVP2P-0 and OBLIVP2P-1 protocols in Python. Our source code is available online [34]. We experimentally evaluate our implementation on DeterLab testbed with 15 servers simulating up to 2^{14} peers in the network. Our experiments demonstrate that OBLIVP2P-0 is limited in scalability with the tracker as the main bottleneck. The throughput for OBLIVP2P-1, in contrast, scales linearly with increase in the number of peers in the network. It attains an overall throughput of 3.19 MBps for a network of 2^{14} peers that corresponds to 7 requests per second for a block size of 512 KB. By design, OBLIVP2P-1 is embarrassingly parallelizable over the computational capacity available in a real P2P network. Further, our protocol exhibits no bottleneck on a single entity in experiment, thereby confirming that the network and the computational overhead can be completely offloaded to

the P2P network.

Contributions. We summarize our contributions below:

- **Problem Formulation.** We formulate the problem of making data access pattern oblivious in P2P systems. This is a necessary and important step in building defenses against long-term traffic analysis.
- **New Protocols.** We propose OBLIVP2P—a first candidate for an oblivious peer-to-peer protocol in content sharing systems. Our main building block is a primitive which we refer to as oblivious selection that makes a novel use of recent advances in Oblivious RAM combined with private information retrieval techniques.
- **System Implementation & Evaluation.** Our prototype implementation is available online [34]. We experimentally evaluate our protocol to measure the overall throughput of our system, latency for accessing resources and the impact of optimizations on the system throughput.

2 Problem

Many P2P applications are not designed with security in mind, making them vulnerable to traffic pattern analysis. We consider BitTorrent as our primary case study. However, the problem we discuss is broadly applicable to other P2P file sharing systems like Gnutella [35], Freenet [3] and Storj [2] or peer-assisted CDNs such as Akamai Netsession [4], Squirrel [5] and APAC [36].

2.1 BitTorrent: A P2P Protocol

The BitTorrent protocol allows sharing of large files between users by dividing it into blocks and distributing it among the peers. It has a dynamic network, made up of a number of nodes that join the network and volunteer themselves as peers. Each peer holds data blocks in its local storage and acts both as a client / requester and server / sender simultaneously. There exists a tracker that tracks which peers are downloading / uploading which file and saves the state of the network. It keeps information regarding the position or the IP addresses of peers holding each resource but does not store any real data blocks. A peer requests the tracker for a particular resource and the tracker responds with a set of IP addresses of peers holding the resource. The requester then communicates with these IP addresses to download the blocks of the desired resource. The peers interact with each other using a P2P protocol¹. The requester concatenates all the blocks received to construct the entire resource.

¹We want to emphasize that there are other models of P2P networks without tracker based on DHT that we are not addressing in this work.

2.2 Threat Model

In our threat model, we consider the tracker as a trusted party and peers as passive honest-but-curious adversaries i.e., the peers are expected to correctly follow the protocol without deviating from it to learn any extra information. In P2P systems including CDNs (content delivery networks) and BitTorrent, passive monitoring is already a significant threat on its own. We consider the following two types of adversaries:

Global Passive Adversary. Since BitTorrent traffic is public, there exist tools like Global BitTorrent Monitor [37] or BitStalker [38] that support accurate and efficient monitoring of BitTorrent. Previous research has shown that any BitTorrent user can be logged within a span of 3 hours, revealing his digital identity and the content downloaded [39]. Further, the adversary can log the communication history of the network traffic to perform offline analysis at a later stage. Hence, we consider it rational to assume the presence of a global adversary with the capability to observe long term traffic in the network.

Passive Colluding Peers. Some of the peers in the P2P network can be controlled by the global adversary. They can further collude to exchange data with other adversarial peers in the system. While colluding these “sybil” peers can share information such as observed / served requests and the contents stored at their local storage. Their goal is to collectively glean information about other peers in the network. A formal definition of passive colluding peers is as follows:

Definition 2.1. (*Passive Colluding peers*) We say that a peer P_i passively colludes with peer P_j if both peers share their views without any modification, where a view consists of: a transcript of the sequence of all accesses made by P_i , a partial or total copy of peer’s private storage, and a transcript of the access pattern induced by the sequence of accesses. We denote by $\mathcal{C}(P_i)$ the set of colluding peers with P_i .

Note that from the above definition, we have a symmetric relation such that if $P_i \in \mathcal{C}(P_j)$ for $i \neq j$, then $P_j \in \mathcal{C}(P_i)$. It follows that if $P_i \notin \mathcal{C}(P_j)$, then $\mathcal{C}(P_i)$ and $\mathcal{C}(P_j)$ are disjoint.

Our protocol tolerates a fraction of c adversarial peers in the network such that $c \in O(N^\varepsilon)$, where N is the total number of peers in the network and $\varepsilon < 1$. Although the P2P network undergoes churn, we assume the fraction of adversarial peers c remains within the asymptotic bounds of $O(N^\varepsilon)$. Our choice of the upper bound for c ensures an exponentially small advantage to the attacker; for an application that can tolerate higher attacker’s advantage, a larger malicious fraction can be allowed.

2.3 Insufficiency of Existing Approaches

Existing techniques propose anonymizing users to prevent traffic pattern analysis attacks. However, these solutions are not sufficient to protect against a global adversary with long term access to communication patterns.

Unlinkability Techniques (e.g. Mixnet). Existing anonymity approaches “unlink” the sender from the receiver (see survey [40]). Chaum proposed the first anonymous network called mix network [11], which shuffles messages from multiple senders using a chain of proxy servers and sends them to the receiver. Another recent system called Riposte guarantees traffic analysis resistance by unlinking a sender from its message [41]. However, all these systems are prone to attack if an adversary can observe multiple request rounds in the network.

For example, consider that *Alice* continuously communicates with *Bob* using a mixnet service. A global adversary observes this communication for a couple of rounds, and records the recipient set in each round. Let the senders’ set consists of $S_1 = \{Alice, a, b, c\}$ and $S_2 = \{a', b', Alice, c'\}$, and the recipients’ set consists of $R_1 = \{x, y, z, Bob\}$ and $R_2 = \{x', y', Bob, z'\}$ for rounds 1 and 2 respectively. The attacker can then infer the link between sender and receiver by intersecting $S_1 \cap S_2 = \{Alice\}$ and $R_1 \cap R_2 = \{Bob\}$. The attacker learns that *Alice* is communicating with *Bob*, and thus breaks the unlinkability. This attack is called the *intersection, hitting set* or *statistical disclosure attack* [25, 26]. Overall, one time unlinkability is not a sufficient level of defense when the adversary can observe traffic for arbitrary rounds.

Path Non-Correlation (e.g. Onion routing). Another approach for guaranteeing anonymity is to route the message from a path such that the sender and the receiver cannot be correlated by a subset of passive adversarial nodes. Onion-routing based systems like Tor enable anonymous communication by using a sequence of relays as intermediate nodes (called circuit) to forward traffic [15, 42]. However, Tor cannot provide sender anonymity when the attacker can see both the ends of the communication, or if a global adversary observes the entire network. Hence, if an attacker controls the entry and the exit peer then the adversarial peers can determine the recipient identity with which the initiator peer is communicating [27–30]. This is a well-known attack called the *end-to-end correlation attack* or *traffic confirmation attack* [43, 44].

2.4 Problem Statement

Our goal is to design a P2P protocol that prevents linking a user to a requested resource using traffic pattern analysis. Section 2.3 shows how previous anonymity based

solutions are susceptible to attacks in our threat model. In this work, we address this problem from a new viewpoint, by making the communication pattern oblivious in the network. We advocate that hiding data / resource access pattern is a necessary and important step in designing traffic pattern analysis resistant P2P systems.

In a P2P system such as BitTorrent, a user accesses a particular resource by either downloading (Fetch) or uploading (Upload) it to the network. We propose to build an oblivious P2P content sharing protocol (OBLIVP2P) that hides the data access patterns of users in the network. We formally define an Oblivious P2P protocol as follows:

Definition 2.2. (Oblivious P2P): Let (P_1, \dots, P_n) and \mathcal{T} be respectively a set of n peers and a tracker in a P2P system. We denote by $\vec{x}_i^j = (x_{i,1}, \dots, x_{i,M})$ a sequence of M accesses made by peer P_i such that $x_{i,j} = (op_{i,j}, fid_{i,j}, file_{i,j})$ where $op_{i,j} = \{\text{Upload}, \text{Fetch}\}$, $fid_{i,j}$ is the filename being accessed, and $file_{i,j}$ is the set of blocks being written in the network if $op_{i,j} = \text{Upload}$.

We denote by $\mathcal{A}(\vec{x}_i^j)$ the access pattern induced by the access sequence \vec{x}_i^j of peer P_i . The access pattern is composed of the memory arrays of all peers accessed while running the sequence \vec{x}_i^j . We say that a P2P is oblivious if for any two equal-length access sequences \vec{x}_i^j and \vec{x}_j^i by two peers P_i and P_j such that

- $P_j \notin \mathcal{C}(P_i)$
- $\forall k \in [M] : x_{i,k} = \text{Fetch} \Leftrightarrow x_{j,k} = \text{Fetch} \wedge x_{i,k} = \text{Upload} \Leftrightarrow x_{j,k} = \text{Upload}$
- $\forall k \in [M], |file_{i,k}| = |file_{j,k}|$

are indistinguishable for all probabilistic poly-time adversaries except for $\mathcal{C}(P_i)$, $\mathcal{C}(P_j)$, and tracker \mathcal{T} .

Scope. OBLIVP2P guarantees resistance against persistent communication traffic analysis i.e., observing the path of communication and thereby linking a sender to a particular resource. OBLIVP2P does not prevent against:

a) *Active Tampering:* An adversarial peer can tamper, alter and deviate from the protocol to learn extra information. Admittedly, this can have an impact on obliviousness, correctness and availability of the network.

b) *Side Channels:* An adversary can monitor any peer in the system to infer its usage’s habits via side channels: the number of requests, time of activity, and total number of uploads. In addition, an adversary can always infer the total file size that any peer is downloading or uploading to the P2P network. Literature shows that some attacks such as website fingerprinting can be based on the length of file requested by peers [45].

c) *Orthogonal Attacks:* Other attacks in P2P file sharing

systems consist of threats such as poisoning of files by uploading corrupted, fake or misleading content [46] or denial of service attacks [47]. However, these attacks do not focus on learning private information about the peers and hence are orthogonal to our problem.

Admittedly, our assumption about honest-but-curious is less than ideal and simplifies analysis. We hope that our construction spurs future work on tackling the active or arbitrary malicious adversaries. Emerging trusted computing primitives (e.g., Intel SGX [48]) or cryptographic measures [49] are promising directions to investigate. Lastly, OBLIVP2P should not be confused with traditional anonymous systems where a user is anonymous among a set of users. OBLIVP2P does not guarantee sender or receiver anonymity, but hides data access patterns of the users.

3 Our Approach

As a defense against traffic pattern analysis, we guarantee oblivious access patterns in P2P systems. We consider Oblivious RAM as a starting point.

3.1 Background: Tree-Based ORAM

Oblivious RAM, introduced by Goldreich and Ostrovsky [33], is a cryptographic primitive that prevents an adversary from inferring any information via the memory access pattern. Tree-based ORAM introduced by Shi et al. [50] offers a poly-logarithmic overhead which is further reduced due to improvements suggested in the follow up works [51–56]. In particular, we use Ring ORAM, [52], one of the latest improvements for tree-based ORAM in our protocol. In Ring ORAM, to store N data blocks, the memory is organized in a (roughly) $\log N$ -height full binary tree, where each node contains z real blocks and s dummy blocks. Whenever a block is accessed in the tree, it is associated to a new randomly selected leaf identifier called, tag. The client stores this association in a position map PosMap along with a private storage (stash). To read and write to the untrusted memory, the client performs an Access followed by an Evict operation described at a high level as follows:

- **Access(adr):** Given address adr , the client fetches the leaf identifier tag from PosMap. Given tag, the client downloads one block per every node in the path $\mathcal{P}(tag)$ that starts from the root and ends with the leaf tag. The client decrypts the retrieved blocks, and retrieves the desired block. This block is appended to the stash.
- **Evict(A, v):** After A accesses, the client selects a path $\mathcal{P}(v)$ based on a deterministic reverse lexicographic order, downloads the path, decrypts it and appends it to the stash. The client runs the

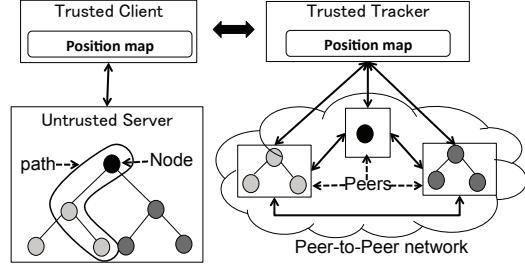

Figure 1: Mapping of a client / server ORAM model to a P2P system

least common ancestor algorithm to sort the blocks as in [51]. Finally, the client freshly encrypts the blocks and writes them back to the nodes in the path.

The stash is upper bounded by $O(\log N)$. The overall bandwidth may reach $\simeq 2.5 \log N$, for N blocks stored. In Ring ORAM, eviction happens periodically after a controllable parameter $A = 2z$ accesses where z is the number of blocks in each bucket [52].

3.2 Mapping an ORAM to a P2P setting

We start from a traditional ORAM in a client / server model where the client is trusted and the server is not, and simulate it on a tracker / peers setting. In particular, we consider that the server’s memory is organized in a tree structure, and we delegate every node in the tree to a peer. That is, a full binary tree of N leaves is now distributed among $N_p = 2N - 1$ peers (refer to Figure 1). In practice, many nodes can be delegated to many peers based on the storage capacity of each peer.

Contrary to the client / server setting where the client is the only one who can fetch, modify or add a block, in P2P, the peers can also request and add new blocks. In addition, the peers are volatile, i.e., many peers can join or leave the network. Moreover, from a security perspective, the network peers do not trust each other, and an adversarial peer can always be interested in finding out the block being retrieved by other peers. To avoid this, the tracker instructs the peers in a P2P system to save encrypted blocks in their local memory (different from the conventional BitTorrent model). Our construction ensures that the peer neither has the keys necessary to decrypt its storage nor can it collude with other adversarial peers to recover it. In this setting, we first present a strawman approach that guarantees our security goal but is restricted in terms of scalability.

3.3 OBLIVP2P-0 : Centralized Protocol

Almost all ORAM constructions are in a client / server setting and not designed for a P2P setting. A simple approach is to map the role of the trusted client in an

ORAM setting (refer to Figure 1) to the trusted tracker in a P2P system. The client in ORAM is simulated by the trusted tracker (storing the position map, private keys and the stash) and the server by the untrusted peers (storing the encrypted blocks). With such a mapping from an ORAM model to a P2P setting, a peer (initiator) can request for a resource to the tracker. To access a particular resource, the tracker fetches the blocks from a path in the tree and decrypts them to get the desired block. It then returns the requested resource to the initiator peer. This simple *plug-&-play* construction satisfies all our P2P security requirements.

In OBLIVP2P-0, the trusted tracker behaves as the client in traditional ORAM model. Whenever a peer requests a block, the tracker performs all the ORAM access work, and then sends the plaintext block to the initiator. The tracker downloads the path composed of a logarithmic number of nodes, writes back the path with a fresh re-encryption before routing the block to the initiator. As long as the tracker is trusted, this ensures the obliviousness property of peers’ accesses, as stated by definition 2.2.

Upload algorithm. To upload a file, the peer divides it into data blocks and sends the blocks to the tracker. The tracker appends the block to the stash stored locally while generating new random tags. The tracker updates accordingly TagMap, and FileMap (refer to Table 1).

Fetch algorithm. To fetch a file, the peer sends the file identifier, as an instance a filename, to the tracker. The tracker fetches from the FileMap and TagMap the corresponding blocks and sends requests to the corresponding peers to retrieve the blocks, following the Ring ORAM Access protocol. For every retrieved block, the tracker sends the plaintext block to the requesting peer.

Sync algorithm. The synchronization happens after every $A \simeq 2z$ accesses [52] (e.g., nearly 8 accesses) at which point the tracker evicts the stash.

Tracker as Bottleneck. In OBLIVP2P-0, the tracker has to transmit / encrypt a logarithmic number of blocks on every access. The tracker requires a bandwidth of $O(\log N \cdot B)$ where B is the block size and the computation cost of $O(\log N \cdot E)$ where E is time for encrypting / decrypting a block. Moreover, our evaluation in Section 5 shows that the eviction step is network-intensive. In a P2P setting with large number of accesses per second, the tracker creates a bottleneck in the network.

3.4 OBLIVP2P-0 Analysis

Our analysis follow from Ring ORAM construction. To access a block the tracker has to transmit $\sim 2.5 \log N \cdot B$ bits per access. During a block access or eviction, any peer at any time transmits $O(B)$ bits. The tracker’s main

computational time consists of decrypting and encrypting the stash. Since the stash has a size of $O(\log N)$ blocks, the tracker does $O(\log N)$ blocks encryption/decryption. In terms of storage, every peer has $(z + s)$ blocks to store, where z is number of real blocks and s is a parameter for dummy blocks. From a security perspective, it is clear that if there are two sequences verifying the constraints of Definition 2.2, a malicious peer monitoring their access pattern cannot infer the retrieved blocks, since after every access the block is assigned to a random path in the simulated ORAM.

4 OBLIVP2P-1: Distributed Protocol

In this section, we describe our main contribution, OBLIVP2P-1 protocol that provides both security and scalability properties. In designing such a protocol, our main goal is to avoid any bottleneck on the tracker i.e., none of the real blocks should route through the tracker for performing an access or evict operations of ORAM. We outline the challenges in achieving this property while still retaining the obliviousness in the network.

4.1 Challenges

First Attempt. A first attempt to reduce tracker’s overhead is to modify OBLIVP2P-0 such that the heavy computation of fetching the path of a tree and decrypting the correct block is offloaded to the initiator peer. On getting a resource request from a peer, the tracker simply sends information to the peer that includes the path of the tree to fetch, the exact position of the requested block and the key to decrypt it. However, unlike standard ORAM, the peer in our model is not trusted. Giving away the exact position of the block to the initiator peer leaks additional information about the requested resource in our model, as we explain next.

Recall that in a tree-based ORAM, blocks are distributed in the tree such that the recently accessed blocks remain in the top of the tree. In fact, after every eviction the blocks in the path are pushed down as far as possible from the root of the tree. As an instance, after N deterministic evictions, all blocks that were never accessed are (very likely) in the leaves. Conversely, consider that an adversarial peer makes two back-to-back accesses. In the first access, it retrieves a block from the top of the tree while in the second access it retrieves a block from a leaf. The adversarial peer (initiator) learns that the first block is a popular resource and is requested before by other peers while the second resource is a less frequently requested resource. This is a well known issue in tree-based ORAM, and is recently formulated as the *block history* problem [57]. Disclosing the block position, while hiding the scheme obliviousness requires to

address the block history challenge in ORAM. Unfortunately, an ORAM hides the block history only if the communication spent to access a block dominates the number of blocks stored in the entire ORAM. This would be asymptotically equivalent to downloading the entire ORAM tree from all the peers. We refer readers to [57] for more details.

Second Attempt. Our second attempt is a protocol that selects a block while *hiding* the block position from the adversary i.e., to hide which node on the path holds the requested block. Note that in a tree-based ORAM, disclosing the path does not break obliviousness, but leaking which node on the path holds the requested block is a source of leakage. One trick is to introduce a circuit, a set of peers from the P2P network, that will simulate the operations of a mixnet. That is, the peers holding the path of the tree send their content to the first peer in the circuit, who then applies a random permutation, adds a new encryption layer, and sends the permuted path to the second peer and so on. The tracker, who knows all the permutations, can send the final block position (unlinked from original position) to the initiator, along with the keys to decrypt the block. The mixing guarantees that the initiator does not learn the actual position of the block. We note that mixing used here is for only one accessed “path”, which is already randomized by ORAM. Hence, it is not susceptible to intersection attack discussed in Section 2.3. Finally, the initiator then peels off all layers of the desired block to output the plaintext block.

However, there is an important caveat remaining in using this method. Note that the initiator has the keys to peel off all the layers of encryption and hence it has access to the same encrypted block fetched from the path in the tree. Thus, it can determine which peer’s encrypted block was finally selected as the output of the mixnet. Hence, delegating the keys to the initiator boils down to giving her the block position. One might think of eliminating this issue by routing the block through the tracker to peel off all layers, but this will just make the tracker again a bottleneck.

So far, our attempts have shown limitations, but pointed out that there is a need to formally define the desired property. Considering a tracker, the initiator, and the peers holding the path, we seek a primitive that given a set of encrypted blocks, the initiator can get the desired plaintext block, while no entity can infer the block position but the tracker. We refer to this primitive as *Oblivious Selection* (*OblivSel*) and describe it next.

4.2 Oblivious Selection

4.2.1 Definitions

We define *OblivSel* and its properties as follows:

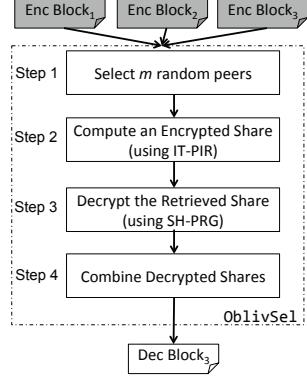

Figure 2: Oblivious Selection protocol using IT-PIR and Seed Homomorphic PRG as base primitives

Definition 4.1. (*Oblivious Selection*). *OblivSel* is a tuple of two probabilistic algorithms (*Gen*, *Select*) such that:

- $(\vec{\sigma}, \vec{r}) \leftarrow \text{Gen}(k, pos)$: a probabilistic algorithm run by the tracker, takes as input a key k and the block position pos , picks uniformly at random m peers (P_1, \dots, P_m) , and outputs $(\vec{\sigma}, \vec{r})$ where $\vec{\sigma} = \{\sigma_1, \dots, \sigma_m\}$ and $\vec{r} = \{r_1, \dots, r_m\}$ such that (σ_i, r_i) is given to the i th peer P_i .
- $\Delta \leftarrow \text{Select}(\vec{\sigma}, \vec{r}, \text{Enc}(k_1, \text{block}_1), \dots, \text{Enc}(k_L, \text{block}_L))$: a probabilistic algorithm run by m peers, takes as input $\vec{\sigma}$, \vec{r} , and a set of encrypted blocks $\text{Enc}(k_i, \text{block}_i)$, for $i \in [L]$, and outputs the value Δ .

Definition 4.2. *OblivSel*, is *correct*, if

$$\Pr[\forall pos \in [L], k \in \{0, 1\}^\lambda, (\vec{\sigma}, \vec{r}) \leftarrow \text{Gen}(k, pos); \Delta \leftarrow \text{Select}(\vec{\sigma}, \vec{r}, \text{Enc}(k_1, \text{block}_1), \dots, \text{Enc}(k_L, \text{block}_L)); \Delta = \text{Dec}(k, \text{Enc}(k_{pos}, \text{block}_{pos}))] = 1$$

For instance, if (Enc, Dec) is a private key encryption, *OblivSel* returns a decrypted block when the key given as input to the *Gen* function is the same as the private key of the block i.e., $\Delta = \text{block}_{pos}$ if $k = k_{pos}$.

Definition 4.3. (*Position Hiding*). We say that *OblivSel* is a position hiding protocol if for all probabilistic polynomial time global adversaries, including the initiator and the m peers, guess the position of the block pos with a negligible advantage in the implicit security parameter.

4.2.2 OblivSel Overview

The intuition for constructing *OblivSel* stems from the fact that the tracker cannot give the position or private key of the desired block to the peers in the network.

To privately select a block from the path without leaking its position, we propose to use an existing cryptographic primitive, called information-theoretical private

Structure	Mapping	Purpose
FileMap	file id fid <u>to</u> block addresses $\{\text{adr}_i\}_{i \in [\frac{f}{B}]}$	Blocks identification
TagMap	block address adr <u>to</u> tag $\overset{\$}{\leftarrow} [N_B]$	Path identification
NetMap	peer id pid <u>to</u> network info $(\text{IP}, \text{port}) \in \{0, 1\}^{128+16}$	Network representation
PosMap	block address adr <u>to</u> path and bucket position $\text{pos} \in [N_p] \times [L \cdot z + \text{stash}]$	Block exact localization
KeyMap	block address adr <u>to</u> key value $k \overset{\$}{\leftarrow} \mathbb{Z}_q$	Input of key block generation
StashList	peers' identifiers $\{\text{pid}_i\}_{i \in [\text{stash}]}$	Stash localization

Table 1: Various meta-information contained in the state s , for OBLIVP2P-0 and OBLIVP2P-1. B is the block size in bits, N_p the number of peers, N_B number of blocks, L the path length, and z the bucket size.

information retrieval (IT-PIR) [58]. IT-PIR requires a *linear* computation proportional to the data size that makes it expensive to use for real time settings. However, note that in our setting, we want to obliviously select a block from a logarithmic number of blocks (i.e., a path of the tree). Thus, applying IT-PIR over tree-based ORAM comes with significant computational improvement, hence making it practical to use in our protocol. The high level idea is to apply IT-PIR primitive only on one path since the obliviousness is already guaranteed by the underlined tree-based ORAM construction.

Figure 2 shows the steps involved in our OblivSel primitive. As a first step, the tracker randomly samples m peers from the network. For a bounded number of colluding adversarial peers in the system, this sample will contain at least one honest peer with high probability. The blocks of the path are fetched by all of the m peers. Each of the m peers then locally computes an encrypted share of the desired block using IT-PIR from the set of input blocks. Note that the tracker must not download the shares or it will violate our scalability requirement. On the other hand, we require to decrypt the block without giving away the private key to the network's peers. For this purpose, we make use of a second cryptographic primitive — a seed homomorphic pseudo-random generator (SH-PRG) [59]. The tracker generates a valid key share for each of the m peers to be used as seeds to the PRG function. Each peer decrypts (or unblinds) its encrypted share using its own key share such that the combination of decrypted shares results in a valid decryption of the original encrypted block in the tree. This property is ensured by SH-PRG and explained in detail in Section 4.2.3. Finally, each peer submits its decrypted share to the initiator peer who combines them to get the desired plaintext block. The colluding peers cannot recover the private key or the encrypted block since there is at least one honest peer who does not disclose its private information. This solves the issues raised in our second attempt.

Remark. OblivSel primitive can be used as a black box

Algorithm 1: IT-PIR protocol by Chor et al. [58]

```

1  $(r_1, \dots, r_m) \leftarrow \text{Query}(q, L, pos)$ 
    • randomly generate  $m - 1$  random vectors such that  $r_i \overset{\$}{\leftarrow} Z_q^L$ 
    • compute  $r_m$  such that for all  $j \in [L] \setminus \{pos\}$ , set
       $r_{m,j} = -\sum_{k=1}^{m-1} r_{k,j}$ , otherwise,  $r_{m,pos} = 1 - \sum_{k=1}^{m-1} r_{k,j}$ 
 $R_i \leftarrow \text{Compute}(r_i, DB)$ 
    • parse database such as  $DB = (\text{block}_1, \dots, \text{block}_L)$ 
    • compute  $R_i = \sum_{j=1}^L r_{i,j} \text{Block}_j$ 
 $\text{block}_{pos} \leftarrow \text{Recover}(R_1, \dots, R_m)$ : compute  $\text{block}_{pos} = \sum_{j=1}^m R_j$ 

```

in different settings such as distributed ORAMs to decrease the communication overhead. We further show in Section 4.2.4 that OblivSel is highly parallelizable and can leverage peers in the network such that the computation takes constant time.

4.2.3 Base Primitives

Information-theoretic PIR. Information-theoretic private information retrieval (IT-PIR) [58] is a cryptographic primitive that performs oblivious read operations while requiring multiple servers $m \geq 2$. In the following, we present the details of one of the first constructions of IT-PIR by Chor et al. [58] which is secure even when $m - 1$ among m servers collude passively, i.e., the servers collude in order to recover the retrieved block while not altering the protocol. An IT-PIR is a tuple of possibly randomized algorithms $\text{IT-PIR} = (\text{Query}, \text{Compute}, \text{Recover})$. Query takes as an input the block position pos to be retrieved, and outputs an IT-PIR query for m servers. Compute runs independently by every server, takes as input the corresponding IT-PIR query and outputs a share. Recover takes as inputs all shares output by all m servers, and outputs the plaintext block. We give the construction in Algorithm 1.

Seed homomorphic PRG (SH-PRG). A seed homomorphic PRG, G , is a pseudo-random generator over algebraic group with the additional property that if given

Algorithm 2: OblivSel with seed-homomorphic PRG

```

1  $(\vec{\sigma}, \vec{r}) \leftarrow \text{Gen}(k, pos)$ 
    • set  $\vec{r} = (r_1, \dots, r_m) \leftarrow \text{IT-PIR.Query}(q, L, pos)$ ;
    • set  $\vec{\sigma} = (\sigma_1, \dots, \sigma_m)$ , s.t.,  $(\sigma_1, \dots, \sigma_{m-1}) \xleftarrow{S} S^{m-1}$ , and
       $\sigma_m = k - \sum_{i=1}^{m-1} \sigma_i$ ;
    block  $\leftarrow \text{Select}(\vec{\sigma}, \vec{r}, DB)$  // Every peer  $P_i$ 
        • compute  $Eshare_i \leftarrow \text{IT-PIR.Compute}(r_i, DB)$ ;
        • set  $Dshare_i = Eshare_i - G(\sigma_i)$ ;
          // Initiator
        • compute  $\Delta = \sum_{i=1}^m Dshare_i$ ;

```

$G(s_1)$ and $G(s_2)$, then $G(s_1 \oplus s_2)$ can be computed efficiently. That is, if the seeds are in a group (S, \oplus) , and outputs in (G, \otimes) , then for any $s_1, s_2 \in S$, $G(s_1 \oplus s_2) = G(s_1) \otimes G(s_2)$. We refer to [60] for more details.

Decryption / Re-encryption using SH-PRG. Leveraging the property of SH-PRG, we explain the encryption, decryption and re-encryption of a block in our protocol. Every block in the tree is encrypted as $\text{Enc}(k_1, \text{block}) = \text{block} + G(k_1)$. The decryption of the block can be then represented as $\text{block} = \text{Dec}(k_1, \text{Enc}(k_1, \text{block})) = \text{block} + G(k_1) - G(k_1)$. For re-encrypting the encrypted block with a different key k_2 , the tracker decrypts the encrypted block with a new secret key of the form $k_1 - k_2$ such that, $\text{Dec}(k_1 - k_2, \text{Enc}(k_1, \text{block})) = \text{block} + G(k_1) - G(k_1 - k_2) = \text{block} + G(k_2) = \text{Enc}(k_2, \text{block})$.

4.2.4 OblivSel Instantiation

In the following, we present an instantiation of OblivSel. We consider a set of L encrypted blocks. Each block block_i is a vector of elements in a finite group G of order q . For every block, the key is generated at random from \mathbb{Z}_q . The tracker has to keep an association between the block key and its position. An algorithmic description is given in Algorithm 2.

The tracker runs the Gen algorithm, which takes as inputs the secret key k with which the block is encrypted and the block's position pos , and outputs a secret shared value of the key, $\vec{\sigma}$, as well as the IT-PIR queries, \vec{r} . Every peer P_i holds a copy of the L encrypted blocks and receives a share of the key, σ_i , as well as its corresponding query, r_i . Next, every peer runs locally an IT-PIR.Compute on the encrypted blocks and outputs a share, $Eshare_i$. After getting the encrypted share $Eshare_i$, each peer subtracts the evaluation of the SH-PRG G on σ_i from $Eshare_i$ ($Eshare_i - G(\sigma_i)$) to get the decrypted share $Dshare$. Finally, initiator outputs the sum of all the $Dshare_i$'s received from the m peers to

get the desired decrypted block. As long as there is one non-colluding peer among the m peers and G is a secure PRG, the scheme is *position hiding*.

Highly Parallelizable. Notice that, in Algorithm 2, each of the m peers performs scalar multiplications proportional to the number of encrypted input blocks. The encrypted blocks can be further distributed to different peers such that each peer performs constant number of scalar multiplications. Given the availability of enough peers in the network, OblivSel is extremely parallelizable and therefore provides a constant time computation.

OblivSel as a building block. OblivSel protocol can be used as a building block in our second and main OBLIVP2P-1. For fetching a block, an invocation of OblivSel is sufficient as it obviously selects the requested block and returns it in plaintext to the initiator. Additional steps such as re-encrypting the block and adding it to stash are required to complete the fetch operation. The details of these steps are in Section 4.3.

However, the eviction operation in ORAM poses an additional challenge. Conceptually, an eviction consists of block sorting, where the tracker re-orders the blocks in the path (and the stash). Fortunately, our protocol can perform eviction by several invocation of OblivSel primitive. Given the new position for each block, the P2P network can be instructed to invoke OblivSel recursively to output the new *sorted* path. The encryption of blocks has to be refreshed, but this is handled within OblivSel protocol itself when refreshing the key, using seed homomorphic PRG. We defer the concrete details of performing oblivious eviction to Section 4.3.

4.3 OBLIVP2P-1: Complete Design

In a P2P protocol for a content sharing system the tracker is responsible for managing the sharing of resources among the peers in the network. To keep a consistent global view on the network, the tracker keeps some *state* information that we formally define below:

Definition 4.4. *P2P network's state consists of: (1) number of possible network connections per peer, and (2) a lookup associating a resource to a (set of) peer identifier.*

The tracker can store more information in the state depending on the P2P protocol instantiating the network. We start first by formalizing a P2P protocol.

Definition 4.5. *A P2P protocol is a tuple of four (possibly interactive) algorithms $P2P = (\text{Setup}, \text{Upload}, \text{Fetch}, \text{Sync})$ involving a tracker, \mathcal{T} , and a set of peers, (P_1, \dots, P_n) , such that:*

- $s' \leftarrow \text{Setup}(s, \{\text{pid}\})$: run by the tracker \mathcal{T} , takes as inputs a state s and a (possibly empty) set of peers identifiers $\{\text{pid}\}$, and outputs an updated state s' .

Scheme	Tracker bandwidth (bits)	Network bandwidth (# blocks)	Tracker # encryption	Network computational overhead	Network Storage overhead	Tracker storage # blocks
OBLIVP2P-0	$O(\log N \cdot B)$	$O(1)$	$O(\log N \cdot E)$	—	$O(1)$	$O(\log N)$
OBLIVP2P-1	$O(\log^3 N)$	$O(\frac{\log N}{N})$	—	$O(\frac{\log^4 N}{N} \cdot \mathcal{E})$	$O(\text{burst})$	—

Table 2: Comparison of OBLIVP2P instantiation per access. B the block size, N the number of blocks in the network, E the overhead of a block encryption, \mathcal{E} a multiplication in elliptic curve group, burst the number of versions

- $(\text{out}, (A'_1, \dots, A'_m), s') \leftarrow \text{Upload}((\text{fid}, \text{file}), (A_1, \dots, A_m), s)$: is an interactive protocol between an initiator peer, a (possibly randomly selected) set of $m \geq 0$ peers, and a tracker \mathcal{T} . The initiator peer has as input a file identifier fid, and the file file, the peers' input is memory array A_i each, while for the tracker its state s. The initiator's output is $\text{out} \in \{\perp, \text{file}\}$, the peers output each a modified local memory A'_i , while the tracker outputs an updated state s' .
- $(\text{file}, \perp, s') \leftarrow \text{Fetch}(\text{fid}, (A_1, \dots, A_m), s)$: is an interactive protocol between an initiator peer, a (possibly randomly selected) set of $m \geq 0$ peers, and a tracker \mathcal{T} . The initiator peer has as input a file identifier fid, the peers' input is a memory array A_i each, while for the tracker its state s. The initiator outputs the retrieved file file, each peer gets \perp , while the tracker outputs an updated state s .
- $((A'_1, \dots, A'_m), s') \leftarrow \text{Sync}((A_1, \dots, A_m), s)$: is an interactive protocol between the tracker and a (possibly randomly selected) set of $m \geq 0$ peers. The peers' input is a memory array A_i each, while for the tracker its state s. The peers output each a (possibly) modified memory array A'_i , while the tracker outputs an updated state s' .

Note that a modification of a file already stored in the network is always considered as uploading a new file.

Setup Algorithm. In a P2P network, different peers have different storage capacities and hence we differentiate between the number of blocks, N_B , and the number of physical peers N_P . For this, we fragment the conceptual ORAM tree into smaller chunks where every peer physically handles a number of buckets depending on its local available storage. In addition, to keep a consistent global view on the network, the tracker keeps some *state* information. In OBLIVP2P-1, the state is composed of different meta-information that are independent of the block size: FileMap, PosMap, TagMap, NetMap, KeyMap, and StashMap. Table 1 gives more details about the metadata. The state also contains a counter recording the last eviction step, and $\sim \frac{B}{\log q}$ points sampled randomly from a q -order elliptic curve group \mathbb{G} to be used for DDH seed homomorphic PRG, where B is the block size. The number of points in the generator needs to be equal to those in the data block. These points are publicly known

Algorithm 3: Fetch(fid, s): OBLIVP2P-1 fetch operation

```

Input: file id fid, and state s
Output: file {block}, and updated state s
// Initiator requests tracker for a file
1 {adr} ← FileMap(fid);
2 for adr in {adr} do
3   (tag, pos) ← (TagMap(adr), PosMap(adr));
4   k ← KeyMap(adr);
5   compute  $(\vec{\sigma}, \vec{r}) := \text{OblivSel.Gen}(k, pos)$ ;
6   set  $A = (\text{stash}, \mathcal{P}(\text{tag}, 1), \dots, \mathcal{P}(\text{tag}, L))$ ;
// Initiator retrieves the block
7   compute block := OblivSel.Select( $\vec{\sigma}, \vec{r}, A$ );
// Re-encryption with a new secret
8   compute  $k \xleftarrow{\$} Z_q$ ;
9   compute  $(\vec{\sigma}, \vec{r}) := \text{OblivSel.Gen}(k, pos)$ ;
10  append  $\Delta := \text{OblivSel.Select}(\vec{\sigma}, \vec{r}, A)$  to the stash, and update state
    s;
11 end

```

to all peers in the network. The tracker randomly distributes the stash among the peers and records this information in the StashList.

Fetch Algorithm. The Fetch process is triggered when a peer requests a particular file. The tracker determines the block tag and position from its state for all the blocks composing the file. The m peers, the tracker, and the initiator runs OblivSel protocol such that the initiator retrieves the desired block. The OblivSel is invoked a second time to add a new layer to the retrieved block and send it to the peer who will hold the stash. The tracker updates its state, in particular, update KeyMap with the new key, update the PosMap with the exact position of the block in the network (in the stash), and TagMap with the new uniformly sampled tag. We provide an algorithmic description of the Fetch process in Algorithm 3.

Sync Algorithm. The Sync in OBLIVP2P-1 consists of: (1) updating the state of the network, but also, (2) evicting the stash. The tracker determines the path to be evicted, $\text{tag} = v \bmod 2^L$ and then fetches the position of all blocks in the stash and the path, $\mathcal{P}(\text{tag})$. The tracker then generates, based on the least common ancestor algorithm (LCA), a permutation π that maps every block in $A = (\text{stash}, \mathcal{P}(v \bmod 2^L, 1), \dots, \mathcal{P}(v \bmod 2^L, L))$ to its new position in A' , a new array that will replace the evicted path and the stash. The block $A[\pi(i)]$ will be mapped *obliviously* to $A'[i]$, for all $i \in [| \text{stash} | + z \cdot L]$. The oblivious mapping between A and A' is performed by invoking OblivSel between the tracker, the peers in

Algorithm 4: Sync(s): OBLIVP2P-1 sync operation

```
Input: tracker state  $s$ 
// Fetch necessary parameters
1  $v \leftarrow s$ ;
2  $\{adr\} \leftarrow PosMap^{-1}(v \bmod 2^L)$ ;
3 for  $adr$  in  $\{adr\}$  do
4   | set  $T = T \cup tag \leftarrow TagMap(adr)$ ;
5 end
6 set  $A = (\text{stash}, \mathcal{P}(v \bmod 2^L, 1), \dots, \mathcal{P}(v \bmod 2^L, L))$ ;
7 Initialize an array  $A'$ ,  $\pi \leftarrow LCA(T, v)$ ;
// tracker generates key shares
8 for  $l$  from 1 to  $L + |\text{stash}|$  do
9   | if  $\exists adr, l = PosMap(adr)$  then
10     |   | set  $k \leftarrow KeyMap(adr)$ ;
11     |   | set  $k'' = k' - k$ ,  $k' \xleftarrow{s} Z_q$ ;
12     |   | compute  $(\vec{\sigma}_l, \vec{r}_l) = \text{OblivSel.Gen}(k'', \pi(l))$ ;
13   | else
14     |   | set  $k'' \xleftarrow{s} Z_q$ , compute  $(\vec{\sigma}_l, \vec{r}_l) = \text{OblivSel.Gen}(k'', \pi(l))$ ;
15   | end
16 end
// Peers generate the new array  $A'$ 
17 for  $j$  from 1 to  $L + |\text{stash}|$  do
18   | set  $A'[j] = \text{OblivSel.Select}(\vec{\sigma}_j, \vec{r}_j, A)$ ;
19 end
20 for  $j \in [m]$ , send  $A'_j[1, \dots, |\text{stash}|]$  and  $A'_j[|\text{stash}| + 1, \dots, L]$  to peers in
 $\mathcal{P}(v)$  and the stash, and update state  $s$ ;
```

the path and m peers, $|\text{stash}| + z \cdot L$ times. Note that (1) the blocks in A' are encrypted with a freshly-generated key, and (2) the mapping is not disclosed to any peers in the path as long as there is one non-colluding peer. Refer to Algorithm 4 for more detail about the Sync algorithm.

Upload Algorithm. A peer can request the tracker to add a file. For this, the tracker selects uniformly at random a set of m peers. The peer sends the file in a form of blocks. Every block is secret shared such that every peer in the m peers receives a share. The tracker generates a secret unique to the block, k . The tracker secret shares k to the m peers. The peers evaluate a seed-homomorphic PRG on the received shares and add it to the block share. Finally, the block is appended to a randomly selected peer in the network to hold a part of the stash.

4.4 Optimization: Handling Bursts

OBLIVP2P-1 has a functional limitation inherited by ORAMs. Any access cannot be started unless the previous one has concluded². In our case, the tracker can handle fetching several blocks before starting the Sync operation. In our setting, we target increasing the P2P network throughput while leveraging the network storage and communication. In order to build a scalable system, we propose several optimizations.

O1: Replication. In Ring ORAM, $A = 3$ accesses can be performed before an eviction is required. To support A parallel accesses, we replicate every block A times in the tree. This absorbs the fetching access time and allows A

²We do not consider a multi-processor architectures as those considered in OPRAM literature [56].

simultaneous accesses, even for requests to the same resource. Additionally, we may replicate every block over A times on different peers, in case that the peer holding the block is offline due to churn, and cannot serve the block to the other peers. Lastly, the network operator can deploy multiple trackers to serve peers simultaneously, which leads to the throughput of OBLIVP2P-1 proportional to the number of trackers.

O2: Pipelining. While the eviction is highly parallelizable in OBLIVP2P-1, an eviction can take a considerable amount of time to terminate. If we denote by f the average number of fetch requests in the P2P network, and by t the time to perform an eviction, then the system can handle all the accesses if $t < \frac{1}{f}$. However, in practice $t > \frac{1}{f}$ and therefore the accesses will be queued and creates a bottleneck. To address this issue, we create multiple copies of the buckets that are run with different instances of OBLIVP2P-1 protocol which overlays on the same network. In the setup phase, every node creates l copies of its bucket space. Every bucket will be associated to different versions of OBLIVP2P-1 instantiations. For example, with replication we can handle A accesses in parallel on the (same) i th version of the buckets, but the upcoming accesses will be made on the $(i+1)$ th version. This will absorb the eviction time. To sum up, having different versions will increase the throughput of the system to $\frac{l}{f}$. In order to prevent pipeline stalls, we need to choose $l \geq t \cdot f$ in our implementation.

Another aspect (not considered for our implementation) for further optimizations in our versioning solution is to distribute the communication overhead of the peers in the network. In fact, the peers holding blocks at the higher level of the tree will be accessed more often compared to lower levels. In order to distribute the communication load on the network peers, peers' location can be changed for different versions such that: the peer at the i th level of the tree in the j th version will be placed at the $(L-i+1)$ th level of the tree in the $(j+1)$ th version.

O3: Parallelizing Computation across m Peers. The scalar multiplication in the elliptic curve is expensive and can easily delay the fetch and sync time. For this, we consider every peer in the OblivSel as a set of peers. Whenever there is a need to perform scalar multiplication over a path, several peers participate in the computation and only the representative of the set will perform the aggregation. This optimization speeds up the OblivSel to be proportional to the number of peers used to parallelize a single peer.

5 Implementation and Evaluation

Implementation. We implement a prototype of OBLIVP2P-0 and OBLIVP2P-1 in Python. The im-

plementation contains 1712 lines of code (LOC) for OBLIVP2P-0 and 3226 for OBLIVP2P-1 accounting to a total of 4938 lines measured using CLOC tool [61]. Our prototype implementation is open source and available online [34]. As our building block primitives, we implement the Ring ORAM algorithm, IT-PIR construction and seed-homomorphic PRG. For Ring ORAM, we have followed the parameters reported by authors [52]. Each bucket contains $z = 4$ blocks and $s = 5$ dummy blocks. The eviction occurs after every 3 accesses. The blocks in OBLIVP2P-0 are encrypted using AES-CBC with 256 bit key from the pycrypto library [62]. For implementing IT-PIR and seed homomorphic PRG in OBLIVP2P-1, we use the ECC library available in Python [63]. We use the NIST P-256 elliptic curve as the underlying group.

Experimental Setup. We use the DeterLab network testbed for our experiments [64]. It consists of 15 servers running Ubuntu 14.04 with dual Intel(R) Xeon(R) hexa-core processors running at 2.2 Ghz with 15 MB cache (24 cores each), Intel VT-x support and 24 GB of RAM. The tracker runs on a single server while each of the remaining servers runs approximately 2400 peers. Every peer process takes up to 4 – 60 MB memory which limits the maximum network size to 2^{14} peers in our experimental set up. The tracker is connected to a 128 MBps link and the peers in each server share a bandwidth link of 128 MBps as well. We simulate the bandwidth link following the observed BitTorrent traffic rate distribution reported in [65]. In our experimental setting, multiple peers are simulated on a single machine hence our reported results here are conservative. In the real BitTorrent setting, every peer has its own separate CPU.

Evaluation Methodology. To evaluate the scalability and efficiency of our system, we perform measurements for a) the overall throughput of the system b) the latency for Fetch and Sync operations and c) the data transferred through the tracker for both OBLIVP2P-0 and OBLIVP2P-1. All our results are the average of 50 runs with 95% confidence intervals for each of them. Along with the experimental results, we plot the theoretical bounds computed based on Table 2. This helps us to check if our experiments match our theoretical expectations. In addition, we perform separate experiments to demonstrate the effect of our optimizations on the throughput of our OBLIVP2P-1 protocol. For our experiments in this section, we leverage the technical optimization introduced in Section 4.4.

We vary the number of peers in the system from 2^4 to 2^{14} peers (capacity of our testbed) and extrapolate them to 2^{21} peers. Note that, when increasing the number of peers, we implicitly increase the total data size in the entire network which is computed as the number of peers \times the block size. That is, our P2P network handles a total

data size that spans from 16 KB to 32 GB. For our evaluation, we consider each peer holds one ORAM bucket because of the limited available memory. In reality, every peer can hold more buckets. Note that, we linearly extrapolate our curves to show the expected results for larger number of peers starting from $2^{15} - 2^{21}$ (shown dotted in the Figures), and therefore larger data size in the network. Aligned to the chunks in BitTorrent, we select our blocksize as 128 KB, 512 KB and 1 MB.

5.1 Linear Scalability with Peers

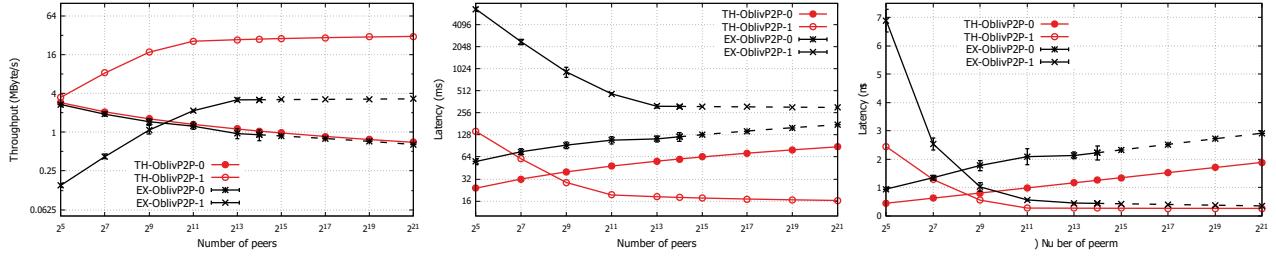

The throughput is an important parameter in designing a scalable P2P protocol. We define the throughput, as the number of bits that the system can serve per second.

From Figure 3a, we observe that the throughput of OBLIVP2P-0 decreases with the increase in the total number of peers in the network. For a network size of 2^{14} peers, the experimental maximum throughput is 0.91 MBps. As we extrapolate to larger network size, the maximum throughput decreases, e.g., for 2^{21} peers, the throughput is 0.64 MBps. This shows that as the network size increases, the tracker starts queuing the requests that will eventually lead to a saturation. However, for OBLIVP2P-1, the maximum throughput for network size of 2^{14} is 3.19 MBps and is 3.29 MBps when extrapolated to 2^{21} peers. The throughput increases as there are more peers available in the network to distribute the computation costs. The throughput shows a similar behaviour for blocksize of 128 KB and 1 MB (as shown in Figure 5). Hence, we expect OBLIVP2P-1 to provide better throughput in a real setting where more computational and communication capacity for each peer can be provisioned. The throughput values for OBLIVP2P-1 are calculated after applying all the 3 optimizations discussed in Section 4.4. The behaviour of the theoretical throughput matches our experimental results. The theoretical throughput has higher values as it does not capture the network latency in our test environment.

Result 1. Our results show that the centralized protocol is limited in scalability and cannot serve a large network. Whereas, the throughput for OBLIVP2P-1 linearly scales (0.15 – 3.39 MBps) with increasing number of peers ($2^5 - 2^{21}$) in the network.

Result 2. For a block of size 512 KB and 2^{14} peers, OBLIVP2P-1 serves around 7 requests / second which can be enhanced with multiple copies of ORAM trees in the network.

Remark. The throughput may be acceptable to privacy-conscious users (e.g., whistleblowers), where privacy concerns outweigh download / upload latencies. As long as the number of request initiators is small, the perceived throughput remains competitive with a non-

(a) The throughput for OBLIVP2P-1 linearly scales with the increase in network size.

(b) The latency for fetching a block for OBLIVP2P-1 reduces up to 2^{13} and then becomes constant.

(c) The latency for sync operation for OBLIVP2P-1 reduces up to 2^{13} and then becomes constant.

Figure 3: Theoretical (Th) and experimental (Ex) comparison of OBLIVP2P-0 and OBLIVP2P-1 parameters for block size of 512 KB

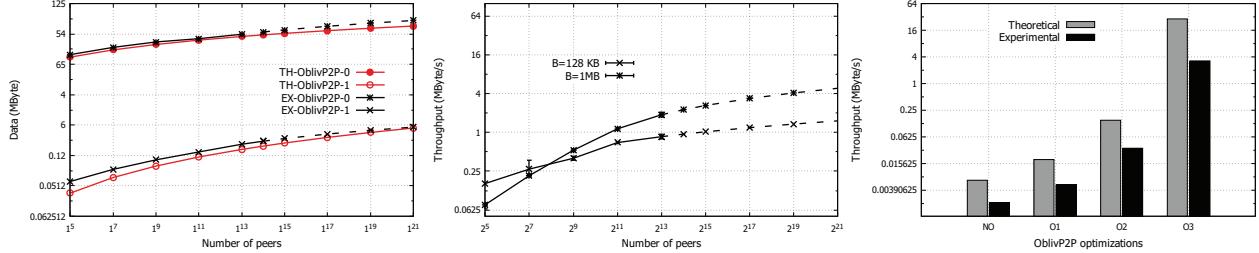

Figure 4: The data transferred through the tracker for OBLIVP2P-0 increases linearly with the number of peers

Figure 5: The throughput for blocksize 128 KB and 1 MB increases with increase in the network size.

Figure 6: Impact of optimizations (O1-O3) on the throughput of OBLIVP2P-1 for 2^{14} peers and blocksize of 512 KB.

oblivious P2P system. Further, the network operator can deploy multiple trackers to serve peers simultaneously, which leads to the throughput of OBLIVP2P-1 proportional to the number of trackers.

5.2 Latency Overhead and Breakdown

We define the latency as the time required to perform one ORAM operation in our P2P protocol. We measure the latency for the following operations:

Fetch. Figure 3b shows that the average time for fetching a block of 512 KB increases for OBLIVP2P-0 with increase in the size of the network. This is due to the increased computation and bandwidth overhead at the tracker. However, for OBLIVP2P-1, the latency initially reduces with the increasing number of peers (from 2^5 to 2^{11}) and then becomes constant after the network is large enough (around 2^{13}) to distribute the computation cost in the network³. OBLIVP2P-1 has a higher latency for fetch as compared to OBLIVP2P-0 due to the expensive computation required for performing scalar multiplication. The average time for fetching a block of size 512 KB is around 0.31 s for a network size of 2^{14} peers and

remains steady with increase in the number of peers.

Sync. We measure the time for performing a sync operation for different network sizes. Figure 3c shows that the time for performing a sync operation increases in OBLIVP2P-0 with increase in the number of peers. Whereas for OBLIVP2P-1, the sync time reduces gradually at first and then becomes steady after the network size reaches 2^{13} peers which is as expected through our theoretical calculation. OBLIVP2P-1 uses the peers in the network to distribute the computation load and hence the sync time tends to be steady for large network sizes.

Data transferred through tracker. Figure 4 shows the amount of data that is transferred through the tracker per request. We perform this measurement to show that the centralized tracker becomes a bottleneck in OBLIVP2P-0. The amount of data that the tracker has to process increases with increase in the number of peers. At 2^{21} peers, the amount of data is 118 MB (almost) reaching the bandwidth limit (128 MBps) of the tracker. Whereas, for OBLIVP2P-1 the amount of data transferred is around 1 MB for 2^{21} peers. This implies that the tracker could manage up to 128 copies of ORAM tree in parallel, which will increase the overall throughput by 128 times.

Result 3. OBLIVP2P has no centralized infrastructure as a bottleneck, ensuring that communication and computational overhead can be completely offloaded to the network.

³Since a large number of nodes (e.g., over 1000 nodes) share one physical machine, its limited computation power drastically affects our result. Therefore, to be more realistic, we use the ideal computing and decoding/encoding time for each node solely in one physical machine as the computing time per node, and simulate our experiments for OBLIVP2P-1.

5.3 Optimization Measurements

We perform incremental experiments to quantify the impact of each of the introduced optimizations on the overall throughput in Section 4.4, as shown in Figure 6. We fix the number of peers in the network to be equal to 2^{14} and the block size to 512 KB. We chose our optimization parameters based on our results in section 5.3. We fix the number of replicas to be equal to $A = 3$, i.e., the same data block is replicated three times. The burst parameter needs to be in $O(\frac{B}{\log q} \log N_p)$, where N_p is the number of peers, B the block size, and q the elliptic curve group order. Finally, we fix the number of parallel peers in the OblivSel.Select algorithm to be in $O(\frac{B}{\log q} \log N_p)$.

O1: Replication. Replication enables to perform $A = 3$ fetch operations in parallel. This implies that the throughput *theoretically* increases 3 times when compared to our baseline without any optimizations. Our experimental results show that we have 2.55 times improvement over the baseline, as expected theoretically.

O2: Pipelining. We evaluate the effect of our optimization (O2) that absorbs the eviction time by pipelining the fetch requests to different versions of the ORAM tree in the P2P network. We show that this optimization, when coupled to (O1), has theoretically increased the overall throughput by 23.05 times if compared to the baseline. Our experiments are aligned to our theoretical results and show 17.2 times improvement over the baseline with a burst parameter of 17. Clearly, if the number of versions increases beyond 17, then OBLIVP2P-1 can handle parallel accesses, hence increasing the system throughput.

O3: Parallelizing m peers. We measure the effect of parallelizing the computation load of m peers by leveraging more peers in the network on the overall throughput of the system. We increase the number of peers to 116 peers that are used to compute the fetch and sync operations. Our theoretical result shows an improvement of 4398 times over the baseline, when coupled with (O1) and (O2). Our experiments support this result and demonstrates 1589 times improvement, the difference is due to the real network latency are not considered in our theoretical calculation.

Result 4. OBLIVP2P-1 is subject to several optimizations due to its highly parallelizable design.

6 OBLIVP2P-1 Analysis

In this section, we present the theoretical analysis on computation / communication overhead of tracker / peers and security analysis for OBLIVP2P-1.

6.1 Performance

We report OBLIVP2P-1 computation and communication overhead for the tracker and the network in Table 2. In particular, OBLIVP2P-1’s tracker transmits a number of bits *independent* of the block size, the tracker does not perform any computation on the blocksize or store any block locally.

Tracker overhead. To fetch a block, the tracker invokes OblivSel twice. While for the eviction, the tracker performs OblivSel $(L \cdot z + |\text{stash}|)$ times. That is, it is sufficient to first analyze OblivSel overhead and than just conclude for the overall tracker overhead.

Within one instance of OblivSel, the tracker computes an IT – PIR.Query that outputs m vectors for m peers, each of size $L \cdot z + |\text{stash}|$. Each IT – PIR.Query vector costs $\log q(L \cdot z + |\text{stash}|)$ bits, where q is the group order. The tracker also needs to generate shares for the key, where the shares are in \mathbb{Z}_q . That is, one OblivSel costs the tracker $O(m \cdot \log q \cdot (L \cdot z + |\text{stash}|))$.

That is, the tracker has to transmit $O(m \cdot \log q \cdot (L \cdot z + |\text{stash}|)^2)$ bits. Considering $L, |\text{stash}| \in O(\log N)$, q the group order in $\text{poly}(N)$, m the number of peers and z the bucket size as constants, then the tracker needs to send $O(\log^3 N)$ bits independently of the block size. That is, if $\text{block} \in \Omega(\log^3 N)$, the tracker has a constant communication work per block. Moreover, the tracker is very lightweight as it does not perform any heavy computation such as encryption, decryption of blocks, which permits the tracker to handle frequent accesses.

Peers overhead. Considering the communication between the peers, the main communication overhead comes from block transfer from the peers holding the path to the selected m peers. The m peers are selected uniformly at random. Each peer receives $(z \cdot L + |\text{stash}|)$ blocks from the peers in the selected path and the stash. That is, in terms of communication overhead, the peers sends on average $\sum_{i=0}^L \frac{z}{2^i} + \frac{(z \cdot L + |\text{stash}|)}{N} + \frac{z}{N}$ blocks per peers in the network. Considering z constant and $L, |\text{stash}| \in O(\log N)$, implies that every peer is expected to transmit $O(\frac{\log N}{N})$ blocks per access.

In terms of computation, the main computational bottleneck consists of the scalar multiplication from the seed homomorphic PRG. For every OblivSel, every peer needs to perform $(z \cdot L + |\text{stash}|) \cdot \frac{B}{\log q}$ scalar multiplications per block. The second term, $\frac{B}{\log q}$, represents the number of points that a block contains. We also have $(z \cdot L + |\text{stash}|)$ instances of OblivSel during the eviction. That is, the total number of scalar multiplication equals $O((z \cdot L + |\text{stash}|)^2 \cdot \frac{B}{\log q})$. Finally, the amortized computation over the total number of peers in the network equals $O(\frac{\log^4 N}{N})$ multiplications per eviction, considering $B \in \Omega(\log^3 N)$ and $q \in \text{poly}(N)$.

6.2 Security Analysis

We show that OBLIVP2P-1 is an *oblivious* P2P as stated by Definition 2.2. For this, it is sufficient to show that an adversary cannot distinguish between a randomly generated string and the access pattern leaked by any peer’s real access. This underlines the fact that the access pattern is independent of the address of the requested block. In our threat model, the adversary can have access to the content of buckets, monitors the communication between the peers, and has a total view of the internal state of dishonest peers. Buckets’ content is assumed to be transmitted without any additional layer of encryption.

We present our *address-tag* experiment AT that captures our security definition. Let OBLIVP2P = (Setup, Upload, Fetch, Sync) represents an oblivious P2P protocol. Let $\mathcal{E} = (\text{Gen}, \text{Enc}, \text{Dec})$ be an IND\$ – CPA encryption scheme. Let \mathcal{G} be a secure pseudo-random generator. $\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}$ refers to the instantiation of the *address-tag* experiment by algorithms OBLIVP2P, \mathcal{E} , \mathcal{G} , and adversary \mathcal{A} . We denote by Col the event that m peers in the network collude and set $\Pr[\text{Col}] = \delta_m$, by \mathcal{B}_{δ_m} the Bernoulli distribution, and λ the security parameter.

In the following, we fix the number of colluding peers $c \in O(N^\varepsilon)$, for $0 < \varepsilon < 1$. We consider every peer in the network as a random variable distributed based on a Bernoulli distribution with probability equal to $\frac{c}{N} \in O(N^{\varepsilon-1})$. Let us denote by (X_1, \dots, X_m) the random variables of the selected peers for every instantiation of OblivSel. Note that $\Pr[\text{Col}] = \Pr[X_1 = 1 \text{ AND } \dots \text{ AND } X_m = 1]$. Since all X_i ’s are independent, then, $\Pr[\text{Col}] = \prod_{i=1}^m \Pr[X_i = 1] = (\frac{c}{N})^m$. That is, $\delta_m = (\frac{c}{N})^m$ which implies under our assumptions that $\delta_m \in O(2^{\log N \cdot m \cdot (\varepsilon-1)})$.

In the following experiment, we only consider the Fetch algorithm for obliviousness analysis. In our model, Upload sequences are indistinguishable by construction assuming that peers uploads blocks that are randomly distributed, and using random key for every block encryption. The experiment $\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, b)$ consists of:

- The adversary \mathcal{A} picks one access operation (Fetch, adr, \perp) and sends it to the challenger \mathcal{C}
- If $b = 1$, pick $X \xleftarrow{\mathcal{B}_{\delta_m}} \{0, 1\}$, if $X = 1$, then set var = adr, otherwise var = \perp and set

$$\begin{aligned} \pi_1 = & \{(\mathcal{P}(\text{tag}, 1), \dots, \mathcal{P}(\text{tag}, L)), \text{tag} \leftarrow \text{TagMap}[adr], \\ & (\text{Enc}(q_1), \dots, \text{Enc}(q_m)), \\ & (q_1, \dots, q_m) \leftarrow \text{IT-PIR.Query}(pos), \\ & pos \leftarrow \text{PosMap}[adr], \text{var}\} \end{aligned}$$

$$\begin{aligned} \text{If } b = 0, \text{ set } \pi_0 = & \{(P_1, \dots, P_L) \xleftarrow{\$} \mathbb{G}^{z \times L}, \\ & (q_1, \dots, q_m) \xleftarrow{\$} \{0, 1\}^{\lambda \times m}, \perp\} \end{aligned}$$

- Adversary \mathcal{A} has access to an oracle $\mathcal{O}^{\text{OblivP2P}}$ that issues the access patterns for polynomial number of accesses (while paths are re-encrypted for every request)
- \mathcal{A} outputs b'
- The output of the experiment is 1 if $b = b'$, otherwise 0. If $\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, b') = 1$, we say that \mathcal{A} won the experiment.

The experiment differentiates between a realistic setting where the adversary can see the access pattern, and in which a possible colluding setting can happen with a pre-fixed probability, δ_m , and an ideal setting where the adversary receives a random string. We slightly reformulate Definition 2.2 below.

Definition 6.1. We say that a P2P is oblivious iff for all PPT adversaries \mathcal{A} , there exists a negligible function negl such that:

$$\Pr[\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, 1) = 1] - \Pr[\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, 0) = 1] \leq \text{negl}(\lambda)$$

Theorem 6.1. If $\forall N > 1$, and $\forall \varepsilon < 1$, $\exists m > 1$ s.t. $2^{\log N \cdot m \cdot (1-\varepsilon)} \in \text{negl}(\lambda)$, \mathcal{G} is a secure pseudo-random generator, \mathcal{E} is IND\$ – CPA secure, then OBLIVP2P-1 is an oblivious P2P as in Definition 6.1.

Proof. To prove our theorem, we proceed with a succession of games as follows:

- Game₀ is exactly the same as $\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, 1)$
- Game₁ is the same as Game₀ except that the blocks in the buckets $\mathcal{P}(\text{tag}, i)$ are replaced with random points from \mathbb{G}
- Game₂ is the same as Game₁ except that the encrypted IT – PIR queries are replaced with random strings

From games’ description, we have

$$\Pr[\text{Game}_0 = 1] = \Pr[\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, 1) = 1], \quad (1)$$

For Game₁, we can build a distinguisher B_1 that reduces security of \mathcal{G} to PRG security such that:

$$\Pr[\text{Game}_0 = 1] - \Pr[\text{Game}_1 = 1] \leq \text{Adv}_{B_1, \mathcal{G}}^{\text{PRG}}(\lambda), \quad (2)$$

Similarly for Game₁, we can build a distinguisher B_2 that reduces \mathcal{E} to IND\$ – CPA security such that:

$$\Pr[\text{Game}_1 = 1] - \Pr[\text{Game}_2 = 1] \leq \text{Adv}_{B_2, \mathcal{E}}^{\text{IND\$-CPA}}(\lambda), \quad (3)$$

We need now to compute $\Pr[\text{Game}_2]$.

$$\begin{aligned} \Pr[\text{Game}_2] = & \Pr[\text{Col}] \cdot \Pr[\text{Game}_2 = 1 \mid \text{Col}] + \\ & \Pr[\overline{\text{Col}}] \cdot \Pr[\text{Game}_2 = 1 \mid \overline{\text{Col}}] \\ = & \delta_m + (1 - \delta_m) \frac{1}{N} \end{aligned}$$

On the other side $\Pr[\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, 0) = 1] = \frac{1}{N}$, since the tag is generated uniformly at random for every access.

$$\Pr[\text{Game}_2] - \Pr[\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, 0) = 1] = \delta_m(1 - \frac{1}{N}) \quad (4)$$

From equations 1, 2, 3, and 4 we obtain:

$$\begin{aligned} \Pr[\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, 1)] - \Pr[\text{AT}_{\mathcal{A}, \mathcal{E}, \mathcal{G}}^{\text{OblivP2P}}(\lambda, 0) = 1] &\leq \\ \delta_m(1 - \frac{1}{N}) + \text{Adv}_{B_2, \mathcal{E}}^{\text{INDS-CPA}} + \text{Adv}_{B_1, \mathcal{G}}^{\text{PRG}}. \end{aligned}$$

Since $\delta_m \in O(2^{\log N \cdot m \cdot (\varepsilon-1)})$, this ends our proof. \square

Quantitatively, if the number of peers in the network equals 2^{20} , number of colluding peers in the network is $c = N^{\frac{1}{2}}$ and $m = 12$, then $\delta_{12} = 2^{-120}$. Given the number of colluding peers and total number of peer, the value of m can always be adjusted to handle the desired colluding probability δ_m . In case of churn, the fraction c can vary and therefore the length of the circuit m has to be adapted to the new value. Furthermore, we implicitly assumed so far that no peer among the m selected leaves in the middle of the OblivSel process. If that occurs, the entire process has to abort, re-calculates the number of required peers m , and perform the OblivSel from scratch.

7 Discussion

Existing approaches. A valid question to investigate is whether existing solutions such as unlinkability or path non-correlation techniques can be extended to handle global adversaries and therefore prevent traffic analysis at the cost of providing more resources. It is easy to see that unlinkability techniques (e.g., mixnet) can provide better security in a P2P network under some assumptions. As an instance, assuming the case where a large number of peers behave as senders and issue requests that will be mixed by *sufficient* network peers before being answered by corresponding receivers' peers. Also, assuming that there is at least one honest peer in the mixing network, this solution would provide slightly the same level of security as OBLIVP2P where a global adversary cannot distinguish the senders' peers access pattern. However, this solution suffers from two downsides. First, there is a need to have *sufficient* number of senders' peers *on-line* in order to prevent intersection attacks. That is, in order to prevent traffic analysis, the number of senders represents a security parameter of the system that has to be maintained throughout the entire run of the system. Second, as the receivers' contents are theirs and are not encrypted, plus, all peers are considered honest-but-curious, a global adversary can easily find out what content is being accessed independently of the sender identity. This therefore does not achieve obliviousness as defined in our work but only a weaker version of it. On

the other hand, path non-correlation techniques conceptually cannot prevent against global adversary as we have detailed in Section 2. To sum up, it is not clear if existing techniques, even if given enough resources, can provide similar security insurances as those in OBLIVP2P.

Does better network & computation help? As empirically demonstrated in our evaluation section, the throughput of OBLIVP2P is around 3.19 MBps while considering only *one* tracker in the network. In a plain-text version of P2P system such as BitTorrent, the network leverages multiple trackers in order to handle more queries, and therefore increase the overall throughput. In OBLIVP2P, if we consider multiple copies of the entire network, we can also handle multiple trackers, and the throughput is expected to increase linearly with the number of trackers. However, as we delegate computation to the peers in OBLIVP2P, increasing the number of trackers beyond a particular threshold might turn out to be useless as the computation would represent a bottleneck of the system. As future work, we plan to investigate the asymptotic and empirical implications of including multiple trackers in the system. Moreover, it would be interesting to find out the relation between the number of trackers, number of peers for an ideal throughput of OBLIVP2P.

8 Related Work

Long-term traffic analysis. Anonymous systems like mix networks and onion routing are susceptible to long-term traffic analysis as shown in Section 2. Statistical disclosure attacks proposed by Danezis and enhanced by other researchers improve the likelihood of de-anonymizing users on these systems [66–73]. Moreover, existing traffic analysis attacks on onion routing based approaches [27–30, 45] can reveal users' identities with observing multiple communication rounds. Other P2P systems like Crowds [19], Tarzan [18], MorphMix [20], AP3 [21], Salsa [22], ShadowWalker [23], Freenet [3] offer anonymity for users. However, these systems show limits against global adversary with long-term traffic analysis capabilities.

Side-Channels. Previous work has shown possible attacks by leveraging side channels such as packet sizes, number of packets and timing. These side channels leak users' private information, e.g., illnesses/medications/surgeries, income and investment secrets [74]. An attacker can employ machine learning techniques (e.g., Support Vector Machines) on network traffic to identify the user's browsing websites [28–30, 45]. However, our focus in this paper is to only prevent long-term pattern traffic analysis. The aforementioned side-channels of traffic analysis are out of scope.

Multi-servers and parallel ORAM. There have been works on how to optimize ORAM constructions while leveraging multiple servers [75–77], multiple CPUs [56, 78], computational servers [53, 54], or distributed under a weaker threat model [55]. However, none of these recent constructions fit to a P2P setting as is. This is *mainly* due to the inherent client / server setting that results on a single entity bottleneck. The client has to either perform non-trivial computation or/and transmit several amount of bits. We briefly discuss these works below.

OblivStore [76], Lu and Ostrovsky [75], and Stefanov and Shi [77] demonstrate how to decrease the communication overhead while leveraging multiple ORAM nodes and servers. However, all these constructions are centralized and route the block through the tracker. This leads to a single entity bottleneck.

Recently, researchers have proposed oblivious parallel RAM (OPRAM) [56, 78]. This was motivated by current multi-cpu architectures that can access the same or multiple resources in parallel. However, OPRAM does not decrease the communication overhead making it as well a single-entity bottleneck. Dachman-Soled et al. introduced oblivious network RAM (ONRAM) [55]. ONRAM can reduce the communication overhead between the client and multiple banks of memory to be constant in the number of blocks. However, it assumes a weak threat model, and cannot achieve obliviousness in the case of a global adversary.

9 Conclusion

We advocate hiding data access patterns as a necessary step in defenses against long-term traffic pattern analysis in P2P content sharing systems. To this end, we propose OBLIVP2P— an oblivious peer-to-peer protocol. Our evaluation demonstrates that OBLIVP2P is parallelizable and linearly scalable with increase in number of peers, without bottleneck on a single entity.

Abstract

Telephones remain a trusted platform for conducting some of our most sensitive exchanges. From banking to taxes, wide swathes of industry and government rely on telephony as a secure fall-back when attempting to confirm the veracity of a transaction. In spite of this, authentication is poorly managed between these systems, and in the general case it is impossible to be certain of the identity (i.e., Caller ID) of the entity at the other end of a call. We address this problem with AuthLoop, the first system to provide cryptographic authentication solely within the voice channel. We design, implement and characterize the performance of an in-band modem for executing a TLS-inspired authentication protocol, and demonstrate its abilities to ensure that the explicit single-sided authentication procedures pervading the web are also possible on all phones. We show experimentally that this protocol can be executed with minimal computational overhead and only a few seconds of user time (≈ 9 instead of ≈ 97 seconds for a naïve implementation of TLS 1.2) over heterogeneous networks. In so doing, we demonstrate that strong end-to-end validation of Caller ID is indeed practical for all telephony networks.

1 Introduction

Modern telephony systems include a wide array of end-user devices. From traditional rotary PSTN phones to modern cellular and VoIP capable systems, these devices remain the de facto trusted platform for conducting many of our most sensitive operations. Even more critically, these systems offer the sole reliable connection for the majority of people in the world today.

Such trust is not necessarily well placed. Caller ID is known to be a poor authenticator [59, 18, 67], and yet is successfully exploited to enable over US\$2 Billion in fraud every year [28]. Many scammers simply block their phone number and exploit trusting users by

asserting an identity (e.g., a bank, law enforcement, etc.), taking advantage of a lack of reliable cues and mechanisms to dispute such claims. Addressing these problems will require the application of lessons from a related space. The Web experienced very similar problems in the 1990s, and developed and deployed the Transport Layer Security (TLS) protocol suite and necessary support infrastructure to assist with the integration of more verifiable identity in communications. While by no means perfect and still an area of active research, this infrastructure helps to make a huge range of attacks substantially more difficult. Unfortunately, the lack of similarly strong mechanisms in telephony means that *not even trained security experts can currently reason about the identity of other callers*.

In this paper, we address this problem with AuthLoop.¹ AuthLoop provides a strong cryptographic authentication protocol inspired by TLS 1.2. However, unlike other related solutions that assume Internet access (e.g., Silent Circle, RedPhone, etc [24, 73, 25, 5, 3, 6, 1, 74, 7]), accessibility to a secondary and concurrent data channel is not a guarantee in many locations (e.g., high density cities, rural areas) nor for all devices, mandating that a solution to this problem be network agnostic. Accordingly, AuthLoop is designed for and transmitted over the only channel certain to be available to all phone systems — audio. The advantage to this approach is that it requires no changes to any network core, which would likely see limited adoption at best. Through the use of AuthLoop, users can quickly and strongly identify callers who may fraudulently be claiming to be organizations including their financial institutions and their government [28].

We make the following contributions:

¹A name reminiscent of the “Local Loop” used to tie traditional phone systems into the larger network, we seek to tie modern telephony systems into the global authentication infrastructure that has dramatically improved transaction security over the web during the past two decades.

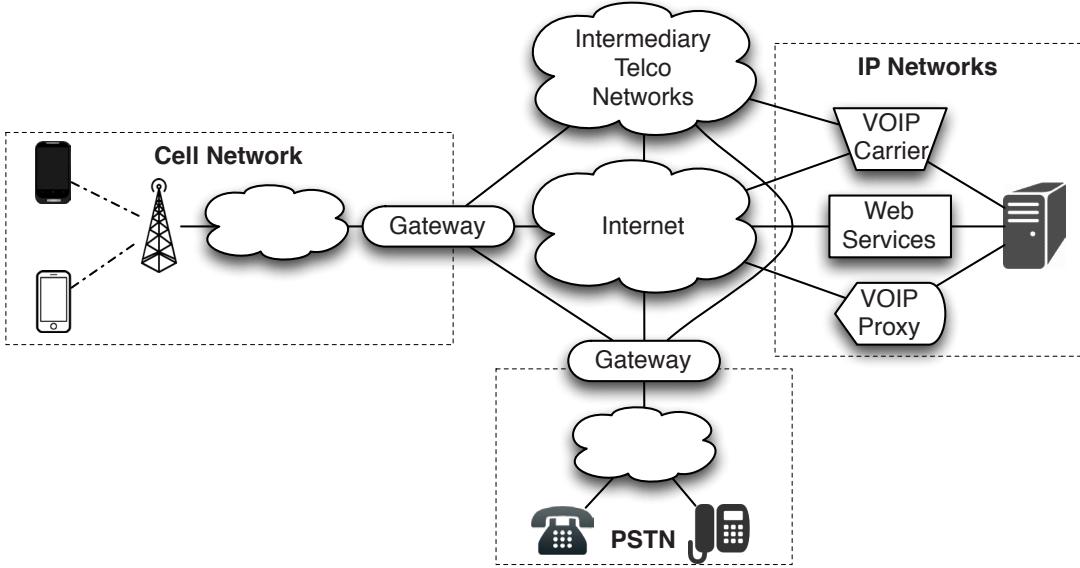

Figure 1: A high-level representation of modern telephony systems. In addition to voice being transcoded at each gateway, all identity mechanisms become asserted rather than attested as calls cross network borders. A strong end-to-end authentication must be designed aware of all such limitations.

- **Design a Complete Transmission Layer:** We design the first codec-agnostic modem that allows for the transmission of data across audio channels. We then create a supporting link layer protocol to enable the reliable delivery of data across the heterogeneous landscape of telephony networks.
- **Design AuthLoop Authentication Protocol:** After characterizing the bandwidth limitations of our data channel, we specify our security goals and design the AuthLoop protocol to provide explicit authentication of one party (i.e., the “Prover”) and optionally weak authentication of the second party (i.e., the “Verifier”).
- **Evaluate Performance of a Reference Implementation:** We implement AuthLoop and test it using three representative codecs — G.711 (for PSTN networks), AMR (for cellular networks) and Speex (for VoIP networks). We demonstrate the ability to create a data channel with a goodput of 500 bps and bit error rates averaging below 0.5%. We then demonstrate that AuthLoop can be run over this channel in an average of 9 seconds (which can be played below speaker audio), compared to running a direct port of TLS 1.2 in an average of 97 seconds (a 90% reduction in running time).

The remainder of this paper is organized as follows: Section 2 provides background information and related

work; Section 3 presents the details of our system including lower-layer considerations; Section 4 discusses our security model; Section 5 formally defines the AuthLoop protocol and parameterizes our system based on the modem; Section 6 discusses our prototype and experimental results; Section 7 provides additional discussion about our system; and Section 8 provides concluding remarks.

2 Background and Related Work

In this section, we provide an overview of modern telephony networks and review current and proposed practices of authentication in those networks.

2.1 Modern Telephony Networks

The landscape of modern telephony is complex and heterogeneous. Subscribers can receive service from mobile, PSTN and VoIP networks, and calls to those subscribers may similarly originate from networks implementing any of the above technologies. Figure 1 provides a high-level overview of this ecosystem.

While performing similar high-level functionality (i.e., enabling voice calls), each of these networks is built on a range of often incompatible technologies. From circuit-switched intelligent network cores to packet switching over the public Internet, very little information beyond the voice signal actually propagates across the borders of these systems. In fact, because many of these

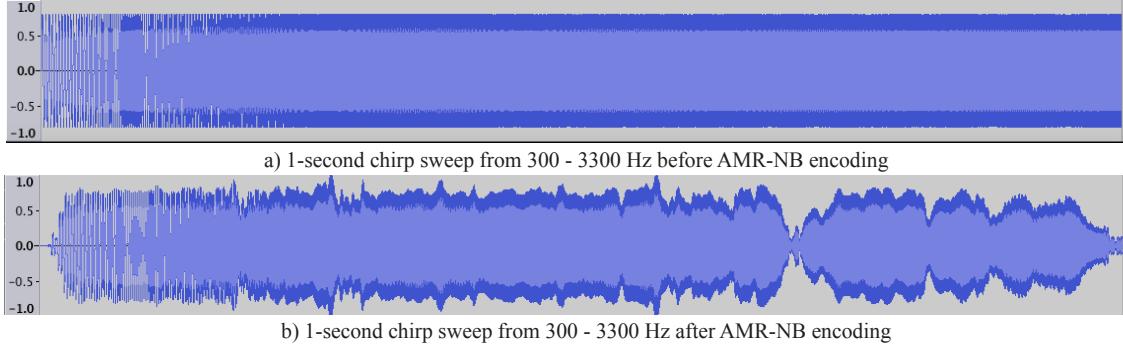

Figure 2: A comparison of a signal (a) before and (b) after being encoded with the AMR codec. Note that while the entirety of the signal is within the range of allowable frequencies for call audio, the received signal differs significantly from its original form. It is therefore critical that a high-fidelity mechanism for delivering data over a mobile audio channel be designed.

networks rely on different codecs for encoding voice, one of the major duties of gateways between these systems is the transcoding of audio. Accordingly, voice encoded at one end of a phone call is unlikely to have the same (or even similar) bitwise representation when it arrives at the client side of the call. As evidence, the top plot of Figure 2 shows a sweep of an audio signal from 300 to 3300 Hz (all within the acceptable band) across 1 second. The bottom plot shows the same signal after it has been encoded using the Adaptive Multi-Rate (AMR) audio codec used in cellular networks, resulting in a dramatically different message. This massive difference is a result of the voice-optimized audio codecs used in different telephony networks. Accordingly, successfully performing end-to-end authentication will require careful design for this non-traditional data channel.

One of the few pieces of digital information that can be optionally passed between networks is the Caller ID. Unfortunately, the security value of this metadata is minimal — such information is asserted by the source device or network, but never validated by the terminating or intermediary networks. As such, an adversary is able to claim any phone number (and therefore identity) as its own with ease. This process requires little technical sophistication, can be achieved with the assistance of a wide range of software and services, and is the enabler of greater than US\$2 Billion in fraud annually [28].

2.2 Authentication in Telephony Networks

Authentication has been the chief security concern of phone networks since their inception because of its strong ties to billing [69]. Little effort was taken for authentication in traditional landline networks as detecting billable activity on a physical link limited the scalability of attacks. First generation (1G) cellular systems were the first to consider such mechanisms given the multi-

user nature of wireless spectrum. Unfortunately, 1G authentication relied solely on the plaintext assertion of each user’s identity and was therefore subject to significant fraud [53]. Second generation (2G) networks (e.g., GSM) designed cryptographic mechanisms for authenticating users to the network. These protocols failed to authenticate the network to the user and lead to a range of attacks against subscribers [44, 26, 19, 68]. Third and fourth generation (3G and 4G) systems correctly implement mutual authentication between the users and providers [11, 12, 13]. Unfortunately, all such mechanisms are designed to allow accurate billing, and do little to help users identify other callers.

While a number of seemingly-cellular mechanisms have emerged to provide authentication between end users (e.g., Zphone, RedPhone) [24, 73, 25, 5, 3, 6, 1, 74, 7, 31, 30], these systems ultimately rely on a data/Internet connection to work, and are themselves vulnerable to a number of attacks [63, 52]. Accordingly, there remains no end-to-end solution for authentication *across voice* networks (i.e., authentication with any non-VoIP phone is not possible).

Mechanisms to deal with such attacks have had limited success. Websites have emerged with reputation data for unknown callers [2]; however, these sites offer no protection against Caller-ID spoofing, and users generally access such information after such a call has occurred. Others have designed heuristic approaches around black lists [4], speaker recognition [71, 16, 72, 17, 66, 41], channel characterization [18, 54], post hoc call data records [58, 47, 23, 40] and timing [61]. Unfortunately, the fuzzy nature of these mechanisms may cause them to fail under a range of common conditions including congestion and evasion.

Authentication between entities on the Internet generally relies on the use of strong cryptographic mecha-

nisms. The SSL/TLS suite of protocols are by far the most widely used, and help provide attestable identity for applications as diverse as web browsing, email, instant messaging and more. SSL/TLS are not without their own issues, including a range of vulnerabilities across different versions and implementations of the protocols [48, 27, 75, 34], weaknesses in the model and deployment of Certificate Authorities [57, 36, 37, 38, 29, 39, 20], and usability [55, 32, 60, 35, 65, 14, 15]. Regardless of these challenges, these mechanisms provide more robust means to reason about identity than the approaches used in telephony.

Telephony can build on the success of SSL/TLS. However, these mechanisms can not simply be built on top of current telephony systems. Instead, and as we will demonstrate, codec-aware protocols that are optimized for the limited bitrate and higher loss of telephony systems must be designed.

3 Voice Channel Data Transmission

To provide end-to-end authentication across any telephone networks, we need a way to transfer data over the voice channel. The following sections detail the challenges that must be addressed, how we implemented a modem that provides a base data rate of 500bps, and how we developed a link layer to address channel errors. We conclude with a discussion of what these technical limitations imply for using standard authentication technologies over voice networks.

3.1 Challenges to Data Transmission

Many readers may fondly remember dial-up Internet access and a time when data transmission over voice channels was a common occurrence. In the heyday of telephone modems, though, most voice channels were connected over high-fidelity analog twisted pair. Although the voice channel was band limited and digital trunks used a low sample rate of 8kHz, the channel was quite “well behaved” from a digital communications and signal processing perspective.

In the last two decades, telephony has been transformed. Cellular voice and Internet telephony now comprise a majority of all voice communications; they are not just ubiquitous, they are unavoidable. While beneficial from a number of perspectives, one of the drawbacks is that both of these modalities rely on heavily compressed audio transmission to save bandwidth. These compression algorithms – audio codecs – are technological feats, as they have permitted cheap, acceptable quality phone calls, especially given that they were developed during eras when computation was expensive. To do this, codec

designers employed a number of technical and psychoacoustic tricks to produce acceptable audio to a human ear, and these tricks resulted in a channel poorly suited for (if not hostile to) the transmission of digital data. As a result, existing voice modems are completely unsuited for data transmission in cellular or VoIP networks.

Voice codecs present several challenges to a general-purpose modem. First, amplitudes are not well preserved by voice codecs. This discounts many common modulation schemes, including ASK, QAM, TCM, and PCM. Second, phase discontinuities are rare in speech, and are not effective to transmit data through popular voice codecs. This discounts PSK, QPSK, and other modulation schemes that rely on correct phase information. Furthermore, many codecs lose phase information on encoding/decoding audio, preventing the use of efficient demodulators that require correct phase (i.e., coherent demodulators). Because of the problems with amplitude and phase modulation, frequency-shift modulation is the most effective technique for transmitting data through voice codecs. Even so, many codecs fail to accurately reproduce input frequencies — even those well within telephone voicebands (300–3400 Hz). Our physical layer protocol addresses these challenges.

3.2 Modem design

The AuthLoop modem has three goals:

1. Support highest bitrate possible
2. At the lowest error rate possible
3. In the presence of deforming codecs

We are not the first to address transmission of data over lossy compressed voice channels. Most prior efforts [70, 51, 42] have focused on transmission over a single codec, though one project, Hermes [33] was designed to support multiple cellular codecs. Unfortunately, that project only dealt with the modulation scheme, and did not address system-level issues like receiver synchronization. Furthermore, the published code did not have a complete demodulator, and our own implementation failed to replicate their results. Thus, we took Hermes as a starting point to produce our modem.

Most modems are designed around the concept of modulating one or more parameters — amplitude, frequency, and/or phase — of one or more sine waves. Our modem modulates a single sine wave using one of three discrete frequencies (i.e. it is a frequency shift key, or FSK, modem). The selection of these frequencies is a key design consideration, and our design was affected by three design criteria.

First, our modem is designed for phone systems, so our choice of frequencies are limited to the 300–3400Hz

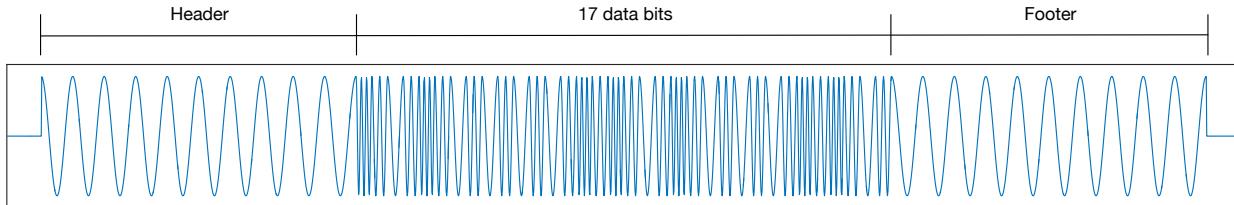

Figure 3: This 74ms modem transmission of a single frame demonstrates how data is modulated and wrapped in headers and footers for synchronization.

range because most landline and cellular phones are limited to those frequencies. Second, because we cannot accurately recover phase information for demodulation, our demodulation must be decoherent; the consequence is that our chosen frequencies must be separated by at least the symbol transmission rate [64]. Third, each frequency must be an integer multiple of the symbol frequency. This ensures that each symbol completes a full cycle, and it also ensures that each cycle begins and ends on a symbol boundary. This produces a continuous phase modulation, and it is critical because some voice codecs will produce artifacts or aliased frequencies in the presence of phase discontinuities. These constraints led to the selection of a 3-FSK system transmitting symbols at 1000 Hz using frequencies 1000, 2000, and 3000 Hz.

Unfortunately, 3-FSK will still fail to perform in many compressed channels simply because those channels distort frequencies, especially frequencies that change rapidly. To mitigate issues with FSK, we use a differential modulation: bits are encoded not as individual symbols, but by the relative difference between two consecutive symbols. For example, a “1” is represented by an increase in two consecutive frequencies, while a “0” is represented by a frequency decrease. Because we only have 3 frequencies available, we have to limit the number of possible consecutive increases or decreases to 2. Manchester encoding, where each bit is expanded into two “half-bits” (e.g. a “1” is represented by “10”, and “0” represented by “01”) limits the consecutive increases or decreases within the limit.

While these details cover the transmission of data, there are a few practical concerns that must be dealt with. Many audio codecs truncate the first few milliseconds of audio. In speech this is unnoticeable, and simplifies the encoding. However, if the truncated audio carries data, several bits will be lost every transmission. This effect is compounded if voice activity detection (VAD) is used (as is typical in VoIP and cellular networks). VAD distinguishes between audio and silence, and when no audio is recorded in a call VAD indicates that no data should be sent, saving bandwidth. However, VAD adds an additional delay before voice is transmitted again.

To deal with early voice clipping by codecs and VAD, we add a 20 ms header and footer at the end of each packet. This header is a 500 Hz sine wave; this frequency is orthogonal to the other 3 transmission frequencies, and is half the symbol rate, meaning it can be used to synchronize the receiver before data arrives. A full modem transmission containing 17 bits of random data can be seen in Figure 3.

To demodulate data, we must first detect that data is being transmitted. We distinguish silence and a transmission by computing the energy of the incoming signal using a short sliding window (i.e., the short-time energy). Then we locate the header and footer of a message to locate the beginning and end of a data transmission. Finally, we compute the average instantaneous frequency for each half-bit and compute differences between each bit. An increase in frequency indicates 1, a decrease indicates 0.

3.3 Link Layer

Despite a carefully designed modem, reception errors will still occur. These are artifacts created by line noise, the channel codec, or an underlying channel loss (e.g., a lost IP packet). To address these issues, we developed a link layer to ensure reliable transmission of handshake messages. This link layer manages error detection, error correction, frame acknowledgment, retransmission, and reassembly of fragmented messages.

Because error rates can sometimes be as high as several percent, a robust retransmission scheme is needed. However, because our available modem data rate is so low, overhead must be kept to a minimum. This rules out most standard transmission schemes that rely on explicit sequence numbers. Instead, our data link layer chunks transmitted frames into small individual blocks that may be checked and retransmitted if lost. We are unaware of other link layers that use this approach. The remainder of this subsection motivates and describes this scheme.

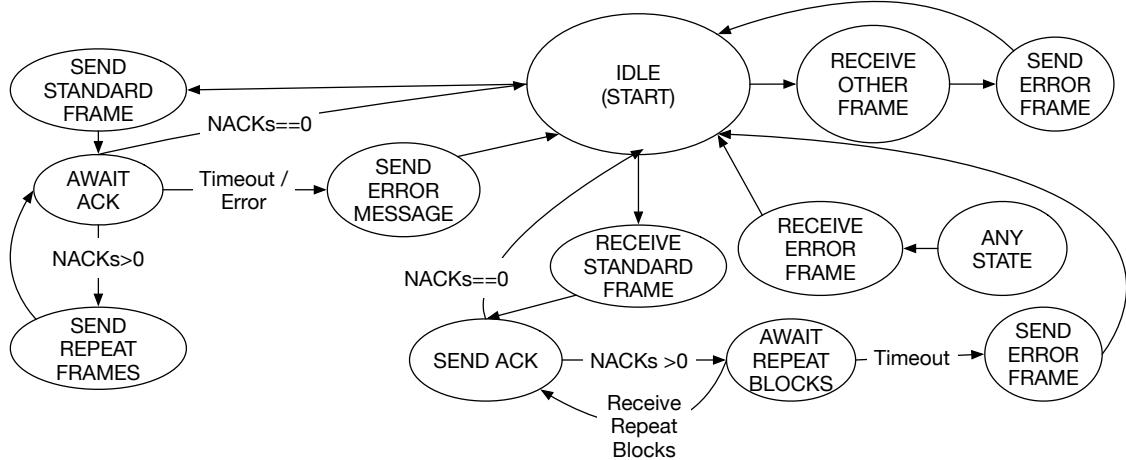

Figure 4: Link Layer State Machine

3.4 Framing and error detection

Most link layers are designed to transmit large (up to 12,144 bits for Ethernet) frames, and these channels either use large (e.g., 32-bit) CRCs² for error detection to retransmit the entire frame, or use expensive but necessary error correcting schemes in lossy media like radio. Error correcting codes recover damaged data by transmitting highly redundant data, often inflating the data transmitted by 100% or more. The alternative, sending large frames with a single CRC, was unlikely to succeed. To see why, note that:

$$P(\text{CorrectCRC}) = (1 - P(\text{biterror}))^{\text{CRClength}} \quad (1)$$

For a 3% bit error rate, the probability of just the CRC being undamaged is less than 38% — meaning two thirds of packets will be dropped for having a bad CRC independent of other errors. Even at lower loss rates, retransmitting whole frames for a single error would cause a massive overhead.

Instead, we divide each frame into 32-bit “blocks”. Each block carries 29 bits of data and a 3-bit CRC. This allows short sections of data to be checked for errors individually and retransmitted, which is closer to optimal transmission. Block and CRC selection was not arbitrary, but rather the result of careful modeling and analysis. In particular, we aimed to find an optimal tradeoff between overhead (i.e., CRC length) and error detection. Intuitively, longer CRCs provide better error detection and reduce the probability of an undetected error. More formally, a CRC of length l can guarantee detection of up to

²A Cyclic Redundancy Check (CRC) is a common checksum that is formed by representing the data as a polynomial and computing the remainder of polynomial division. The polynomial divisor is a design parameter that must be chosen carefully.

HD bit errors³ in a B -length block of data, and can detect more than HD errors probabilistically [43].

The tradeoff is maximizing the block size and minimizing the CRC length while minimizing the probability of a loss in the frame or the probability of an undetected error, represented by the following equations:

$$Pr(\text{lost frame}) = 1 - Pr(\text{successful frame}) \quad (2)$$

$$= 1 - (1 - p)^B \quad (3)$$

$$Pr\left(\frac{\text{undetected}}{\text{error}}\right) = 1 - \sum_{i=0}^{HD} \binom{B}{i} p^i (1-p)^{B-i} \quad (4)$$

where p represents the probability of a single bit error. The probability of undetected error is derived from the cumulative binomial distribution. Using these equations and the common bit error rate of 0.3% (measured in Section 6), we selected 32-bit blocks with a 3-bit CRC. We chose the optimal 3-bit CRC polynomial according to Koopman and Chakravarty [43]. These parameters give a likelihood of undetected error of roughly 0.013%, which will rarely affect a regular user. Even a call center user would see a protocol failure due to bit error once every two weeks, assuming 100 calls per day.

3.5 Acknowledgment and Retransmission

Error detection is only the first step of the error recovery process, which is reflected as a state machine in Figure 4.

When a message frame is received, the receiver computes which blocks have an error and sends an acknowledgment frame (“ACK”) to the transmitter. The ACK frame contains a single bit for each block transmitted to indicate if the block was received successfully or not.

³The Hamming distance of the transmitted and received data

Blocks that were negatively acknowledged are retransmitted; the retransmission will also be acknowledged by the receiver. This process will continue until all original blocks are received successfully.

By using a single bit of acknowledgment for each block we save the overhead of using sequence numbers. However, even a single bit error in an ACK will completely desynchronize the reassembly of correctly received data. Having meta-ACK and ACK retransmission frames would be unwieldy and inelegant. Instead, we transmit redundant ACK data as a form of error correction; we send ACK data 3 times in a single frame and take the majority of any bits that conflict. The likelihood of a damaged ACK is then:

$$\text{Block Count} \times 3 \times \Pr(\text{biterr})^2 \quad (5)$$

instead of

$$1 - (1 - \Pr(\text{biterr}))^{\text{Block Count}} \quad (6)$$

Note that there are effectively distinct types of frames – original data, ACK data, retransmission data, and error frames. We use a four-bit header to distinguish these frames; like ACK data, we send three copies of the header to ensure accurate recovery. We will explore more robust error correcting codes in future work.

3.6 Naïve TLS over Voice Channels

With a modem and link layer design established, we can now examine how a standard authentication scheme — TLS 1.2 — would fare over a voice channel.

Table 1 shows the amount of data in the TLS handshakes of four popular Internet services: Facebook, Google, Bank of America, and Yahoo. These handshakes require from 41,000 to almost 58,000 bits to transmit, and this excludes application data and overhead from the TCP/IP and link layers. At 500 bits per second (the nominal speed of our modem), these transfers would require 83–116 seconds *as a lower bound*. From a usability standpoint, standard TLS handshakes are simply not practical for voice channels. Accordingly, a more efficient authentication protocol is necessary.

4 Security Model

Having demonstrated that data communication is possible but extremely limited via voice channels, we now turn our attention to defining a security model. The combination of our modem and this model can then be used to carefully design the AuthLoop protocol.

The goal of AuthLoop is to mitigate the most common enabler of phone fraud: claiming a false identity via Caller ID spoofing. This attack generally takes the

Table 1: TLS Handshake Sizes

Site Name	Total Bits	Transmission Time (seconds at 500bps)
Facebook	41 544	83.088
Google	42 856	85.712
Bank of America	53 144	106.288
Yahoo	57 920	115.840
Average	48 688	97.732

form of the adversary calling the victim user and extracting sensitive information via social engineering. The attack could also be conducted by sending the victim a malicious phone number to call (e.g., via a spam text or email). An adversary may also attempt to perform a man in the middle attack, calling both the victim user and a legitimate institution and then hanging up the call on either when they wish to impersonate that participant. Finally, an adversary may attempt to perform a call forwarding attack, ensuring that correctly dialed numbers are redirected (undetected to the caller) to a malicious endpoint.

We base our design on the following assumptions. An adversary is able to originate phone calls from any telephony device (i.e., cellular, PSTN, or VoIP) and spoof their Caller ID information to mimic any phone number of their choosing. Targeted devices will either display this spoofed number or, if they contain a directory (e.g., contact database on a mobile phone), a name associated or registered with that number (e.g., “Bank of America”). The adversary can play arbitrary sounds over the audio channel, and may deliver either an automated message or interact directly with the targeted user. Lastly, the adversary may use advanced telephony features such as three-way calling to connect and disconnect parties arbitrarily. This model describes the majority of adversaries committing Caller ID fraud at the time of this work.

Our scenario contains two classes of participants, a Verifier (i.e., the user) and Prover (i.e., either the attacker of the legitimate identity owner). The adversary is active and will attempt to assert an arbitrary identity. As is common on the Web, we assume that Provers have certificates issued by their service provider⁴ containing their public key and that Verifiers may have weak credentials (e.g., account numbers, PINs, etc) but do not have certificates. We seek to achieve the following security goals in the presence of this adversary:

1. **(G1) Authentication of Prover:** The Verifier should be able to explicitly determine the validity of an asserted Caller ID and the identity of the Prover without access to a secondary data channel.

⁴See Section 7 for details.

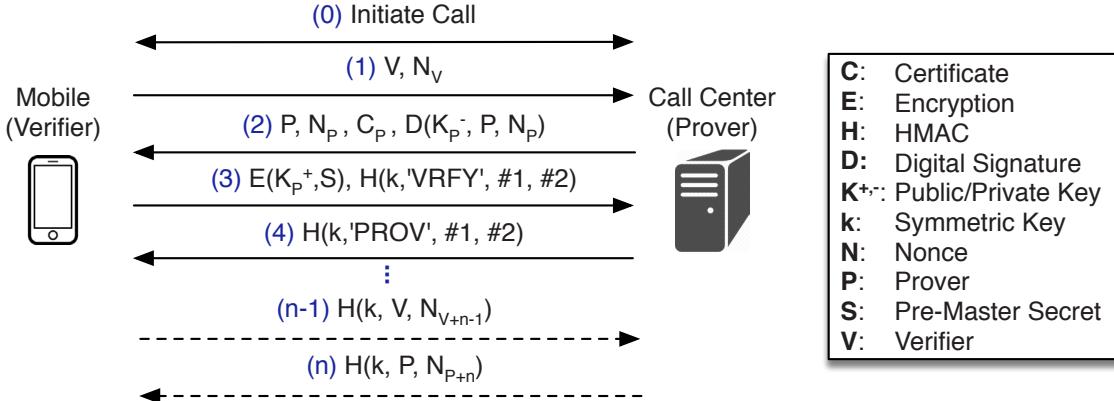

Figure 5: The AuthLoop authentication protocol. Solid arrows indicate the initial handshake message flows, and dotted arrows indicate subsequent authenticated “keep alive” messages. Note that #1 and #2 in messages 2 and 3 indicate that the contents of messages 1 and 2 are included in the calculation of the HMAC, as is done in TLS 1.2.

2. **(G2) Proof of Liveness:** The Prover and Verifier will be asked to demonstrate that they remain on the call throughout its duration.

Note that we do not aim to achieve voice confidentiality. As discussed in Section 2, the path between two telephony participants is likely to include a range of codec transformations, making the bitwise representation of voice vary significantly between source and destination. Accordingly, end-to-end encryption of voice content is not currently possible given the relatively low channel bitrate and large impact of transcoding. Solutions such as Silent Circle [7] and RedPhone [1] are able to achieve this guarantee strictly because they are VoIP clients that traverse *only* data networks and therefore do not experience transcoding. However, as we discuss in Section 7, our techniques enable the creation of a low-bandwidth channel that can be used to protect the confidentiality and integrity of weak client authentication credentials.

5 AuthLoop Protocol

This section describes the design and implementation of the AuthLoop protocol.

5.1 Design Considerations

Before describing the full protocol, this section briefly discusses the design considerations that led to the AuthLoop authentication protocol. As previously mentioned, we are constrained in that there is no fully-fledged Public Key Infrastructure, meaning that Verifiers (i.e., end users) do not universally possess a strong credential. Moreover, because we are limited to transmission over the audio channel, the AuthLoop protocol must be highly bandwidth efficient.

The most natural choice for AuthLoop would be to reuse an authentication protocol such as Needham-Schroeder [50]. Reusing well-understood security protocols has great value. However, Needham-Schroeder is inappropriate because it assumes that both sides have public/private key pairs or can communicate with a third party for session key establishment. Goal G1 is therefore not practically achievable in real telephony systems if Needham-Schroeder is used. This protocol is also unsuitable as it does not establish session keys, meaning that achieving G2 would require frequent re-execution of the entire authentication protocol, which is likely to be highly inefficient.

TLS can achieve goals G1 and G2, and already does so for a wide range of traditional applications on the Web. Unfortunately, the handshaking and negotiation phases of TLS 1.2 require significant bandwidth. As we demonstrate in Section 3, unmodified use of this protocol can require an average of 97 seconds before authentication can be completed. However, because it can achieve goals G1 and G2, TLS 1.2 is useful as a template for our protocol, and we discuss what could be considered a highly-optimized version below. We note that while TLS 1.3 provides great promise for reducing handshaking costs, the current draft version requires more bandwidth than the AuthLoop protocol.

5.2 Protocol Definition

Figure 5 provides a formal definition for our authentication protocol. We describe this protocol below, and provide details about its implementation and parameterization (e.g., algorithm selection) in Section 5.4.

The AuthLoop protocol begins immediately after a

call is terminated.⁵ Either party, the Prover P (e.g., a call center) or the Verifier V (e.g., the end user) can initiate the call. V then transmits its identity (i.e., phone number) and a nonce N_V to P . Upon receiving this message, P transmits a nonce N_P , its certificate C_P , and signs the contents of the message to bind the nonce to its identity. Its identity, P , is transmitted via Caller ID and is also present in the certificate.

V then generates a pre-master secret S , and uses S to generate a session key k , which is the result of $HMAC(S, N_P, N_V)$. V then extracts P 's public key from the certificate, encrypts S using that key and then computes $HMAC(k, 'VRFY', \#1, \#2)$, where 'VRFY' is a literal string, and #1 and #2 represent the contents of messages 1 and 2. V then sends S and the HMAC to P . P decrypts the pre-master secret and uses it to similarly calculate k , after which it calculates $HMAC(k, 'PROV', \#1, \#2)$, which it then returns to V .

At this time, P has demonstrated knowledge of the private key associated with the public key included in its certificate, thereby authenticating the asserted identity. If the Prover does not provide the correct response, its claim of the Caller ID as its identity is rejected. Security goal G1 is therefore achieved. Moreover, P and V now share a session key k , which can be subsequently used to provide continued and efficient proofs (i.e., HMACs over incrementing nonces) that they remain on the call, thereby achieving Goal G2.

We note that the session key generation step between messages 2 and 3 can be extended to provide keys for protecting confidentiality and integrity (as is done in most TLS sessions). While these keys are not of value for voice communications (given the narrow bitrate of our channel), they can be used to protect client authentication credentials. We discuss this in greater detail in Section 7.

5.3 Formal Verification

We believe that our protocol is secure via inspection. However, to provide stronger guarantees, we use the Proverif v1.93 [22] automatic cryptographic protocol verifier to reason about the security of the AuthLoop handshake. Proverif requires that protocols be rewritten as Horn clauses and modeled in Pi Calculus, from which it can then reason about secrecy and authentication in the Dolev-Yao setting. AuthLoop was represented by a total of 60 lines of code, and Proverif verified the secrecy of the session key k . Further details about configuration will be available in our technical report.

⁵This is the telephony term for "delivered to its intended destination," and signifies the beginning of a call, not its end.

Table 2: Authloop Message Sizes

Message Field	Size(Bits)
Verifier Hello	144
Nonce	96
Cert Ident Number	40
Protocol Command	8
Prover Hello	1692
Nonce	96
Certificate (optional)	1592
Protocol Command	8
Verifier Challenge	1312
Encrypted Premaster Secret	1224
HMAC	80
Protocol Command	8
Prover Response	88
HMAC	80
Protocol Command	8
Total With Certificate	3236
Total Without Certificate	1648

5.4 Implementation Parameters

Table 2 provides accounting of every bit used in the AuthLoop protocol for each message. Given the tight constraints on the channel, we use the following parameters and considerations to implement our protocol as efficiently as possible while still providing strong security guarantees.

We use elliptic curve cryptography for public key primitives. We used the Pyelliptic library for Python [9], which is a Python wrapper around OpenSSL. Keys were generated on curve `sect283r1`, and keys on this curve provide security equivalent to RSA 3456 [56]. For keyed hashes, we use SHA-256 as the underlying hash function for HMACs. To reduce transmission time, we compute the full 256-bit HMAC and truncate the result to 80 bits. Because the security factor of HMAC is dependent almost entirely on the length of the hash, this truncation maintains a security factor of 2^{-80} [21]. This security factor is a commonly accepted safe value [49] for the near future, and as our data transmission improves, the security factor can increase as well.

While similar to TLS 1.2, we have made a few important changes to reduce overhead. For instance, we do not perform cipher suite negotiation in every session and instead assume the default use of AES256-GCM and SHA256. Our link layer header contains a bit field indicating whether negotiation is necessary; however, it is our belief that starting with strong defaults and negotiating in the rare scenario where negotiation is necessary is critical to saving bandwidth for AuthLoop. Similarly, we are able to exclude additional optional information (e.g.,

compression types supported) and the rigid TLS Record format to ensure that our overhead is minimized.

We also limit the contents of certificates. Our certificates consist of a protocol version, the prover’s phone number, claimed identification (i.e., a name), validity period, unique certificate identification number, the certificate owner’s ECC public key and a signature. Because certificate transmission comprises nearly half of the total transmission time, we implemented two variants of AuthLoop: the standard handshake and a version with a verifier-cached certificate. Certificate caching enables a significantly abbreviated handshake. For certificate caching, we include a 16-bit certificate identifier that the verifier sends to the prover to identify which certificate is cached. We discuss how we limit transmitted certificate chain size to a single certificate in Section 7.

Finally, we keep the most security-sensitive parameters as defined in the TLS specification, including recommended sizes for nonces (96 bits).

While our protocol implementation significantly reduces the overhead compared to TLS 1.2 for this application, there is still room for improvement. In particular, the encrypted pre-master secret requires 1224 bits for the 256-bit premaster secret. This expansion is due to the fact that while RSA has a simple primitive for direct encryption of a small value, with ECC one must use a hybrid encryption model called the Integrated Encryption Scheme (IEC), so a key must be shared separately from the encrypted data. Pyelliptic also includes a SHA-256 HMAC of the ECC keyshare and encrypted data to ensure integrity of the message (which is standard practice in IEC). Because the message already includes an HMAC, in future work we plan to save 256 bits (or 15% of the cached certificate handshake) by including the HMAC of the ECC share into the message HMAC.

6 Evaluation

Previous sections established the need for a custom authentication protocol using a voice channel modem to provide end-to-end authentication for telephone calls. In this section, we describe and evaluate our prototype implementation. In particular, we characterize the error performance of the modem across several audio codecs, compute the resulting actual throughput after layer 2 effects are taken into account, and finally measure the end to end timing of complete handshakes.

6.1 Prototype Implementation

Our prototype implementation consists of software implementing the protocol, link layer, and modem running on commodity PCs. While we envision that AuthLoop

Table 3: Bit Error Rates

Codec	Average Bit Error	Std. Dev
G.711	0.0%	0.0%
AMR-NB	0.3%	0.2%
Speex	0.5%	5%

will eventually be a stand-alone embedded device or implemented in telephone hardware/software, a PC served as an ideal prototyping platform to evaluate the system.

We implemented the AuthLoop protocol in Python using the Pyelliptic library for cryptography. We also implemented the link layer in Python. Our modem was written in Matlab, and that code is responsible for modulating data, demodulating data, and sending and receiving samples over the voice channel. We used the Python Engine for Matlab to integrate our modem with Python. Our choice of Matlab facilitated rapid prototyping and development of the modem, but the Matlab runtime placed a considerable load on the PCs running the prototype. Accordingly, computation results, while already acceptable, should improve for embedded implementations.

We evaluate the modem and handshake using software audio channels configured to use one of three audio codecs: G.711 (μ -law), Adaptive MultiRate Narrow Band (AMR-NB), and Speex. These particular codecs were among the most common codecs used for landline audio compression, cellular audio, and VoIP audio, respectively. We use the sox[10] implementations of G.711 and AMR-NB and the ffmpeg[8] implementation of Speex. We use software audio channels to provide a common baseline of comparison, as no VoIP client or cellular device supports all of these codecs.

As link layer performance depends only on the bit error characteristics of the modem, we evaluate the link layer using a software loopback with tunable loss characteristics instead of a voice channel. This allowed us to fully and reproducibly test and evaluate the link layer.

6.2 Modem Evaluation

The most important characteristic of the modem is its resistance to bit errors. To measure bit error, we transmit 100 frames of 2000 random bits⁶ each and measure the bit error after reception.

Table 3 shows the average and standard deviation of the bit error for various codecs. The modem saw no bit errors on the G.711 channel; this is reflective of the fact that G.711 is high-quality channel with very minimal processing and compression. AMR-NB and Speex

⁶2000 bits was chosen as the first “round” number larger than the largest message in the AuthLoop handshake.

Table 4: Link Layer Transmission of 2000 bits

Bit Error Rate	Transmission Time	Goodput
0.1%	4.086 s (0.004)	490 bps
1%	6.130 s (0.009)	326 bps
2%	11.652 s (0.007)	172 bps

both saw minimal bit error as well, though Speex had a much higher variance in errors. Speex had such a high variance because one frame was truncated, resulting in a higher average error despite the fact the other 99 frames were received *with no error*.

6.3 Link Layer Evaluation

The most important characteristic of the link layer is its ability to optimize goodput – the actual amount of application data transmitted per unit time (removing overhead from consideration).

Table 4 shows as a function of bit error the transmission time and the goodput of the protocol compared to the theoretical optimal transmission time and goodput. The optimal numbers are computed from the optimal bit time (at 500 bits per second) plus 40ms of header and footer. The experimental numbers are the average of transmission of 50 messages with 2000 bits each. The table shows that in spite of high bit error rates (up to 2%) the link layer is able to complete message transmission. Of course, the effect of bit errors on goodput is substantial at larger rates. Fortunately, low bit error rates (e.g. 0.1%) result in a minor penalty to goodput – only 5bps lower than the optimal rate. Higher rates have a more severe impact, resulting in 65.8% and 34.7% of optimal goodput for 1% and 2% loss. Given our observations of bit error rates at less than 0.5% for all codecs, these results demonstrate that our Link Layer retransmission parameters are set with an acceptable range.

6.4 Handshake Evaluation

To evaluate the complete handshake, we measure the complete time from handshake start to handshake completion from the verifier’s perspective. We evaluate both variants of the handshake: with and without the prover sending a certificate. Handshakes requiring a certificate exchange will take much longer than handshakes without a certificate. This is a natural consequence of simply sending more data.

Table 5 shows the total handshake times for calls over each of the three codecs. These results are over 10 calls each. Note that these times are corrected to remove the effects of instrumentation delays and artificial delays caused by IPC among the different components of our

prototype that would be removed or consolidated in deployment.

From the verifier perspective, we find that cached-certificate exchanges are quite fast – averaging 4.844 seconds across all codecs. When certificates are not cached, our overall average time is 8.977 seconds. Differences in times taken for certificate exchanges for different codecs are caused by the relative underlying bit error rate of each codec. G.711 and Speex have much lower error rates than AMR-NB, and this results in a lower overall handshake time. In fact, because those codecs saw no errors during the tests, their execution times were virtually identical.

Most of the time spent in the handshake is spent in transmitting messages over the voice channel. In fact, transmission time accounts for 99% of our handshake time. Computation and miscellaneous overhead average to less than 50 milliseconds for all messages. This indicates that AuthLoop is computationally minimal and can be implemented on a variety of platforms.

7 Discussion

This section provides a discussion of client authentication, public key infrastructure, and deployment considerations for AuthLoop.

7.1 Client Credentials

Up until this point, we have focused our discussion around strong authentication of one party in the phone call (i.e., the Prover). However, clients already engage in a weaker “application-layer” authentication when talking to many call centers. For instance, when calling a financial institution or ISP, users enter their account number and additional values including PINs and social security numbers. Without one final step, our threat model would allow for an adversary to successfully steal such credentials as follows: An adversary would launch a 3-Way call to both the victim client and the targeted institution. After passively observing the successful handshake, the adversary could capture the client’s credentials (i.e., DTMF tone inputs) and hang up both ends of the call. The adversary could then call the targeted institution back spoofing the victim’s Caller ID and present the correct credentials.

One of the advantages of TLS is that it allows for the generation of multiple session keys, for use not only in continued authentication, but also in the protection of data confidentiality and integrity. AuthLoop is no different. While the data throughput enabled by our modem is low, it is sufficiently large enough to carry encrypted copies of client credentials. Accordingly, an adversary attempting to execute the above attack would be unable to do so successfully because this sensitive information

Table 5: Handshake completion times

Codec	Cached Certificate	Certificate Exchanged
G.711	4.463 s (0.000)	8.279 s (0.000)
AMR-NB	5.608 s (0.776)	10.374 s (0.569)
Speex	4.427 s (0.000)	8.279 s (0.000)
Average	4.844 s	8.977 s

could easily be passed through AuthLoop (and therefore useless in a second session). Moreover, because users are already accustomed to entering such information when interacting with these entities, the user experience could continue without any observable difference.

7.2 Telephony PKI

One of the most significant problems facing SSL/TLS is its trust model. X.509 certificates are issued by a vast number of Certificate Authorities (CAs), whose root certificates can be used to verify the authenticity of a presented certificate. Unfortunately, the unregulated nature of who can issue certificates to whom (i.e., what authority does X have to verify and bind names to entity Y ?) and even who can act as a CA have been known since the inception of the current Public Key Infrastructure [37]. This weakness has lead to a wide range of attacks, and enabled both the mistaken identity of domain owners and confusion as to which root-signed certificate can be trusted. Traditional certificates present another challenge in this environment - the existence of long verification chains in the presence of the bitrate limited audio channel means that the blind adoption of the Internet's traditional PKI model will simply fail if applied to telephony systems. As we demonstrated in our experiment in Table 1, transmitting the entirety of long certificate chains would simply be detrimental to the performance of AuthLoop.

The structure of telephony networks leads to a natural, single rooted PKI system. Competitive Local Exchange Carriers (CLECs) are assigned blocks of phone numbers by the North American Numbering Plan Association (NANPA), and ownership of these blocks is easily confirmed through publicly posted resources such as NPA/NXX databases in North America. A similar observation was recently made in the secure Internet routing community, and resulted in the proposal of the Resource Public Key Infrastructure (RPKI) [45]. The advantage to this approach is that because all allocation of phone numbers is conducted under the ultimate authority of NANPA, all valid signatures on phone numbers must ultimately be rooted in a NANPA certificate. This Telephony Public Key Infrastructure (TPKI) reduces the length of certificate chains and allows us to easily store the root and all CLEC certificates in the US and asso-

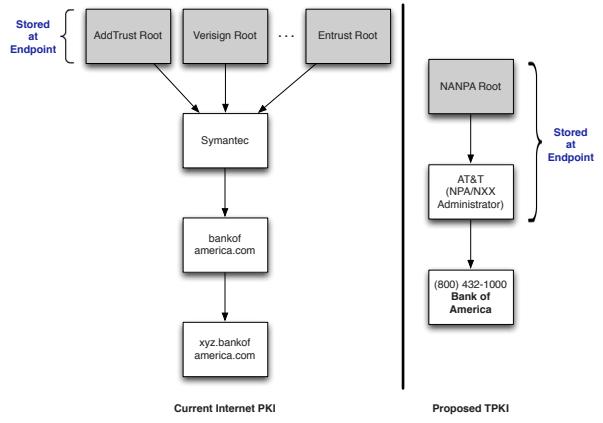

Figure 6: The Telephony Public Key Infrastructure (TPKI). Unlike in Internet model, the TPKI has a single root (NANPA) which is responsible for all block allocation, and a limited second level of CLECs who administer specific numbers. Accordingly, only the certificate for the number claimed in the current call needs to be sent during the handshake.

ciated territories (≈ 700 [46]) in just over 100 KiB of storage (1600 bits per certificate \times 700). Alternatively, if certificates are only needed for toll free numbers, a single certificate for the company that administers all such numbers (i.e., Somos, Inc.) would be sufficient.

Figure 6 shows the advantages of our approach. Communicating with a specific server (xyz.bankofamerica.com) may require the transmission of three or more certificates before identity can be verified. Additionally, the existence of different roots adds confusion to the legitimacy of any claimed identity. Our proposed TPKI relies on a single NANPA root, and takes advantage of the relatively small total number of CLECs to require only single certificate for the calling number to be transmitted during the handshake. We leave further discussion of the details of the proposed TPKI (e.g., revocation, etc) to our future work.

7.3 Deployment Considerations

As our experiments demonstrate that AuthLoop is bandwidth and not processor bound, we believe that these

techniques can be deployed successfully across a wide range of systems. For instance, AuthLoop can be embedded directly into new handset hardware. Moreover, it can be used immediately with legacy equipment through external adapters (e.g., Raspberry Pi). Alternatively, AuthLoop could be loaded onto mobile devices through a software update to the dialer, enabling large numbers of devices to immediately benefit.

Full deployments have the opportunity to make audio signaling of AuthLoop almost invisible to the user. If AuthLoop is in-line with the call audio, the system can remove AuthLoop transmissions from the audio sent to the user. In other words, users will never hear the AuthLoop handshakes or keep-alive messages. While our current strategy is to minimize the volume of the signaling so as to not interrupt a conversation (as has been done in other signaling research [62]), we believe that the in-line approach will ultimately provide the greatest stability and least intrusive user experience.

Lastly, we note that because AuthLoop is targeted across all telephony platforms, a range of security indicators will be necessary for successfully communicating authenticated identity to the user. However, given the limitations of space and the breadth of devices and their interfaces, we leave this significant exploration to our future work.

8 Conclusions

Phone systems serve as the trusted carriers of some of our most sensitive communications. In spite of this trust, authentication between two end points across this heterogeneous landscape was previously not possible. In this paper, we present AuthLoop to address this challenge. We began by designing a modem and supporting link layer protocol for the reliable delivery of data over a voice channel. With the limitations of this channel understood, we then presented a security model and protocol to provide explicit authentication of an assertion of Caller ID, and discussed ways in which client credentials could be subsequently protected. Finally, we demonstrated that AuthLoop reduced execution time by over an order of magnitude on average when compared to the direct application of TLS 1.2 to this problem. In so doing, we have demonstrated that end-to-end authentication is indeed possible across modern telephony networks.

Acknowledgment

Abstract

We propose new privacy attacks to infer attributes (e.g., locations, occupations, and interests) of online social network users. Our attacks leverage seemingly innocent user information that is publicly available in online social networks to infer missing attributes of targeted users. Given the increasing availability of (seemingly innocent) user information online, our results have serious implications for Internet privacy – private attributes can be inferred from users' publicly available data unless we take steps to protect users from such inference attacks.

To infer attributes of a targeted user, existing inference attacks leverage either the user's publicly available social friends or the user's behavioral records (e.g., the webpages that the user has liked on Facebook, the apps that the user has reviewed on Google Play), but not both. As we will show, such inference attacks achieve limited success rates. However, the problem becomes *qualitatively* different if we consider both social friends and behavioral records. To address this challenge, we develop a novel model to integrate social friends and behavioral records and design new attacks based on our model. We theoretically and experimentally demonstrate the effectiveness of our attacks. For instance, we observe that, in a real-world large-scale dataset with 1.1 million users, our attack can correctly infer the *cities a user lived in* for 57% of the users; via *confidence estimation*, we are able to increase the attack success rate to over 90% if the attacker selectively attacks a half of the users. Moreover, we show that our attack can correctly infer attributes for significantly more users than previous attacks.

1 Introduction

Online social networks (e.g., Facebook, Google+, and Twitter) have become increasingly important platforms for users to interact with each other, process information, and diffuse social influence. A user in an online social

network essentially has a list of social friends, a digital record of behaviors, and a profile. For instance, behavioral records could be a list of pages liked or shared by the user on Facebook, or they could be a set of mobile apps liked or rated by the user in Google+ or Google Play. A profile introduces the user's self-declared attributes such as majors, employers, and cities lived. To address users' privacy concerns, online social network operators provide users with fine-grained privacy settings, e.g., a user could limit some attributes to be accessible only to his/her friends. Moreover, a user could also create an account without providing any attribute information. *As a result, an online social network is a mixture of both public and private user information.*

One privacy attack of increasing interest revolves around these user attributes [18, 27, 46, 39, 15, 33, 11, 26, 42, 29, 8, 25, 20, 21, 23]. In this *attribute inference attack*, an attacker aims to propagate attribute information of social network users with publicly visible attributes to users with missing or incomplete attribute data. Specifically, the attacker could be any party (e.g., cyber criminal, online social network provider, advertiser, data broker, and surveillance agency) who has interests in users' private attributes. To perform such privacy attacks, the attacker only needs to collect publicly available data from online social networks. Apart from privacy risks, the inferred user attributes can also be used to perform various security-sensitive activities such as spear phishing [37] and attacking personal information based backup authentication [17]. Moreover, an attacker can leverage the inferred attributes to link online users across multiple sites [4, 14, 2, 13] or with offline records (e.g., publicly available voter registration records) [38, 32] to form composite user profiles, resulting in even bigger security and privacy risks.

Existing attribute inference attacks can be roughly classified into two categories, *friend-based* [18, 27, 46, 39, 15, 33, 11, 26, 20, 21, 23] and *behavior-based* [42, 29, 8, 25]. Friend-based attacks are based on the intu-

ition of *you are who you know*. Specifically, they aim to infer attributes for a user using the publicly available user attributes of the user’s friends (or all other users in the social network) and the social structure among them. The foundation of friend-based attacks is *homophily*, meaning that two linked users share similar attributes [30]. For instance, if more than half of friends of a user major in Computer Science at a certain university, the user might also major in Computer Science at the same university with a high probability. Behavior-based attacks infer attributes for a user based on the public attributes of users that are similar to him/her, and the similarities between users are identified by using their behavioral data. The intuition behind behavior-based attacks is *you are how you behave*. In particular, users with the same attributes have similar interests, characteristics, and cultures so that they have similar behaviors. For instance, if a user liked apps, books, and music tracks on Google Play that are similar to those liked by users originally from China, the user might also be from China. Likewise, previous measurement study [43] found that some apps are only popular in certain cities, implying the possibility of inferring cities a user lived in using the apps the user used or liked.

However, these inference attacks consider either social friendship structures or user behaviors, but not both, and thus they achieve limited inference accuracy as we will show in our experiments. Moreover, the problem of inferring user attributes becomes qualitatively different if we consider both social structures and user behaviors because features derived from them differ from each other, show different sparsity, and are at different scales. We show in our evaluation that simply concatenating features from the two sources of information regresses the overall results and reduces attack success rates.

Our work: In this work, we aim to combine social structures and user behaviors to infer user attributes. To this end, we first propose a *social-behavior-attribute (SBA)* network model to gracefully integrate social structures, user behaviors, and user attributes in a unified framework. Specifically, we add additional nodes to a social structure, each of which represents an attribute or a behavior; a link between a user and an attribute node represents that the user has the corresponding attribute, and that a user has a behavior is encoded by a link between the user and the corresponding behavior node.

Second, we design a *vote distribution attack (VIAL)* under the SBA model to perform attribute inference. Specifically, VIAL iteratively distributes a fixed vote capacity from a *targeted user* whose attributes we want to infer to all other users in the SBA network. A user receives a high vote capacity if the user and the targeted user are structurally similar in the SBA network, e.g., they have similar social structures and/or have performed similar behaviors. Then, each user votes for its attributes

via dividing its vote capacity to them. We predict the target user to own attributes that receive the highest votes.

Third, we evaluate VIAL both theoretically and empirically; and we extensively compare VIAL with several previous attacks for inferring majors, employers, and locations using a large-scale dataset with 1.1 million users collected from Google+ and Google Play. For instance, we observe that our attack can correctly infer the cities a user lived in for 57% of the users; via *confidence estimation*, we are able to increase the success rate to over 90% if the attacker selectively attacks a half of the users. Moreover, we find that our attack VIAL substantially outperforms previous attacks. Specifically, for Precision, VIAL improves upon friend-based attacks and behavior-based attacks by over 20% and around 100%, respectively. These results imply that an attacker can use our attack to successfully infer private attributes of substantially more users than previous attacks.

In summary, our key contributions are as follows:

- We propose the *social-behavior-attribute (SBA)* network model to integrate social structures, user behaviors, and user attributes.
- We design the *vote distribution attack (VIAL)* under the SBA model to perform attribute inference.
- We demonstrate the effectiveness of VIAL both theoretically and empirically. Moreover, we observe that VIAL correctly infers attributes for substantially more users than previous attacks via evaluations on a large-scale dataset collected from Google+ and Google Play.

2 Problem Definition and Threat Model

Attackers: The attacker could be any party who has interests in user attributes. For instance, the attacker could be a cyber criminal, online social network provider, advertiser, data broker, or surveillance agency. Cyber criminals can leverage user attributes to perform targeted social engineering attacks (now often referred to as spear phishing attacks [37]) and attacking personal information based backup authentication [17]; online social network providers and advertisers could use the user attributes for targeted advertisements; data brokers make profit via selling the user attribute information to other parties such as advertisers, banking companies, and insurance industries [1]; and surveillance agency can use the attributes to identify users and monitor their activities.

Collecting publicly available social structures and behaviors: To perform attribute inference attacks, an attacker first needs to collect publicly available information. In particular, in our attacks, an attacker needs to

collect social structures, user profiles, and user behaviors from online social networks. Such information can be collected via writing web crawlers or leveraging APIs developed by the service providers. Next, we formally describe these publicly available information.

We use an undirected¹ graph $G_s = (V_s, E_s)$ to represent a social structure, where edges in E_s represent social relationships between the nodes in V_s . We denote by $\Gamma_{u,S} = \{v | (u, v) \in E_s\}$ as the set of social neighbors of u . In addition to social network structure, we have behaviors and categorical attributes for nodes. For instance, in our Google+ and Google Play dataset, nodes are Google+ users, and edges represent friendship between users; behaviors include the set of items (e.g., apps, books, and movies) that users rated or liked on Google Play; and node attributes are derived from user profile information and include fields such as major, employer, and cities lived.

We use binary representation for user behaviors. Specifically, we treat various objects (e.g., the Android app “Angry Birds”, the movie “The Lord of the Rings”, and the webpage “facebook.com”) as binary variables, and we denote by m_b the total number of objects. Behaviors of a node u are then represented as a m_b -dimensional binary column vector \vec{b}_u with the i th entry equal to 1 when u has performed a certain action on the i th object (*positive behavior*) and -1 when u does not perform the action on it (*negative behavior*). For instance, when we consider user review behaviors for Google+ users, objects could be items such as apps, books, and movies available in Google Play, and the action is *review*; 1 represents that the user reviewed the corresponding item and -1 means the opposite. For Facebook users, objects could be webpages; 1 represents that the user liked or shared the corresponding webpage and -1 means that the user did not. We denote by $\mathbf{B} = [\vec{b}_1 \vec{b}_2 \cdots \vec{b}_{n_s}]$ the behavior matrix for all nodes.

We distinguish between *attributes* and *attribute values*. For instance, major, employer, and location are different attributes; and each attribute could have multiple attribute values, e.g., major could be Computer Science, Biology, or Physics. A user might own a few attribute values for a single attribute. For example, a user that studies Physics for undergraduate education but chooses to pursue a Ph.D. degree in Computer Science has two values for the attribute major. Again, we use a binary representation for each attribute value, and we denote the number of distinct attribute values as m_a . Then attribute information of a node u is represented as a m_a -dimensional binary column vector \vec{a}_u with the i th entry equal to 1 when u has the i th attribute value (*positive attribute*) and -1 when u does not have it (*negative attribute*).

¹Our attacks can also be generalized to directed graphs.

tribute). We denote by $\mathbf{A} = [\vec{a}_1 \vec{a}_2 \cdots \vec{a}_{n_s}]$ the attribute matrix for all nodes.

Attribute inference attacks: Roughly speaking, an attribute inference attack is to infer the attributes of a set of targeted users using the collected publicly available information. Formally, we define an attribute inference attack as follows:

Definition 1 (Attribute Inference Attack). *Suppose we are given $T = (G_s, \mathbf{A}, \mathbf{B})$, which is a snapshot of a social network G_s with a behavior matrix \mathbf{B} and an attribute matrix \mathbf{A} , and a list of targeted users V_t with social friends $\Gamma_{v,S}$ and binary behavior vectors \vec{b}_v for all $v \in V_t$, the attribute inference attack is to infer the attribute vectors \vec{a}_v for all $v \in V_t$.*

We note that a user setting the friend list to be private could also be vulnerable to inference attacks. This is because the user’s friends could set their friend lists publicly available. The attacker can collect a social relationship between two users if at least one of them sets the friend list to be public. Moreover, we assume the users and the service providers are not taking other steps (e.g., obfuscating social friends [19] or behaviors [42, 9]) to defend against inference attacks.

Applying inferred attributes to link users across multiple online social networks and with offline records: We stress that an attacker could leverage our attribute inference attacks to further perform other attacks. For instance, a user might provide different attributes on different online social networks. Thus, an attacker could combine user attributes across multiple online social networks to better profile users, and an attacker could leverage the inferred user attributes to do so [4, 14, 2, 13]. Moreover, an attacker can further use the inferred user attributes to link online users with offline records (e.g., voter registration records) [38, 32], which results in even bigger security and privacy risks, e.g., more sophisticated social engineering attacks. We note that even if the inferred user attributes (e.g., major, employer) seem not private for some targeted users, an attacker could use them to link users across multiple online sites and with offline records.

3 Social-Behavior-Attribute Framework

We describe our *social-behavior-attribute (SBA)* network model, which integrates social structures, user behaviors, and user attributes in a unified framework. To perform our inference attacks, an attacker needs to construct a SBA network from his/her collected publicly available social structures, user attributes, and behaviors.

Given a social network $G_s = (V_s, E_s)$ with m_b behavior objects, a behavior matrix \mathbf{B} , m_a distinct attribute values, and an attribute matrix \mathbf{A} , we create an augmented

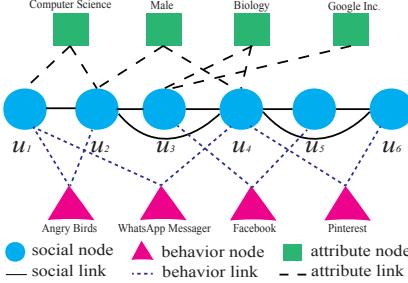

Figure 1: Social-behavior-attribute network.

network by adding m_b additional nodes to G_s , with each node corresponding to a behavior object, and another m_a additional nodes to G_s , with each additional node corresponding to an attribute value. For each node u in G_s with positive attribute a or positive behavior b , we create an undirected link between u and the additional node corresponding to a or b in the augmented network. Moreover, we add the targeted users into the augmented network by connecting them to their friends and the additional nodes corresponding to their positive behaviors. We call this augmented network *social-behavior-attribute (SBA)* network since it integrates the interactions among social structures, user behaviors, and user attributes.

Nodes in the SBA framework corresponding to nodes in G_s or targeted users in V_t are called *social nodes*, nodes representing behavior objects are called *behavior nodes*, and nodes representing attribute values are called *attribute nodes*. Moreover, we use S , B , and A to represent the three types of nodes, respectively. Links between social nodes are called *social links*, links between social nodes and behavior nodes are called *behavior links*, and links between social nodes and attribute nodes are called *attribute links*. Note that there are no links between behavior nodes and attribute nodes. Fig. 1 illustrates an example SBA network, in which the two social nodes u_5 and u_6 correspond to two targeted users. The behavior nodes in this example correspond to Android apps, and a behavior link represents that the corresponding user used the corresponding app. Intuitively, the SBA framework explicitly describes the sharing of behaviors and attributes across social nodes.

We also place weights on various links in the SBA framework. These link weights balance the influence of social links versus behavior links versus attribute links.² For instance, weights on social links could represent the tie strengths between social nodes. Users with stronger tie strengths could be more likely to share the same attribute values. The weight on a behavior link could in-

dicate the predictiveness of the behavior in terms of the user’s attributes. In other words, a behavior link with a higher weight means that performing the corresponding behavior better predicts the attributes of the user. For instance, if we want to predict user gender, the weight of the link between a female user and a mobile app tracking women’s monthly periods could be larger than the weight of the link between a male user and the app. Weights on attribute links can represent the degree of affinity between users and attribute values. For instance, an attribute link connecting the user’s hometown could have a higher weight than the attribute link connecting a city where the user once travelled. We discuss how link weights can be learnt via machine learning in Section 8.

We denote a SBA network as $G = (V, E, w, t)$, where V is the set of nodes, $n = |V|$ is the total number of nodes, E is the set of links, $m = |E|$ is the total number of links, w is a function that maps a link to its link weight, i.e., w_{uv} is the weight of link (u, v) , and t a function that maps a node to its node type, i.e., t_u is the node type of u . For instance, $t_u = S$ means that u is a social node. Additionally, for a given node u in the SBA network, we denote by Γ_u , $\Gamma_{u,S}$, $\Gamma_{u,B}$, and $\Gamma_{u,A}$ respectively the sets of *all neighbors*, *social neighbors*, *behavior neighbors*, and *attribute neighbors* of u . Moreover, for links that are incident from u , we use d_u , $d_{u,S}$, $d_{u,B}$, and $d_{u,A}$ to denote the sum of weights of all links, weights of links connecting social neighbors, weights of links connecting behavior neighbors, and weights of links connecting attribute neighbors, respectively. More specifically, we have $d_u = \sum_{v \in \Gamma_u} w_{uv}$ and $d_{u,Y} = \sum_{v \in \Gamma_{u,Y}} w_{uv}$, where $Y = S, B, A$.

Furthermore, we define two types of *hop-2 social neighbors* of a social node u , which share common behavior neighbors or attribute neighbors with u . In particular, a social node v is called a *behavior-sharing social neighbor* of u if v and u share at least one common behavior neighbor. For instance, in Fig. 1, both u_2 and u_4 are behavior-sharing social neighbors of u_1 . We denote the set of behavior-sharing social neighbors of u as $\Gamma_{u,BS}$. Similarly, we denote the set of attribute-sharing social neighbors of u as $\Gamma_{u,AS}$. Formally, we have $\Gamma_{u,BS} = \{v | t(v) = S \& \Gamma_{v,B} \cap \Gamma_{u,B} \neq \emptyset\}$ and $\Gamma_{u,AS} = \{v | t(v) = S \& \Gamma_{v,A} \cap \Gamma_{u,A} \neq \emptyset\}$. We note that our definitions of $\Gamma_{u,BS}$ and $\Gamma_{u,AS}$ also include the social node u itself. These notations will be useful in describing our attack.

4 Vote Distribution Attack (VIAL)

4.1 Overview

Suppose we are given a SBA network G which also includes the social structures and behaviors of the targeted users, our goal is to infer attributes for every targeted user. Specifically, for each targeted user v , we compute

²In principle, we could also assign weights to nodes to incorporate their relative importance. However, our attack does not rely on node weights, so we do not discuss them.

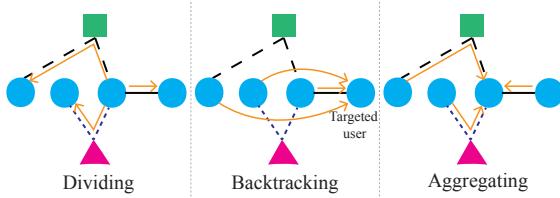

Figure 2: Illustration of our three local rules.

the similarity between v and each attribute value, and then we predict that v owns the attribute values that have the highest similarity scores. In a high-level abstraction, VIAL works in two phases.

- **Phase I.** VIAL iteratively distributes a fixed vote capacity from the targeted user v to the rest of users in Phase I. The intuitions are that a user receives a high vote capacity if the user and the targeted user are structurally similar in the SBA network (e.g., share common friends and behaviors), and that the targeted user is more likely to have the attribute values belonging to users with higher vote capacities. After Phase I, we obtain a vote capacity vector \vec{s}_v , where \vec{s}_{vu} is the vote capacity of user u .
- **Phase II.** Intuitively, if a user with a certain vote capacity has more attribute values, then, according to the information of this user alone, the likelihood of each of these attribute values belonging to the targeted user decreases. Moreover, an attribute value should receive more votes if more users with higher vote capacities have the attribute value. Therefore, in Phase II, each social node votes for its attribute values via dividing its vote capacity among them, and each attribute value sums the vote capacities that are divided to it by its social neighbors. We treat the summed vote capacity of an attribute value as its similarity with v . Finally, we predict v has the attribute values that receive the highest votes.

4.2 Phase I

In Phase I, VIAL iteratively distributes a fixed vote capacity from the targeted user v to the rest of users. We denote by $\vec{s}_v^{(i)}$ the vote capacity vector in the i th iteration, where $\vec{s}_{vu}^{(i)}$ is the vote capacity of node u in the i th iteration. Initially, v has a vote capacity $|V_s|$ and all other social nodes have vote capacities of 0. Formally, we have:

$$\vec{s}_{vu}^{(0)} = \begin{cases} |V_s| & \text{if } u = v \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

In each iteration, VIAL applies three local rules. They are *dividing*, *backtracking*, and *aggregating*. Intuitively,

if a user u has more (hop-2) social neighbors, then each neighbor could receive less vote capacity from u . Therefore, our dividing rule splits a social node's vote capacity to its social neighbors and hop-2 social neighbors. The backtracking rule takes a portion of every social node's vote capacity and assigns them back to the targeted user v , which is based on the intuition that social nodes that are closer to v in the SBA network are likely to be more similar to v and should get more vote capacities. A user could have a higher vote capacity if it is linked to more social neighbors and hop-2 social neighbors with higher vote capacities. Thus, for each user u , the aggregating rule collects the vote capacities that are shared to u by its social neighbors and hop-2 social neighbors. Fig. 2 illustrates the three local rules. Next, we elaborate the three local rules.

Dividing: A social node u could have social neighbors, behavior-sharing social neighbors, and attribute-sharing social neighbors. To distinguish them, we use three weights w_S , w_{BS} , and w_{AS} to represent the shares of them, respectively. For instance, the total vote capacity shared to social neighbors of u in the t th iteration is $\vec{s}_{vu}^{(t-1)} \times \frac{w_S}{w_S + w_{BS} + w_{AS}}$. Then we further divide the vote capacity among each type of neighbors according to their link weights. We define $I_{u,Y} = 1$ if the set of neighbors $\Gamma_{u,Y}$ is non-empty, otherwise $I_{u,Y} = 0$, where $Y = S, BS, AS$. The variables $I_{u,S}$, $I_{u,BS}$, and $I_{u,AS}$ are used to consider the scenarios where u does not have some type(s) of neighbors, in which u 's vote capacity is divided among less than three types of social neighbors. For convenience, we denote $w_T = w_S I_{u,S} + w_{BS} I_{u,BS} + w_{AS} I_{u,AS}$.

- **Social neighbors.** A social neighbor $x \in \Gamma_{u,S}$ receives a higher vote capacity from u if their link weight (e.g., tie strength) is higher. Therefore, we model the vote capacity $p_v^{(i)}(u,x)$ that is divided to x by u in the i th iteration as:

$$p_v^{(i)}(u,x) = \vec{s}_{vu}^{(i-1)} \cdot \frac{w_S}{w_T} \cdot \frac{w_{ux}}{d_{u,S}}, \quad (2)$$

where $d_{u,S}$ is the summation of weights of social links that are incident from u .

- **Behavior-sharing social neighbors.** A behavior-sharing social neighbor $x \in \Gamma_{u,BS}$ receives a higher vote capacity from u if they share more behavior neighbors with higher predictiveness. Thus, we model vote capacity $q_v^{(i)}(u,x)$ that is divided to x by u in the i th iteration as:

$$q_v^{(i)}(u,x) = \vec{s}_{vu}^{(i-1)} \cdot \frac{w_{BS}}{w_T} \cdot w_B(u,x), \quad (3)$$

where $w_B(u,x) = \sum_{y \in \Gamma_{u,B} \cap \Gamma_{x,B}} \frac{w_{uy}}{d_{u,B}} \cdot \frac{w_{xy}}{d_{y,S}}$, representing the overall share of vote capacity that u divides

to x because of their common behavior neighbors. Specifically, $\frac{w_{uy}}{d_{u,B}}$ characterizes the fraction of vote capacity u divides to the behavior neighbor y and $\frac{w_{xy}}{d_{y,S}}$ characterizes the fraction of vote capacity y divides to x . Large weights of w_{uy} and w_{xy} indicate y is a predictive behavior of the attribute values of u and x , and having more such common behavior neighbors make x share more vote capacity from u .

- **Attribute-sharing social neighbors.** An attribute-sharing social neighbor $x \in \Gamma_{u,AS}$ receives a higher vote capacity from u if they share more attribute neighbors with higher degree of affinity. Thus, we model vote capacity $r_v^{(i)}(u,x)$ that is divided to x by u in the i th iteration as:

$$r_v^{(i)}(u,x) = \vec{s}_{vu}^{(i-1)} \cdot \frac{w_{AS}}{w_T} \cdot w_A(u,x), \quad (4)$$

where $w_A(u,x) = \sum_{y \in \Gamma_{u,A} \cap \Gamma_{x,A}} \frac{w_{uy}}{d_{u,A}} \cdot \frac{w_{xy}}{d_{y,S}}$, representing the overall share of vote capacity that u divides to x because of their common attribute neighbors. Specifically, $\frac{w_{uy}}{d_{u,A}}$ characterizes the fraction of vote capacity u divides to the attribute neighbor y and $\frac{w_{xy}}{d_{y,S}}$ characterizes the fraction of vote capacity y divides to x . Large weights of w_{uy} and w_{xy} indicate y is an attribute value with a high degree of affinity, and having more such common attribute values make x share more vote capacity from u .

We note that a social node x could be multiple types of social neighbors of u (e.g., x could be social neighbor and behavior-sharing social neighbor of u), in which x receives multiple shares of vote capacity from u and we sum them as x 's final share of vote capacity.

Backtracking: For each social node u , the backtracking rule takes a portion α of u 's vote capacity back to the targeted user v . Specifically, the vote capacity backtracked to v from u is $\alpha \vec{s}_{vu}^{(i-1)}$. Considering backtracking, the vote capacity divided to the social neighbor x of u in the dividing step is modified as $(1 - \alpha)p_v^{(i)}(u,x)$. Similarly, the vote capacities divided to a behavior-sharing social neighbor and an attribute-sharing social neighbor x are modified as $(1 - \alpha)q_v^{(i)}(u,x)$ and $(1 - \alpha)r_v^{(i)}(u,x)$, respectively. We call the parameter α *backtracking strength*. A larger backtracking strength enforces more vote capacity to be distributed among the social nodes that are closer to v in the SBA network. $\alpha = 0$ means no backtracking. We will show that, via both theoretical and empirical evaluations, VIAL achieves better accuracy with backtracking.

We can verify that $\sum_{x \in \Gamma_{u,S}} \frac{w_{ux}}{d_{u,S}} = 1$, $\sum_{x \in \Gamma_{u,BS}} w_B(u,x) = 1$, and $\sum_{x \in \Gamma_{u,AS}} w_A(u,x) = 1$ for every user u in the dividing step. In other words, every user divides all its

13     $error \leftarrow |\vec{s}_v^{(i)} - \vec{s}_v^{(i-1)}| / |V_s|$ 
14  end
15  return  $\vec{s}_v^{(i)}$ 
16 end

```

vote capacity to its neighbors (including the user itself if the user has hop-2 social neighbors). Therefore, the total vote capacity keeps unchanged in every iteration, and the vote capacity that is backtracked to the targeted user is $\alpha|V_s|$.

Aggregating: The aggregating rule computes a new vote capacity for u by aggregating the vote capacities that are divided to u by its neighbors in the i th iteration. For the targeted user v , we also collect the vote capacities that are backtracked from all social nodes. Formally, our aggregating rule is represented as Equation 5.

Matrix representation: We derive the Phase I of our attack using matrix terminologies, which makes it easier to iteratively compute the vote capacities. Towards this end, we define a *dividing matrix* $\mathbf{M} \in R^{|V_s| \times |V_s|}$, which is formally represented in Equation 6. The dividing matrix encodes the dividing rule. Specifically, u divides \mathbf{M}_{ux} fraction of its vote capacity to the neighbor x in the dividing step. Note that \mathbf{M} includes the dividing rule for all three types of social neighbors. With the dividing matrix \mathbf{M} , we can represent the backtracking and aggregating rules in the i th iteration as follows:

$$\vec{s}_v^{(i)} = \alpha \vec{e}_v + (1 - \alpha) \mathbf{M}^T \vec{s}_v^{(i-1)}, \quad (7)$$

where \vec{e}_v is a vector with the v th entry equals $|V_s|$ and all other entries equal 0, and \mathbf{M}^T is the transpose of \mathbf{M} .

Given an initial vote capacity vector specified in Equation 1, we iteratively apply Equation 7 until the difference between the vectors in two consecutive iterations is smaller than a predefined threshold. Algorithm 1 shows Phase I of our attack.

Our aggregating rule to compute the new vote capacity $\vec{s}_{vu}^{(i)}$ for u :

$$\vec{s}_{vu}^{(i)} = \begin{cases} (1 - \alpha)(\sum_{x \in \Gamma_{u,S}} p_v^{(i)}(x, u) + \sum_{x \in \Gamma_{u,BS}} q_v^{(i)}(x, u) + \sum_{x \in \Gamma_{u,AS}} r_v^{(i)}(x, u)) & \text{if } u \neq v \\ (1 - \alpha)(\sum_{x \in \Gamma_{u,S}} p_v^{(i)}(x, u) + \sum_{x \in \Gamma_{u,BS}} q_v^{(i)}(x, u) + \sum_{x \in \Gamma_{u,AS}} r_v^{(i)}(x, u)) + \alpha|V_s| & \text{otherwise} \end{cases} \quad (5)$$

Our dividing matrix:

$$\mathbf{M}_{ux} = \begin{cases} \delta_{ux,S} \cdot \frac{w_S}{w_T} \cdot \frac{w_{ux}}{d_{u,S}} + \delta_{ux,BS} \cdot \frac{w_{BS}}{w_T} \cdot w_B(u, x) + \delta_{ux,AS} \cdot \frac{w_{AS}}{w_T} \cdot w_A(u, x) & \text{if } x \in \Gamma_{u,S} \cup \Gamma_{u,BS} \cup \Gamma_{u,AS} \\ 0 & \text{otherwise,} \end{cases} \quad (6)$$

where $\delta_{ux,Y} = 1$ if $x \in \Gamma_{u,Y}$, otherwise $\delta_{ux,Y} = 0$, $Y = S, BS, AS$.

4.3 Phase II

In Phase I, we obtained a vote capacity for each user. On one hand, the targeted user could be more likely to share attribute values with the users with higher vote capacities. On the other hand, if a user has more attribute values, then the likelihood of each of these attribute values belonging to the targeted user could be smaller. For instance, if a user with a high vote capacity once studied in more universities for undergraduate education, then according to this user's information alone, the likelihood of the targeted user studying in each of those universities could be smaller.

Moreover, among a user's attribute values, an attribute value that has a higher degree of affinity (represented by the weight of the corresponding attribute link) with the user could be more likely to be an attribute value of the targeted user. For instance, suppose a user once lived in two cities, one of which is the user's hometown while the other of which is a city where the user once travelled; the user has a high vote capacity because he/she is structurally close (e.g., he/she shares many common friends with the targeted user) to the targeted user; then the targeted user is more likely to be from the hometown of the user than from the city the user once travelled.

Therefore, to capture these observations, we divide the vote capacity of a user to its attribute values in proportion to the weights of its attribute links; and each attribute value sums the vote capacities that are divided to it by the users having the attribute value. Intuitively, an attribute value receives more votes if more users with higher vote capacities link to the attribute value via links with higher weights. Formally, we have

$$\vec{t}_{va} = \sum_{u \in \Gamma_{a,S}} \vec{s}_{vu} \cdot \frac{w_{au}}{d_{u,A}}, \quad (8)$$

where \vec{t}_{va} is the final votes of the attribute value a , $\Gamma_{a,S}$ is the set of users who have the attribute value a , $d_{u,A}$ is the sum of weights of attribute links that are incident from u .

We treat the summed votes of an attribute value as its similarity with v . Finally, we predict v has the attribute values that receive the highest votes.

4.4 Confidence Estimation

For a targeted user, a *confidence estimator* takes the final votes for all attribute values as an input and produces a confidence score. A higher confidence score means that attribute inference for the targeted user is more trustworthy. We design a confidence estimator based on clustering techniques. A targeted user could have multiple attribute values for a single attribute, and our attack could produce close votes for these attribute values. Therefore, we design a confidence estimator called *clusterness* for our attack. Specifically, we first use a clustering algorithm (e.g., k-means [24]) to group the votes that our attack produces for all candidate attribute values into two clusters. Then we compute the average vote in each cluster, and the clusterness is the difference between the two average votes. The intuition of our clusterness is that if our attack successfully infers the targeted user's attribute values, there could be a cluster of attribute values whose votes are significantly higher than other attribute values'.

Suppose the attacker chooses a confidence threshold and only predicts attributes for targeted users whose confidence scores are higher than the threshold. Via setting a larger confidence threshold, the attacker will attack less targeted users but could achieve a higher success rate. In other words, an attacker can balance between the success rates and the number of targeted users to attack via confidence estimation.

5 Theoretical Analysis

We analyze the convergence of VIAL and derive the analytical forms of vote capacity vectors, discuss the importance of the backtracking rule, and analyze the complexity of VIAL.

5.1 Convergence and Analytical Solutions

We first show that for any backtracking strength $\alpha \in (0, 1]$, the vote capacity vectors converge.

Theorem 1. *For any backtracking strength $\alpha \in (0, 1]$, the vote capacity vectors $\vec{s}_v^{(0)}, \vec{s}_v^{(1)}, \vec{s}_v^{(2)}, \dots$ converge, and the converged vote capacity vector is $\alpha(I - (1 - \alpha)\mathbf{M}^T)^{-1}\vec{e}_v$. Formally, we have:*

$$\vec{s}_v = \lim_{i \rightarrow \infty} \vec{s}_v^{(i)} = \alpha(I - (1 - \alpha)\mathbf{M}^T)^{-1}\vec{e}_v, \quad (9)$$

where I is an identity matrix and $(I - (1 - \alpha)\mathbf{M}^T)^{-1}$ is the inverse of $(I - (1 - \alpha)\mathbf{M}^T)$.

Proof. See Appendix A. \square

Next, we analyze the convergence of VIAL and the analytical form of the vote capacity vector when the backtracking strength $\alpha = 0$.

Theorem 2. *When $\alpha = 0$ and the SBA network is connected, the vote capacity vectors $\vec{s}_v^{(0)}, \vec{s}_v^{(1)}, \vec{s}_v^{(2)}, \dots$ converge, and the converged vote capacity vector is proportional to the unique stationary distribution of the Markov chain whose transition matrix is \mathbf{M} . Mathematically, the converged vote capacity vector \vec{s}_v can be represented as:*

$$\vec{s}_v = |V_s| \vec{\pi}, \quad (10)$$

where $\vec{\pi}$ is the unique stationary distribution of the Markov chain whose transition matrix is \mathbf{M} .

Proof. See Appendix B. \square

With Theorem 2, we have the following corollary, which states that the vote capacity of a user is proportional to its weighted degree for certain assignments of the shares of social neighbors and hop-2 social neighbors in the dividing step.

Corollary 1. *When $\alpha = 0$, the SBA network is connected, and for each user u , the shares of social neighbors, behavior-sharing social neighbors, and attribute-sharing social neighbors in the dividing step are $w_S = \tau \cdot d_{u,S}$, $w_{BS} = \tau \cdot d_{u,B}$, and $w_{AS} = \tau \cdot d_{u,A}$, respectively, then we have:*

$$\vec{s}_{vu} = |V_s| \frac{d_u}{D}, \quad (11)$$

where τ is any positive number, d_u is the weights of all links of u and D is the twice of the total weights of all links in the SBA network, i.e., $D = \sum_u d_u$.

Proof. See Appendix C. \square

5.2 Importance of Backtracking

Theorem 2 implies that when there is no backtracking, the converged vote capacity vector is independent with the targeted users. In other words, VIAL with no backtracking predicts the same attribute values for all targeted users. This explains why VIAL with no backtracking achieves suboptimal performance. We will further empirically evaluate the impact of backtracking strength in our experiments, and we found that VIAL’s performance significantly degrades when there is no backtracking.

5.3 Time Complexity

The major cost of VIAL is from Phase I, which includes computing \mathbf{M} and iteratively computing the vote capacity vector. \mathbf{M} only needs to be computed once and is applied to all targeted users. \mathbf{M} is a sparse matrix with $O(m)$ non-zero entries, where m is the number of links in the SBA network. To compute \mathbf{M} , for every social node, we need to go through its social neighbors and hop-2 social neighbors; and for a hop-2 social neighbor, we need to go through the common attribute/behavior neighbors between the social node and the hop-2 social neighbor. Therefore, the time complexity of computing \mathbf{M} is $O(m)$.

Using sparse matrix representation of \mathbf{M} , the time complexity of each iteration (i.e., applying Equation 7) in computing the vote capacity vector is $O(m)$. Therefore, the time complexity of computing the vote capacity vector for one targeted user is $O(d \cdot m)$, where d is the number of iterations. Thus, the overall time complexity of VIAL is $O(d \cdot m)$ for one targeted user.

6 Data Collection

We collected a dataset from Google+ and Google Play to evaluate our VIAL attack and previous attacks. Specifically, we collected social structures and user attributes from Google+, and user review behaviors from Google Play. Google assigns each user a 21-digit universal ID, which is used in both Google+ and Google Play. We first collected a social network with user attributes from Google+ via iteratively crawling users’ friends. Then we crawled review data of users in the Google+ dataset. All the information that we collected is publicly available.

6.1 Google+ Dataset

Each user in Google+ has an outgoing friend list (i.e., “in your circles”), an incoming friend list (i.e., “have you in circles”), and a profile. Shortly after Google+ was launched in late June 2011, Gong et al. [16, 15] began to crawl daily snapshots of public Google+ social network structure and user profiles (e.g., *major*, *employer*,

and *cities lived*). Their dataset includes 79 snapshots of Google+ collected from July 6 to October 11, 2011. Each snapshot was a large Weakly Connected Component of Google+ social network at the time of crawling.

We obtained one collected snapshot from Gong et al. [16, 15]. To better approximate friendships between users, we construct an undirected social network from the crawled Google+ dataset via keeping an undirected link between a user u and v if u is in v 's both incoming friend list and outgoing friend list. After preprocessing, our Google+ dataset consists of 1,111,905 users and 5,328,308 undirected social links.

User attributes: We consider three attributes, *major*, *employer*, and *cities lived*. We note that, although we focus on these attributes that are available to us at a large scale, our attack is also applicable to infer other attributes such as sexual orientation, political views, and religious views. Moreover, some targeted users might not view inferring these attributes as an privacy attack, but an attacker can leverage these attributes to further link users across online social networks [4, 14, 2, 13] or even link them with offline records to perform more serious security and privacy attacks [38, 32].

We take the strings input by a user in its Google+ profile as attribute values. We found that most attribute values are owned by a small number of users while some are owned by a large number of users. Users could fill in their profiles freely in Google+, which could be one reason that we observe many infrequent attribute values. Specifically, different users might have different names for the same attribute value. For instance, the major of Computer Science could also be abbreviated as CS by some users. Indeed, we find that 20,861 users have Computer Science as their major and 556 users have CS as their major in our dataset. Moreover, small typos (e.g., one letter is incorrect) in the free-form inputs make the same attribute value be treated as different ones. Therefore, we manually label a set of attribute values.

1) *Major*. We consider the top-100 majors that are claimed by the most users. We manually merge the majors that actually refer to the same one, e.g., Computer Science and CS, BTech and Biotechnology. After preprocessing, we obtain 62 distinct majors. 8.4% of users in our dataset have at least one of these majors.

2) *Employer*. Similar to major, we select the top-100 employers that are claimed by the most users and manually merge the employers that refer to the same one. We obtain 78 distinct employers, and 3.1% of users have at least one of these employers.

3) *Cities lived*. Again, we select the top-100 cities in which most users in the Google+ dataset claimed they have lived in. After we manually merge the cities that actually refer to the same one, we obtain 70 distinct cities. 8% of users have at least one of these attribute values.

Table 1: Basic statistics of our SBA.

#nodes			#links		
social	behavior	attri.	social	behavior	attri.
1,111,905	48,706	210	5,328,308	3,635,231	269,997

Summary and limitations: In total, we consider 210 popular distinct attribute values, including 62 majors, 78 employers, and 70 cities. We acknowledge that our Google+ dataset might not be a representative sample of the recent entire Google+ social network, and thus the inference attack success rates obtained in our experiments might not represent those of the entire Google+ social network.

6.2 Crawling Google Play

There are 7 categories of items in Google Play. They are *apps*, *tv*, *movies*, *music*, *books*, *newsstand*, and *devices*. Google Play provides two review mechanisms for users to provide feedback on an item. They are the *liking* mechanism and the *rating* mechanism. In the liking mechanism, a user simply clicks a like button to express his preference about an item. In the rating mechanism, a user gives a rating score which is in the set {1,2,3,4,5} as well as a detailed comment to support his/her rating. A score of 1 represents low preference and a score of 5 represents high preference. We call a user *reviewed* an item if the user rated or liked the item.

User reviews are publicly available in Google Play. Specifically, after a user u logs in Google Play, u can view the list of items reviewed by any user v once u can obtain v 's Google ID. We crawled the list of items re-reviewed by each user in the Google+ dataset.

We find that 33% of users in the Google+ dataset have reviewed at least one item. In total, we collected 260,245 items and 3,954,822 reviews. Since items with too few reviews might not be informative to distinguish users with different attribute values, we use items that were re-reviewed by at least 5 users. After preprocessing, we have 48,706 items and 3,635,231 reviews.

6.3 Constructing SBA Networks

We take each user in the Google+ dataset as a social node and links between them as social links. For each item in our Google Play dataset, we add a corresponding behavior node. If a user reviewed an item, we create a link between the corresponding social node and the corresponding behavior node. That a user reviewed an item means that the user once used the item. Using similar items could indicate similar interests, user characteristics, and user attributes. To predict attribute values, we further

add additional attribute nodes to represent attribute values, and we create a link between a social node and an attribute node if the user has the attribute value. Table 1 shows the basic statistics of our constructed SBA for predicting attribute values.

In this work, we set the weights of all links in the SBA to be 1. Therefore, our attacking result represents a lower bound on what an attacker can achieve in practice. An attacker could leverage machine learning techniques (we discuss one in Section 8) to learn link weights to further improve success rates.

7 Experiments

7.1 Experimental Setup

We describe the metrics we adopt to evaluate various attacks, training and testing, and parameter settings.

Evaluation metrics: All attacks we evaluate essentially assign a score for each candidate attribute value. Given a targeted user v , we predict top- K candidate attribute values that have the highest scores for each attribute including major, employer, and cities lived. We use Precision, Recall, and F-score to evaluate the top- K predictions. In particular, Precision is the fraction of predicted attribute values that belong to v . Recall is the fraction of v 's attribute values that are among the predicted K attribute values. We address score ties in the manner described by McSherry and Najork [31]. Precision characterizes how accurate an attacker's inferences are while Recall characterizes how many user attributes are correctly inferred by an attacker. In particular, Precision for top-1 prediction is the fraction of users that the attacker can correctly infer at least one attribute value. F-score is the harmonic mean of Precision and Recall, i.e., we have

$$\text{F-score} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}.$$

Moreover, we average the three metrics over all targeted users. For convenience, we will also use P, R, and F to represent Precision, Recall, and F-Score, respectively.

We also define *performance gain* and *relative performance gain* of one attack \mathcal{A} over another attack \mathcal{B} to compare their relative performances. We take Precision as an example to show their definitions as follows:

Performance gain:

$$\Delta P = \text{Precision}_{\mathcal{A}} - \text{Precision}_{\mathcal{B}}$$

Relative performance gain:

$$\Delta P\% = \frac{\text{Precision}_{\mathcal{A}} - \text{Precision}_{\mathcal{B}}}{\text{Precision}_{\mathcal{B}}} \times 100\%$$

Training and testing: For each attribute value, we sample 5 users uniformly at random from the users that have the attribute value and have reviewed at least 5 items, and we treat them as test (i.e., targeted) users. In total, we have around 1,050 test users. For test users, we remove their attribute links from the SBA network and use them as groundtruth. We repeat the experiments 10 times and average the evaluation metrics over the 10 trials.

Parameter settings: In the dividing step, we set equal shares for social neighbors, behavior-sharing social neighbors, and attribute-sharing social neighbors, i.e., $w_S = w_{BS} = w_{AS} = \frac{1}{3}$. The number of iterations to compute the vote capacity vector is $d = \lfloor \log |V_s| \rfloor = 20$, after which the vote capacity vector converges. Unless otherwise stated, we set the backtracking strength $\alpha = 0.1$.

7.2 Compared Attacks

We compare VIAL with friend-based attacks, behavior-based attacks, and attacks that use both social structures and behaviors. These attacks essentially assign a score for each candidate attribute value, and return the K attribute values that have the highest scores. Suppose v is a test user and a is an attribute value, and we denote by $S(v, a)$ the score assigned to a for v .

Random: This baseline method computes the fraction of users in the training dataset that have a certain attribute value a , and it treats such fraction as the score $S(v, a)$ for all test users.

Friend-based attacks: We compare with three friend-based attacks, i.e., CN-SAN, AA-SAN, and RWwR-SAN [15]. They were shown to outperform previous attacks such as LINK [46, 15].

- **CN-SAN.** $S(v, a)$ is the number of common social neighbors between v and a .
- **AA-SAN.** This attack weights the importance of each common social neighbor between v and a proportional to the inverse of the log of its number of neighbors. Formally, $S(v, a) = \sum_{u \in \Gamma_{v,S} \cap \Gamma_{a,S}} \frac{1}{\log |\Gamma_u|}$.
- **RWwR-SAN.** RWwR-SAN augments the social network with additional attribute nodes. Then it performs a random walk that is initialized from the test user v on the augmented graph. The stationary probability of the attribute node that corresponds to a is treated as the score $S(v, a)$.

Behavior-based attacks: We also evaluate three behavior-based attacks.

- **Logistic regression (LG-B-I) [42].** LG-B-I treats each attribute value as a class and learns a multi-class logistic regression classifier with the training

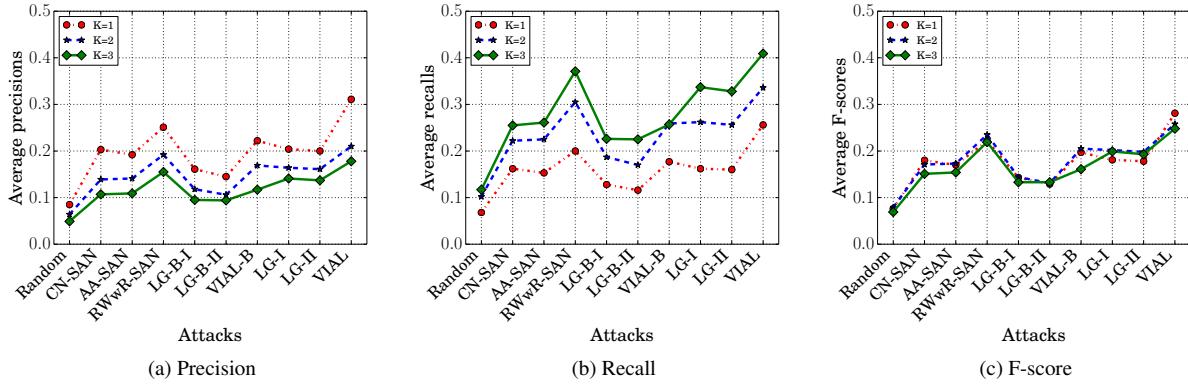

Figure 3: Precision, Recall, and F-Score for inferring majors. Although these attacks do not have temporal orderings, we connect them via curves in the figures to better contrast them.

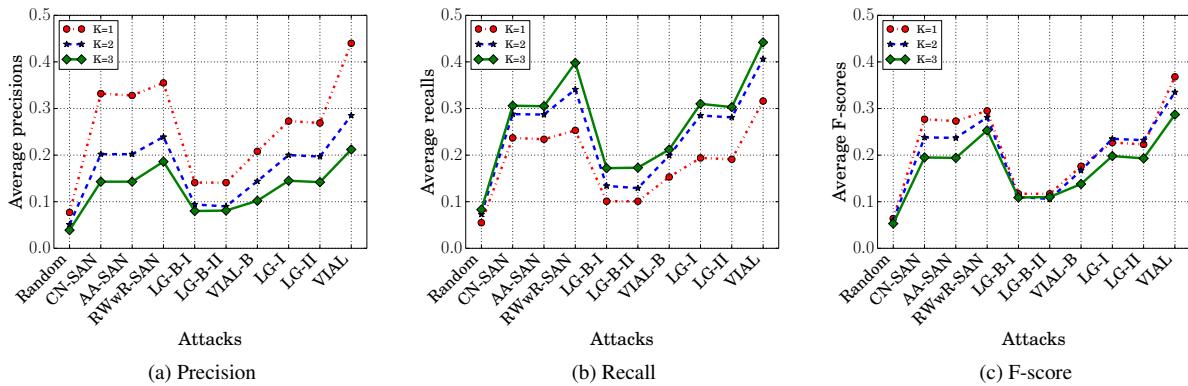

Figure 4: Precision, Recall, and F-Score for inferring employers.

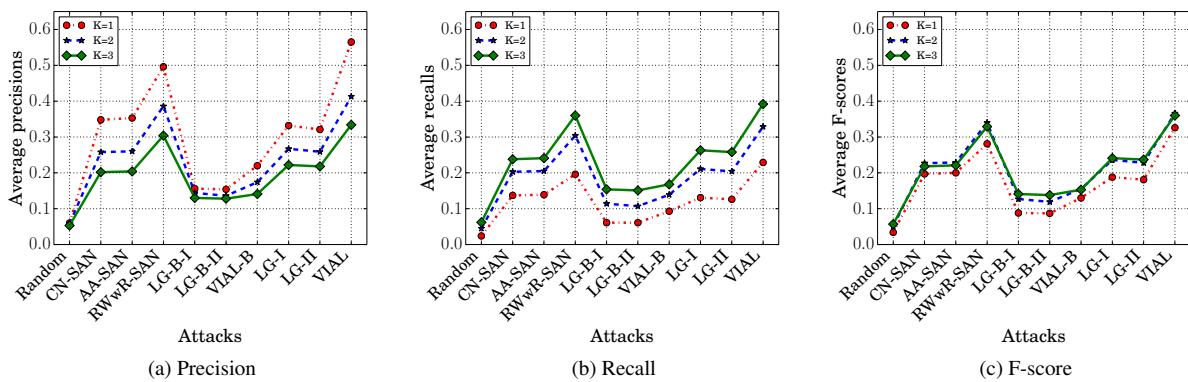

Figure 5: Precision, Recall, and F-Score for inferring cities.

Table 2: Performance gains and relative performance gains of RWwR-SAN over other friend-based attacks, where $K = 1$. Results are averaged over all attributes. We find that RWwR-SAN is the best friend-based attack.

Attack	ΔP	$\Delta P\%$	ΔR	$\Delta R\%$	ΔF	$\Delta F\%$
CN-SAN	0.07	24%	0.04	24%	0.05	24%
AA-SAN	0.08	26%	0.04	26%	0.05	26%

Table 3: Performance gains and relative performance gains of VIAL-B over other behavior-based attacks, where $K = 1$. We find that VIAL-B is the best behavior-based attack.

Attack	ΔP	$\Delta P\%$	ΔR	$\Delta R\%$	ΔF	$\Delta F\%$
LG-B-I	0.06	42%	0.04	47%	0.05	45%
LG-B-II	0.07	47%	0.05	52%	0.06	50%

dataset. Specifically, LG-B-I extracts a feature vector whose length is the number of items for each user that has review data, and a feature has a value of the rating score that the user gave to the corresponding item. Google Play allows users to rate or like an item, and we treat a liking as a rating score of 5. For a test user, the learned logistic regression classifier returns a posterior probability distribution over the possible attribute values, which are used as the scores $S(v, a)$. Weinsberg et al. [42] showed that logistic regression classifier outperforms other classifiers including SVM [10] and Naive Bayes [29].

- **Logistic regression with binary features (LG-B-II) [25].** The difference between LG-B-II and LG-B-I is that LG-B-II extracts binary feature vectors for users. Specifically, a feature has a value of 1 if the user has reviewed the corresponding item.
- **VIAL-B.** A variant of VIAL that only uses behavior data. Specifically, we remove social links from the SBA network and perform our VIAL attack using the remaining links.

Attacks combining social structures and behaviors: Intuitively, we can combine social structures and behaviors via concatenating social structure features with behavior features. We compare with two such attacks.

- **Logistic regression (LG-I).** LG-I extracts a binary feature vector whose length is the number of users from social structures for each user, and a feature has a value of 1 if the user is a friend of the person that corresponds to the feature. Then LG-I concatenates this feature vector with the one used in LG-B-I and learns multi-class logistic regression classifiers.

Table 4: Performance gains and relative performance gains of VIAL over other attacks combining social structures and behaviors, where $K = 1$. We find that VIAL substantially outperforms other attacks.

Attack	ΔP	$\Delta P\%$	ΔR	$\Delta R\%$	ΔF	$\Delta F\%$
LG-I	0.17	61%	0.10	65%	0.13	63%
LG-II	0.18	65%	0.11	69%	0.13	67%

Table 5: Performance gains and relative performance gains of VIAL over Random, RWwR-SAN (the best friend-based attack), and VIAL-B (the best behavior-based attack), where $K = 1$.

Attack	ΔP	$\Delta P\%$	ΔR	$\Delta R\%$	ΔF	$\Delta F\%$
Random	0.36	526%	0.22	535%	0.27	534%
RWwR-SAN	0.07	20%	0.05	23%	0.06	22%
VIAL-B	0.22	102%	0.13	99%	0.16	100%

- **Logistic regression with binary features (LG-II).** LG-II concatenates the binary social structure feature vector with the binary behavior feature vector used by LG-B-II.

We use the popular package LIBLINEAR [12] to learn logistic regression classifiers.

7.3 Results

Fig. 3-Fig. 5 demonstrate the Precision, Recall, and F-score for top- K inference of major, employer, and city, where $K = 1, 2, 3$. Table 2-Table 5 compare different attacks using results that are averaged over all attributes. Our metrics are averaged over 10 trials. We find that standard deviations of the metrics are very small, and thus we do not show them for simplicity. Next, we describe several key observations we have made from these results.

Comparing friend-based attacks: We find that RWwR-SAN performs the best among the friend-based attacks. Our observation is consistent with the previous work [15]. To better illustrate the difference between the friend-based attacks, we show the performance gains and relative performance gains of RWwR-SAN over other friend-based attacks in Table 2. Please refer to Section 7.1 for formal definitions of (relative) performance gains. The (relative) performance gains are averaged over all attributes (i.e., major, employer, and city). The reason why RWwR-SAN outperforms other friend-based attacks is that RWwR-SAN performs a random walk among the augmented graph, which better leverages the graph structure, while other attacks simply count the number of common neighbors or weighted common neighbors.

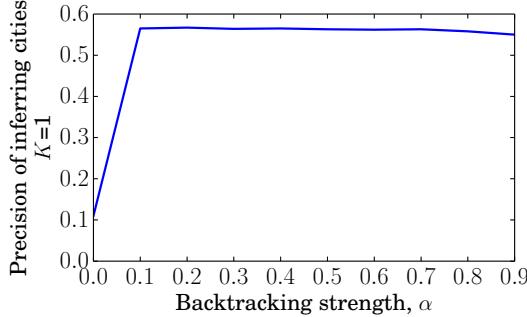

Figure 6: Impact of the backtracking strength on the Precision of VIAL for inferring cities. We observe that backtracking substantially improves VIAL’s performance.

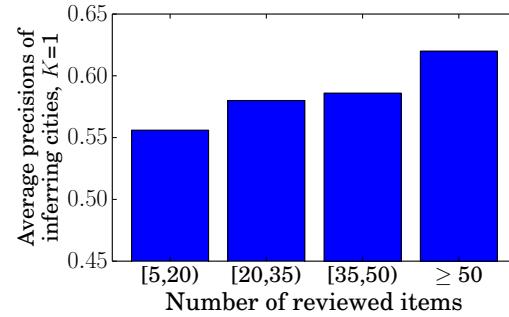

Figure 7: Impact of the number of reviewed items on the Precision of our attack VIAL for inferring cities. We observe that, when users share more behaviors, our attack is able to more accurately predict their attributes.

Comparing behavior-based attacks: We find that VIAL-B performs the best among the behavior-based attacks. Table 3 shows the average performance gains and relative performance gains of VIAL-B over other behavior-based attacks. Our results indicate that our graph-based attack is a better way to leverage behavior structures, compared to LG-B-I and LG-B-II, which flatten the behavior structures into feature vectors. Moreover, LG-B-I and LG-B-II achieve very close performances, which indicates that the rating scores carry little information about user attributes.

Comparing attacks combining social structure and behavior: We find that VIAL performs the best among the attacks combining social structures and behaviors. Table 4 shows the average performance gains and relative performance gains of VIAL over other attacks. Our results imply that, compared to flattening the structures into feature vectors, our graph-based attack can better integrate social structures and user behaviors.

Comparing VIAL with the best friend-based attack and the best behavior-based attack: Table 4 shows the average performance gains and relative performance gains of VIAL over Random, the best friend-based attack, and the best behavior-based attack. We find that VIAL significantly outperforms these attacks, indicating the importance of combining social structures and behaviors to perform attribute inference. This implies that, when an attacker wants to attack user privacy via inferring their private attributes, the attacker can successfully attack substantially more users using VIAL.

Impact of backtracking strength: Fig. 6 shows the impact of backtracking strength on the Precision of VIAL for inferring cities. According to Theorem 1, VIAL with $\alpha = 1$ reduces to random guessing, and thus we do not show the corresponding result in the figure. $\alpha = 0$ corresponds to the case in which VIAL does not use backtracking. We observe that not using backtracking sub-

stantially decreases the performance of VIAL. The reason might be that 1) $\alpha = 0$ makes VIAL predict the same attribute values for all test users, according to Theorem 2, and 2) a user’ attributes are close to the user in the SBA network and backtracking makes it more likely for votes to be distributed among these attribute nodes. Moreover, we find that inference accuracies are stable across different backtracking strengths once they are larger than 0. The reason is that when we increase the backtracking strength, attribute values receive different votes, but the ones with top ranked votes only change slightly. We observe similar results for other attributes.

Impact of the number of reviewed items: Figure 7 shows the Precision as a function of the number of reviewed items for inferring cities lived. We average Precisions for test users whose number of reviewed items falls under a certain interval (i.e., [5,20), [20,35), [35,50), or ≥ 50). We observe that our attack can more accurately infer attributes for users who share more digital behaviors (i.e., reviewed items in our case).

Confidence estimation: Figure 8 shows the trade-off between the Precision and the fraction of users that are attacked via our confidence estimator. We observe that an attacker can increase the Precision ($K = 1$) of inferring cities from 0.57 to over 0.92 if the attacker attacks a half of the test users that are selected via confidence estimation. We also tried the confidence estimator called *gap statistic* [34], in which the confidence score for a targeted user is the difference between the score of the highest ranked attribute value and the score of the second highest ranked one. Our confidence estimator slightly outperforms gap statistic because a test user could have multiple attribute values and our attack could produce close scores for them.

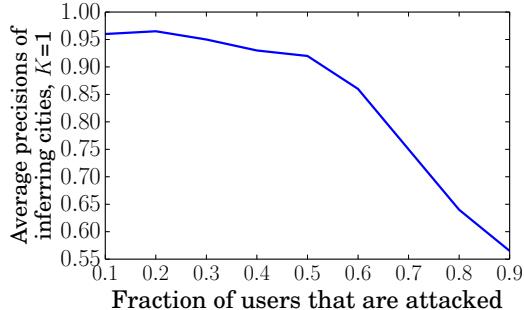

Figure 8: Confidence estimation: trade-off between the Precision of our attack and the fraction of test users that are attacked. An attacker can substantially improve the attack success rates when attacking less users that are selected by our confidence estimator.

8 Discussion

This work focuses on propagating vote capacity among the SBA network with given link weights, and our method VIAL is applicable to any link weights. However, it is an interesting future work to learn the link weights, which could further improve the attacker’s success rates. In the following, we discuss one possible approach to learn link weights. Phase I of VIAL essentially iteratively computes the vote capacity vector according to Equation 7. Therefore, Phase 1 of VIAL can be viewed as performing a *random walk with a restart* [40] on the subgraph consisting of social nodes and social links, where the matrix \mathbf{M}^T and α are the transition matrix and restart probability of the random walk, respectively. Therefore, the attacker could adapt *supervised random walk* [3] to learn the link weights. Specifically, the attacker already has a set of users with publicly available attributes and the attacker can use them as a training dataset to learn the link weights; the attacker removes these attributes from the SBA network as ground truth, and the link weights are learnt such that VIAL can predict attributes for these users the most accurately.

9 Related Work

Friend-based attribute inference: He et al. [18] transformed attribute inference to Bayesian inference on a Bayesian network that is constructed using the social links between users. They evaluated their method using a LiveJournal social network dataset with *synthesized* user attributes. Moreover, it is well known in the machine learning community that Bayesian inference is not scalable. Lindamood et al. [27] modified Naive Bayes classifier to incorporate social links and other attributes of users to infer some attribute. For instance, to infer

a user’s major, their method used the user’s other attributes such as employer and cities lived, the user’s social friends and their attributes. However, their approach is not applicable to users that share no attributes at all.

Zheleva and Getoor [46] studied various approaches to consider both social links and groups that users joined to perform attribute inference. They found that, with only social links, the approach LINK achieves the best performance. LINK represents each user as a binary feature vector, and a feature has a value of 1 if the user is a friend of the person that corresponds to the feature. Then LINK learns classifiers for attribute inference using these feature vectors. Gong et al. [15] transformed attribute inference to a link prediction problem. Moreover, they showed that their approaches CN-SAN, AA-SAN, and RWWR-SAN outperform LINK.

Mislove et al. [33] proposed to identify a local community in the social network by taking some seed users that share the same attribute value, and then they predicted all users in the local community to have the shared attribute value. Their approach is not able to infer attributes for users that are not in any local communities. Moreover, this approach is data dependent since detected communities might not correlate with the attribute value. For instance, Trauda et al. [41] found that communities in a MIT male network are correlated with residence but a female network does not have such property.

Thomas et al. [39] studied the inference of attributes such as gender, political views, and religious views. They used multi-label classification methods and leveraged features from users’ friends and wall posts. Moreover, they proposed the concept of multi-party privacy to defend against attribute inference.

Behavior-based attribute inference: Weinsberg et al. [42] investigated the inference of gender using the rating scores that users gave to different movies. In particular, they constructed a feature vector for each user; the i th entry of the feature vector is the rating score that the user gave to the i th movie if the user reviewed the i th movie, otherwise the i th entry is 0. They compared a few classifiers including Logistic Regression (LG) [22], SVM [10], and Naive Bayes [29], and they found that LG outperforms the other approaches. Bhagat et al. [6] studied attribute inference in an active learning framework. Specifically, they investigated which movies we should ask users to review in order to improve the inference accuracy the most. However, this approach might not be applicable in real-world scenarios because users might not be interested in reviewing the selected movies.

Chaabane et al. [8] used the information about the musics users like to infer attributes. They augmented the musics with the corresponding Wikipedia pages and then used topic modeling techniques to identify the latent similarities between musics. A user is predicted to share

attributes with those that like similar musics with the user. Kosinski et al. [25] tried to infer various attributes based on the list of pages that users liked on Facebook. Similar to the work performed by Weinsberg et al. [42], they constructed a feature vector from the Facebook likes and used Logistic Regression to train classifiers to distinguish users with different attributes. Luo et al. [28] constructed a model to infer household structures using users' viewing behaviors in Internet Protocol Television (IPTV) systems, and they showed promising results.

Other approaches: Bonneau et al. [7] studied the extraction of private user data in online social networks via various attacks such as account compromise, malicious applications, and fake accounts. These attacks can not infer user attributes that users do not provide in their profiles, while our attack can. Otterbacher [35] studied the inference of gender using users' writing styles. Zamal et al. [45] used a user's tweets and her neighbors' tweets to infer attributes. They didn't consider social structures nor user behaviors. Gupta et al. [17] tried to infer interests of a Facebook user via sentiment-oriented mining on the Facebook pages that were liked by the user. Zhong et al. [47] demonstrated the possibility of inferring user attributes using the list of locations where the user has checked in. These studies are orthogonal to ours since they exploited information sources other than the social structures and behaviors that we focus on.

Attribute inference using social structure and behavior could also be solved by a social recommender system (e.g., [44]). However, such approaches have higher computational complexity than our method for attacking a targeted user, and it is challenging for them to have theoretical guarantees as our attack. For instance, the approach proposed by Ye et al. [44] has a time complexity of $O(m \cdot k \cdot f \cdot d)$ on a single machine, where m is the number of edges, k is the latent topic size, f is the average number of friends, and d is the number of iterations. Note that both our VIAL and this approach can be parallelized on a cluster.

10 Conclusion and Future Work

In this work, we study the problem of attribute inference via combining social structures and user behaviors that are publicly available in online social networks. To this end, we first propose a *social-behavior-attribute (SBA)* network model to gracefully integrate social structures, user behaviors, and their interactions with user attributes. Based on the SBA network model, we design a *vote distribution attack (VIAL)* to perform attribute inference. We demonstrate the effectiveness of our attack both theoretically and empirically. In particular, via empirical evaluations on a real-world large scale dataset with 1.1

million users, we find that attribute inference is a serious practical privacy attack to online social network users and an attacker can successfully attack more users when considering both social structures and user behaviors. The fundamental reason why our attack succeeds is that private user attributes are statistically correlated with publicly available information, and our attack captures such correlations to map publicly available information to private user attributes.

A few interesting directions for future work include learning the link weights of a SBA network, generalizing VIAL to infer hidden social relationships between users, as well as defending against our inference attacks.

A Proof of Theorem 1

According to Equation 7, we have:

$$\vec{s}_v^{(i)} = (1 - \alpha)^i (\mathbf{M}^T)^i \vec{s}_v^{(0)} + \alpha \left(\sum_{k=0}^{i-1} (1 - \alpha)^k (\mathbf{M}^T)^k \right) \vec{e}_v. \quad (12)$$

Therefore,

$$\begin{aligned} \lim_{i \rightarrow \infty} \vec{s}_v^{(i)} &= \lim_{i \rightarrow \infty} \alpha \left(\sum_{k=0}^{i-1} (1 - \alpha)^k (\mathbf{M}^T)^k \right) \vec{e}_v \\ &= \alpha (I - (1 - \alpha) \mathbf{M}^T)^{-1} \vec{e}_v. \end{aligned} \quad (13)$$

We note that the matrix $(I - (1 - \alpha) \mathbf{M}^T)$ is nonsingular because it is strictly diagonally dominant.

B Proof of Theorem 2

The matrix \mathbf{M} has non-negative entries, and each row of \mathbf{M} sums to be 1. Therefore, \mathbf{M} can be viewed as a transition matrix. In particular, \mathbf{M} can be viewed as a transition matrix of the following Markov chain on the SBA network: each social node is a state of the Markov chain; the transition probability from a social node u to another social node x is \mathbf{M}_{ux} , i.e., a social node u can only transit to its social neighbors or hop-2 social neighbors with non-zero probabilities.

When the SBA network is connected, the above Markov chain is *irreducible* and *aperiodic*. Therefore, the Markov chain has a unique stationary distribution $\vec{\pi}$. Moreover, according to the Perron-Frobenius theorem [36], we have:

$$\lim_{i \rightarrow \infty} (\mathbf{M}^T)^i = [\vec{\pi} \ \vec{\pi} \cdots \vec{\pi}]$$

When $\alpha = 0$, we have $\vec{s}_v^{(i)} = (\mathbf{M}^T)^i \vec{s}_v^{(0)}$. Thus, we have

$$\begin{aligned} \vec{s}_v &= \lim_{i \rightarrow \infty} \vec{s}_v^{(i)} \\ &= \lim_{i \rightarrow \infty} (\mathbf{M}^T)^i \vec{s}_v^{(0)} \\ &= [\vec{\pi} \ \vec{\pi} \cdots \vec{\pi}] \vec{s}_v^{(0)} \\ &= |V_s| \vec{\pi}, \end{aligned}$$

where $|V_s|$ is the sum of the entries of $\vec{s}_v^{(0)}$.

C Proof of Corollary 1

When $w_S = \tau \cdot d_{u,S}$, $w_{BS} = \tau \cdot d_{u,B}$, and $w_{AS} = \tau \cdot d_{u,A}$ for each user u , the Markov chain defined by the transition matrix \mathbf{M} is a random walk on a weighted graph $G_w = (V_w, E_w)$, which is defined as follows: $V_w = V_s$, an edge (u, x) in E_w means that x is u 's social neighbor or hop-2 social neighbor in the SBA network, and the weight of the edge $(u, x) \in E_w$ is $\delta_{ux,S} \cdot w_{ux} + \delta_{ux,BS} \cdot d_{u,B} \cdot w_B(u, x) + \delta_{ux,AS} \cdot d_{u,A} \cdot w_A(u, x)$. We can verify that, on the graph G_w , the weights of all edges that are incident to a node u sum to d_u . Therefore, the stationary distribution $\vec{\pi}$ [5] of the random walk on G_w is:

$$\vec{\pi} = \left[\frac{d_{u_1}}{D} \ \frac{d_{u_2}}{D} \cdots \frac{d_{u_{|V_s|}}}{D} \right]^T. \quad (14)$$

Thus, according to Theorem 2, we have $\vec{s}_{vu} = |V_s| \frac{d_u}{D}$.

Internet Jones and the Raiders of the Lost Trackers: An Archaeological Study of Web Tracking from 1996 to 2016

Abstract

Though web tracking and its privacy implications have received much attention in recent years, that attention has come relatively recently in the history of the web and lacks full historical context. In this paper, we present longitudinal measurements of third-party web tracking behaviors from 1996 to present (2016). Our tool, *TrackingExcavator*, leverages a key insight: that the Internet Archive’s Wayback Machine opens the possibility for a retrospective analysis of tracking over time. We contribute an evaluation of the Wayback Machine’s view of past third-party requests, which we find is imperfect—we evaluate its limitations and unearth lessons and strategies for overcoming them. Applying these strategies in our measurements, we discover (among other findings) that third-party tracking on the web has increased in prevalence and complexity since the first third-party tracker that we observe in 1996, and we see the spread of the most popular trackers to an increasing percentage of the most popular sites on the web. We argue that an understanding of the ecosystem’s historical trends—which we provide for the first time at this scale in our work—is important to any technical and policy discussions surrounding tracking.

1 Introduction

Third-party web tracking is the practice by which third parties like advertisers, social media widgets, and website analytics engines—embedded in the first party sites that users visit directly—re-identify users across domains as they browse the web. Web tracking, and the associated privacy concerns from tracking companies building a list of sites users have browsed to, has inspired a significant and growing body of academic work in the computer security and privacy community, attempting to understand, measure, and defend against such tracking (e.g., [3, 4, 6, 8, 14, 15, 18–20, 22, 24, 25, 27–30, 32–34, 37, 39–43, 45, 46, 51, 57, 60, 61, 64–66, 70, 71]).

However, the research community’s interest in web tracking comes relatively recently in the history of web. To our knowledge, the earliest measurement studies began in 2005 [42], with most coming after 2009—while display advertising and the HTTP cookie standard date to the mid-1990s [44, 48]. Though numerous studies have now been done, they typically consist of short-term measurements of specific tracking techniques. We argue that public and private discussions surrounding web tracking—happening in technical, legal, and policy arenas (e.g., [49, 72])—ought to be informed not just by a single snapshot of the web tracking ecosystem but by a comprehensive knowledge of its trajectory over time. We provide such a comprehensive view in this paper, conducting a measurement study of third-party web tracking across 20 years since 1996.

Measurement studies of web tracking are critical to provide transparency for users, technologists, policy-makers, and even those sites that include trackers, to help them understand how user data is collected and used, to enable informed decisions about privacy, and to incentivize companies to consider privacy. However, the web tracking ecosystem is continuously evolving, and others have shown that web privacy studies at a single point in time may only temporarily reduce the use of specific controversial tracking techniques [63]. While one can study tracking longitudinally starting in the present, as we and others have (e.g., [42, 63]), ideally any future developments in the web tracking ecosystem can be contextualized in a comprehensive view of that ecosystem over time—i.e., since the very earliest instance of tracking on the web. We provide that longitudinal, historical context in this paper, asking: how has the third-party web tracking ecosystem evolved since its beginnings?

To answer this question, we apply a key insight: the Internet Archive’s *Wayback Machine* [31] enables a retrospective analysis of third-party tracking on the web

*Co-first authors listed in alphabetical order.

over time. The Wayback Machine¹ contains archives of full webpages, including JavaScript, stylesheets, and embedded resources, dating back to 1996. To leverage this archive, we design and implement a retrospective tracking detection and analysis platform called *TrackingExcavator* (Section 3), which allows us to conduct a longitudinal study of third-party tracking from 1996 to present (2016). *TrackingExcavator* logs in-browser behaviors related to web tracking, including: third-party requests, cookies attached to requests, cookies programmatically set by JavaScript, and the use of other relevant JavaScript APIs (e.g., HTML5 LocalStorage and APIs used in browser fingerprinting [15, 57], such as enumerating installed plugins). *TrackingExcavator* can run on both live as well as archived versions of websites.

Harnessing the power of the Wayback Machine for our analysis turns out to be surprisingly challenging (Section 4). Indeed, a key contribution of this paper is our evaluation of the historical data provided by the Wayback Machine, and a set of lessons and techniques for extracting information about trends in third-party content over time. Through a comparison with ground truth datasets collected in 2011 (provided to us by the authors of [60]), 2013, 2015, and 2016, we find that the Wayback Machine’s view of the past, as it relates to included third-party content, is imperfect for many reasons, including sites that were not archived due to `robots.txt` restrictions (which are respected by the Wayback Machine’s crawlers), the Wayback Machine’s occasional failure to archive embedded content, as well as site resources that were archived at different times than the top-level site. Though popular sites are typically archived at regular intervals, their embedded content (including third-party trackers) may thus be only partially represented. Whereas others have observed similar limitations with the Wayback Machine, especially as it relates to content visible on the top-level page [10, 38, 53], our analysis is focused on the technical impact of missing third-party elements, particularly with respect to tracking. Through our evaluation, we characterize what the Wayback Machine lets us measure about the embedded third parties, and showcase some techniques for best using the data it provides and working around some of its weaknesses (Section 4).

After evaluating the Wayback Machine’s view into the past and developing best practices for using its data, we use *TrackingExcavator* to conduct a longitudinal study of the third-party web tracking ecosystem from 1996–2016 (Sections 5). We explore how this ecosystem has changed over time, including the prevalence of different web tracking behaviors, the identities and scope of popular trackers, and the complexity of relationships within

the ecosystem. Among our findings, we identify the earliest tracker in our dataset in 1996 and observe the rise and fall of important players in the ecosystem (e.g., the rise of Google Analytics to appear on over a third of all popular websites). We find that websites contact an increasing number of third parties over time (about 5% of the 500 most popular sites contacted at least 5 separate third parties in early 2000s, whereas nearly 40% do so in 2016) and that the top trackers can track users across an increasing percentage of the web’s most popular sites. We also find that tracking behaviors changed over time, e.g., that third-party popups peaked in the mid-2000s and that the fraction of trackers that rely on referrals from other trackers has recently risen.

Taken together, our findings show that third-party web tracking is a rapidly growing practice in an increasingly complex ecosystem—suggesting that users’ and policy-makers’ concerns about privacy require sustained, and perhaps increasing, attention. Our results provide hitherto unavailable historical context for today’s technical and policy discussions.

In summary, our contributions are:

1. *TrackingExcavator*, a **measurement infrastructure** for detecting and analyzing third-party web tracking behaviors in the present and—leveraging the Wayback Machine—in the past (Section 3).
2. An **in-depth analysis** of the scope and accuracy of the Wayback Machine’s view of historical web tracking behaviors and trends, and techniques for working around its weaknesses (Section 4).
3. A **longitudinal measurement study** of third-party cookie-based web tracking from 1996 to present (2016)—to the best of our knowledge, the longest longitudinal study of tracking to date (Section 5).

This paper and any updates, including any data or code we publish, will be made available at <http://trackingexcavator.cs.washington.edu/>.

2 Background and Motivation

Third-party web tracking is the practice by which entities (“trackers”) embedded in webpages re-identify users as they browse the web, collecting information about the websites that they visit [50, 60]. Tracking is typically done for the purposes of website analytics, targeted advertising, and other forms of personalization (e.g., social media content). For example, when a user visits `www.cnn.com`, the browser may make additional requests to `doubleclick.net` to load targeted ads and to `facebook.com` to load the “Like” button; as a result, Doubleclick and Facebook learn about that user’s visit to CNN. Cookie-based trackers re-identify users by setting unique identifiers in browser cookies, which are then automatically included with requests to the tracker’s domain. Figure 1 shows a basic example; we discuss

¹<https://archive.org>

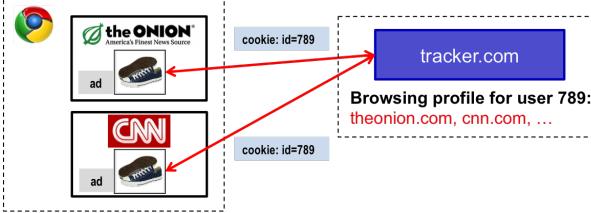

Figure 1: Overview of basic cookie-based web tracking. The third-party domain `tracker.com` uses a browser cookie to re-identify users on sites that embed content from `tracker.com`. This example shows *vanilla* tracking according to the taxonomy from [60]; other behaviors are described in Section 3.

more complex cookie-based tracking behaviors in Section 3. Though cookie-based tracking is extremely common [60], other types of tracking behaviors have also emerged, including the use of other client-side storage mechanisms, such as HTML5 LocalStorage, or the use of browser and/or machine fingerprinting to re-identify users without the need to store local state [15, 57].

Because these embedded trackers are often invisible to users and not visited intentionally, there has been growing concern about the privacy implications of third-party tracking. In recent years, it has been the subject of repeated policy discussions (Mayer and Mitchell provide an overview as of 2012 [50]); simultaneously, the computer science research community has studied tracking mechanisms (e.g., [50, 57, 60, 71]), measured their prevalence (e.g., [3, 20, 42, 60]), and developed new defenses or privacy-preserving alternatives (e.g., [6, 22, 25, 61, 64]). We discuss related works further in Section 6.

However, the research community’s interest in web tracking is relatively recent, with the earliest measurements (to our knowledge) beginning in 2005 [42], and each study using a different methodology and measuring a different subset of known tracking techniques (see Englehardt et al. [18] for a comprehensive list of such studies). The practices of embedding third-party content and targeted advertising on websites predate these first studies [48], and longitudinal studies have been limited. However, longitudinal studies are critical to ensure the sustained effects of transparency [63] and to contextualize future measurements. Thus, to help ground technical and policy discussions surrounding web tracking in historical trends, we ask: how has the third-party tracking ecosystem evolved over the lifetime of the web?

We investigate questions such as:

- How have the **numbers, identities, and behaviors** of dominant trackers changed over time?
- How has the **scope** of the most popular trackers (i.e., the number of websites on which they are embedded) changed over time?
- How has the **prevalence** of tracking changed over time? For example, do websites include many more

third-party trackers now than they did in the past?

- How have the **behaviors** of web trackers (e.g., JavaScript APIs used) changed over time?

By answering these questions, we are able to provide a systematic and longitudinal view of third-party web tracking over the last 20 years, retroactively filling this gap in the research literature, shedding a light on the evolution of third-party tracking practices on the web, and informing future technical and policy discussions.

The Wayback Machine. To conduct our archeological study, we rely on data from the Internet Archive’s Wayback Machine (<https://archive.org>). Since 1996, the Wayback Machine has archived full webpages, including JavaScript, stylesheets, and any resources (including third-party JavaScript) that it can identify statically from the site contents. It mirrors past snapshots of these webpages on its own servers; visitors to the archive see the pages as they appeared in the past, make requests for all resources from the Wayback Machine’s archived copy, and execute all JavaScript that was archived. We evaluate the completeness of the archive, particularly with respect to third-party requests, in Section 4.

3 Measurement Infrastructure: TrackingExcavator

To conduct a longitudinal study of web tracking using historical data from the Wayback Machine, we built a tool, TrackingExcavator, with the capability to (1) detect and analyze third-party tracking-related behaviors on a given web page, and (2) run that analysis over historical web pages archived and accessed by the Wayback Machine. In this section, we introduce TrackingExcavator. Figure 2 provides an overview of TrackingExcavator, which is organized into four pipeline stages:

(1) Input Generation (Section 3.1): TrackingExcavator takes as input a list of top-level sites on which to measure tracking behaviors (such as the Alexa top 500 sites), and, in “Wayback mode,” a timestamp for the desired archival time to create `archive.org` URLs.

(2) Data Collection (Section 3.2): TrackingExcavator includes a Chrome browser extension that automatically visits the pages from the input set and collects tracking-relevant data, such as third-party requests, cookies, and the use of certain JavaScript APIs.

(3) Data Analysis (Section 3.3): TrackingExcavator processes collected measurement events to detect and categorize third-party web tracking behaviors.

(4) Data Visualization: Finally, we process our results into visual representations (included in Section 5).

3.1 Input Generation

In the input generation phase, we provide TrackingExcavator with a list of top-level sites to use for measurement.

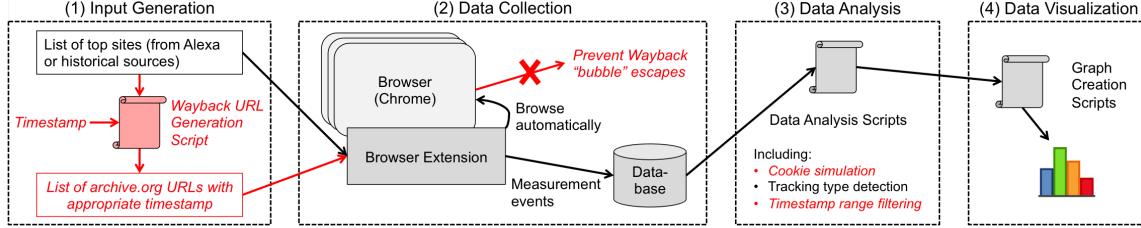

Figure 2: Overview of our infrastructure, TrackingExcavator, organized into four pipeline stages. Red/italic elements apply only to “Wayback mode” for historical measurements, while black/non-italics elements apply also to present-day measurements.

For historical measurements, TrackingExcavator must take a list of top-level URLs along with historical timestamps and transform them into appropriate URLs on archive.org. For example, the URL for the Wayback Machine’s February 10, 2016 snapshot of <https://www.usenix.org/conference/usenixsecurity16> is <https://web.archive.org/web/20160210050636/><https://www.usenix.org/conference/usenixsecurity16>.

We use the Memento API to find the nearest archived snapshot of a website occurring before the specified measurement date [36]. Though this process ensures a reasonable timestamp for the top-level page, embedded resources may have been archived at different times [5]. During analysis, we thus filter out archived resources whose timestamps are more than six months from our measurement timestamp, to ensure minimal overlap and sufficient spacing between measurements of different years.

3.2 Data Collection

To collect data, TrackingExcavator uses a Chrome extension to automatically visit the set of input sites. Note that we cannot log into sites, since the Wayback Machine cannot act as the original server. Our browser is configured to allow third-party cookies as well as pop-ups, and we visit the set of sites twice: once to prime the cache and the cookie store (to avoid artifacts of first-time browser use), and once for data collection. During these visits, we collect the following information relevant to third-party web tracking and store it in a local database:

- All request and response headers (including `set-cookie`).
- All cookies programmatically set by JavaScript (using `document.cookie`).
- All accesses to fingerprint-related JavaScript APIs, as described below.
- For each request: the requested URL, (if available) the referrer, and (if available) information about the originating tab, frame, and window.

We later process this data in the analysis phase of TrackingExcavator’s pipeline (Section 3.3 below).

Fingerprint-Related APIs. Since cookie-based web tracking is extremely common (i.e., it is “classic” web tracking), we focus largely on it—and third-party requests in general—to capture the broadest view of the web tracking ecosystem over time. However, we also collect information about the uses of other, more recently emerged tracking-related behaviors, such as JavaScript APIs that may be used to create browser or machine fingerprints [15, 57]. To capture any accesses a webpage makes to a fingerprint-related JavaScript API (such as `navigator.userAgent`), TrackingExcavator’s Chrome extension Content Script overwrites these APIs on each webpage to (1) log the use of that API and (2) call the original, overwritten function. The set of APIs that we hook was collected from prior work on fingerprint-based tracking [3, 4, 15, 56, 57] and is provided in Appendix A.

Preventing Wayback “Escapes”. In archiving a page, the Wayback Machine transforms all embedded URLs to archived versions of those URLs (similar to our own process above). However, sometimes the Wayback Machine fails to properly identify and rewrite embedded URLs. As a result, when that archived page is loaded on archive.org, some requests may “escape” the archive and reference resources on the live web [9, 38]. In our data collection phase, we block such requests to the live web to avoid anachronistic side effects. However, we record the domain to which such a request was attempted, since the archived site did originally make that request, and thus we include it in our analysis.

3.3 Data Analysis

In designing TrackingExcavator, we chose to separate data collection from data analysis, rather than detecting and measuring tracking behaviors on the fly. This modular architecture simplifies data collection and isolates it from possible bugs or changes in the analysis pipeline—allowing us to rerun different analyses on previously collected data (e.g., to retroactively omit certain domains).

“Replaying” Events. Our analysis metaphorically “replays” collected events to simulate loading each page in the measurement. For historical measurements, we modify request headers to replace “live web” Set-Cookie headers with X-Archive-Orig-Set-Cookie headers

added by `archive.org`, stripping the Wayback Machine prefixes from request and referrer URLs, and filling our simulated cookie jar (described further below). During the replay, TrackingExcavator analyzes each event for tracking behaviors.

Classifying Tracking Behaviors. For *cookie-based trackers*, we base our analysis on a previously published taxonomy [60].² We summarize—and augment—that taxonomy here. Note that a tracker may fall into multiple categories, and that a single tracker may exhibit different behaviors across different sites or page loads:

1. *Analytics Tracking*: The tracker provides a script that implements website analytics functionality. Analytics trackers are characterized by a script, sourced from a third party but run in the first-party context, that sets first-party cookies and later leaks those cookies to the third-party domain.
2. *Vanilla Tracking*: The tracker is included as a third party (e.g., an iframe) in the top-level page and uses third-party cookies to track users across sites.
3. *Forced Tracking*: The tracker forces users to visit its domain directly—for example, by opening a popup or redirecting the user to a full-page ad—allowing it to set cookies from a first-party position.
4. *Referred Tracking*: The tracker relies on another tracker to leak unique identifiers to it, rather than on its own cookies. In a hypothetical example, `adnetwork.com` might set its own cookie, and then explicitly leak that cookie in requests to referred tracker `ads.com`. In this case, `ads.com` need not set its own cookies to perform tracking.
5. *Personal Tracking*: The tracker behaves like a Vanilla tracker but is visited by the user directly in other contexts. Personal trackers commonly appear as social widgets (e.g., “Like” or “tweet” buttons).

In addition to these categories previously introduced [60], we discovered an additional type of tracker related to but subtly different from Analytics tracking:

6. *Referred Analytics Tracking*: Similar to an Analytics tracker, but the domain which sets a first-party cookie is *different* from the domain to which the first-party cookie is later leaked.

Beyond cookie-based tracking behaviors, we also consider the use of fingerprint-related JavaScript APIs, as described above. Though the use of these APIs does not necessarily imply that the caller is fingerprinting the user—we know of no published heuristic for determining fingerprinting automatically—but the use of many such APIs may suggest *fingerprint-based tracking*.

Finally, in our measurements we also consider *third-party requests* that are not otherwise classified as track-

²We are not aware of other taxonomies of this granularity for cookie-based tracking.

ers. If contacted by multiple domains, these third-parties have the *ability* to track users across sites, but may or may not actually do so. In other words, the set of all domains to which we observe a third-party request provides an upper bound on the set of third-party trackers.

We tested TrackingExcavator’s detection and classification algorithms using a set of test websites that we constructed and archived using the Wayback Machine, triggering each of these tracking behaviors.

Reconstructing Archived Cookies. For many tracking types, the presence or absence of cookies is a key factor in determining whether the request represents a tracking behavior. In our live measurements, we have the actual `Cookie` headers attached by Chrome during the crawl. On archived pages, the Wayback Machine includes past `Set-Cookie` headers as `X-Archive-Orig-Set-Cookie` headers on archived responses. To capture the cookies that would have actually been set during a live visit to that archived page, TrackingExcavator must simulate a browser cookie store based on these archival cookie headers and JavaScript cookie set events recorded during data collection.

Unfortunately, cookie engines are complicated and standards non-compliant in major browsers, including Chrome [11]. Python’s cookie storage implementation is compliant with RFC 2965, obsoleted by RFC 6265, but these standards proposals do not accurately represent modern browser practices [7, 13, 21]. For efficiency, we nevertheless use Python’s cookie jar rather than attempting to re-implement Chrome’s cookie engine ourselves.

We found that Python’s cookie jar computed cookies exactly matching Chrome’s for only 71% of requests seen in a live run of the top 100. However, for most types of tracking, we only need to know whether *any* cookies would have been set for the request, which we correctly determine 96% of the time. Thus our tool captures most tracking despite using Python’s cookie jar.

Classifying Personal Trackers in Measurements. For most tracker types, classification is independent of user behaviors. Personal trackers, however, are distinguished from Vanilla trackers based on whether the user visits that domain as a top-level page (e.g., Facebook or Google). To identify likely Personal trackers in automated measurement, we thus develop a heuristic for user browsing behaviors: we use popular sites from each year, as these are (by definition) sites that many users visited.

Alexa’s top sites include several that users would not typically visit directly, e.g., `googleadservices.com`. Thus, we manually examined lists of popular sites for each year to distinguish between domains that users *typically* visit intentionally (e.g., Facebook, Amazon) from those which ordinary users never or rarely visit intentionally (e.g., ad networks or CDNs). Two researchers

independently classified the domains on the Alexa top 100 sites for each year where we have Alexa data, gathering information about sites for which they were unsure. The researchers examined 435 total domains: for the top 100 domains in 2015, they agreed on 100% and identified 94 sites as potential Personal trackers; for the 335 additional domains in the previous years’ lists, they agreed on 95.4% and identified 296 Personal tracker domains.

4 Evaluating the Wayback Machine as an Archaeological Data Source for Tracking

The Wayback Machine provides a unique and comprehensive source of historical web data. However, it was not created for the purpose of studying third-party web tracking and is thus imperfect for that use. Nevertheless, the only way to study web tracking *prior* to explicit measurements targeting it is to leverage materials previously archived for other purposes. Therefore, before using the Wayback Machine’s archived data, it is essential to systematically characterize and analyze its capabilities and flaws in the context of third-party tracking.

In this section we thus study the extent to which data from the Wayback Machine allows us to study historical web tracking behaviors. Beyond providing confidence in the trends of web tracking over time that we present in Section 5, we view this evaluation of the Wayback Machine as a contribution of this paper. While others have studied the quality of the Wayback Machine’s archive, particularly with respect to the quality of the archived content displayed on the top-level page (e.g., [10, 38, 53]), we are the first to systematically study the quality of the Wayback Machine’s data about *third-party requests*, the key component of web tracking.

To conduct our evaluation, we leverage four ground truth data sets collected from the live web in 2011, 2013, 2015, and 2016. The 2011 data was originally used in [60] and provided to us by those authors. All datasets contain classifications of third-party cookie-based trackers (according to the above taxonomy) appearing on the Alexa top 500 sites (from the time of each measurement). The 2015 and 2016 data was collected by TrackingExcavator and further contains all HTTP requests, including those not classified as tracking.³ We plan to release our ground truth datasets from 2013, 2015, and 2016.

We organize this section around a set of lessons that we draw from this evaluation. We apply these lessons in our measurements in Section 5. We believe our findings can assist future researchers seeking to use the Wayback Machine as a resource for studying tracking (or other web properties relying on third-party requests) over time.

³For comparison, the published results based on the 2011 dataset [60] measured tracking on the homepages of the top 500 websites as well as four additional pages on that domain; for the purposes of our work, we re-analyzed the 2011 data using only homepages.

	August 1	August 25	September 1
All Third-Parties	324	304	301
Analytics	7	13	11
Vanilla	127	115	108
Forced	0	0	0
Referred	3	3	3
Personal	23	21	21
Referred Analytics	21	17	18

Table 1: Natural variability in the trackers observed on different visits to the Alexa top 100 in 2015. This variability can result from non-static webpage content, e.g., ad auctions that result in different winners.

4.1 Lesson (Challenge): The Wayback Machine provides a partial view of third-party requests

A key question for using the Wayback Machine for historical measurements is: how complete is the archive’s view of the past, both for the top-level pages and for the embedded content? In this lesson, we explore why its view is incomplete, surfacing challenges that we will overcome in subsequent lessons. We identify several reasons for the differences between the live and Wayback measurements, and quantify the effects of each.

Variation Between Visits. Different trackers and other third parties may appear on a site when it is loaded a second time, even if these views are close together; an example of this variation would be disparity in tracking behaviors between ads in an ad network.

To estimate the degree of variation between page views, we compare three live runs from August–September 2015 of the Alexa top 100 sites (Table 1). We find that variation between runs even a week apart is notable (though not enough to account for all of the differences between Wayback and live datasets). For the number of Vanilla trackers found, the August 25th and September 1st runs vary by 7 trackers, or 6%.

Non-Archived and Blocked Requests. There are several reasons that the Wayback Machine may fail to archive a response to a request, or provide a response that TrackingExcavator must ignore (e.g., from a far different time than the one we requested or from the live web). We describe these conditions here, and evaluate them in the context of a Wayback Machine crawl of the top 500 pages archived in 2015, according to the 2015 Alexa top 500 rankings; we elaborate on this dataset in Section 5. Table 2 summarizes how often the various conditions occur in this dataset, for requests, unique URLs, and unique domains. In the case of domains, we count only those domains for which *all* requests are affected, since those are the cases where we will *never* see a cookie or any other subsequent tracking indicators for that domain.

Robots.txt Exclusions (403 errors). If a domain’s robots.txt asks that it not be crawled, the Wayback Machine will respect that restriction and thus not archive

Type of Blocking	Fraction Missed
Robots Exclusions	Requests 1115 / 56,173 (2.0%)
	URLs 609 / 27,532 (2.2%)
	Domains 18 / 1150 (1.6%)
Not Archived	Requests 809 / 56,173 (1.4%)
	URLs 579 / 27,532 (2.1%)
	Domains 8 / 1150 (0.7%)
Wayback Escapes	Requests 9025 / 56,173 (16.1%)
	URLs 4730 / 27,532 (17.2%)
	Domains 132 / 1150 (11.5%)
Inconsistent Timestamps	Requests 404 / 56,173 (0.7%)
	URLs 156 / 27,532 (0.6%)
	Domains 55 / 1150 (4.8%)

Table 2: For the archived versions of the Alexa top 500 sites from 2015, the fraction of requests, unique URLs, and unique domains affected by robots exclusion (403 errors), not archived (404), Wayback escapes (blocked by TrackingExcavator), or inconsistent timestamps (filtered by TrackingExcavator).

the response. As a result, we will not receive any information about that site (including cookies, or use of Javascript) nor will we see any subsequent resources that would have resulted from that request.

We find that only a small fraction of all requests, unique URLs, and (complete) domains are affected by robots exclusion (Table 2). We note that robots exclusions are particularly common for popular trackers. Of the 20 most popular trackers on the 2015 live dataset, 12 (60%) are blocked at least once by robots.txt in the 2015 Wayback measurement. By contrast, this is true for only 74/456, or 16.23%, of all Vanilla trackers seen in live.

Other Failures to Archive (404 errors). The Wayback Machine may fail to archive resources for any number of reasons. For example, the domain serving a certain resource may have been unavailable at the time of the archive, or changes in the Wayback Machine’s crawler may result in different archiving behaviors over time. As shown in Table 2, missing archives are rare.

URL Rewriting Failures (Wayback “Escapes”). Though the Wayback Machine’s archived pages execute the corresponding archived JavaScript within the browser when TrackingExcavator visits them, the Wayback Machine does not execute JavaScript during its archival crawls of the web. Instead, it attempts to statically extract URLs from HTML and JavaScript to find additional sites to archive. It then modifies the archived JavaScript, rewriting the URLs in the included script to point to the archived copy of the resource. This process may fail, particularly for dynamically generated URLs. As a result, when TrackingExcavator visits archived pages, dynamically generated URLs not properly redirected to their archived versions will cause the page to attempt to make a request to the live web, i.e., “escape” the archive. TrackingExcavator blocks such escapes (see Section 3). As a result, the script never runs on the archived site, never sets a cookie or leaks it, and thus TrackingExcavator

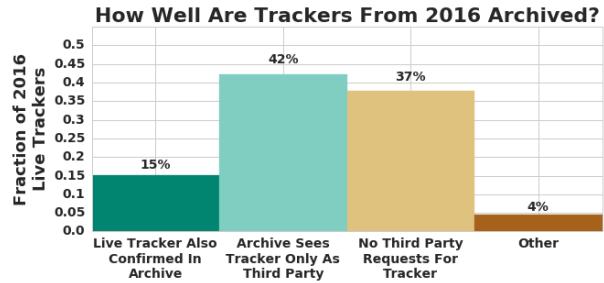

Figure 3: The fraction of domains categorized as Vanilla trackers in the live 2015 crawl which, in the archival 2015 crawl, (1) set and leaked cookies and thus were confirmed as trackers, (2) were only third-party requests (had at least one third-party request but no cookies), (3) did not appear at all, or (4) other (e.g., had cookies but not at the time of a third-party request, or cookies were not attached due to a cookie simulation bug).

tor does not witness the associated tracking behavior.

We find that Wayback “escapes” are more common than robots exclusion or missing archives (Table 2): 16.1% of all requests attempted to “escape” (i.e., were not properly rewritten by the Wayback Machine) and were blocked by TrackingExcavator.

Inconsistent Timestamps. As others have documented [10], embedded resources in a webpage archived by the Wayback Machine may occasionally have a timestamp far from the timestamp of the top-level page. As described in Section 3, we ignore responses to requests for resources with timestamps more than six months away.

Cascading Failures. Any of the above failures can lead to cascading failures, in that non-archived responses or blocked requests will result in the omission of any subsequent requests or cookie setting events that would have resulted from the success of the original request. The “wake” of a single failure cannot be measured within an archival dataset, because events following that failure are simply missing. To study the effect of these cascading failures, we must compare an archival run to a live run from the same time; we do so in the next subsection.

4.2 Lesson (Opportunity): Consider all third-party requests, in addition to confirmed trackers

In the previous section, we evaluated the Wayback Machine’s view of third-party requests *within* an archival measurement. For requests affected by the issues in Table 2, TrackingExcavator observes the existence of these requests — i.e., counts them as third parties — but without the corresponding response may miss additional information (e.g., set cookies) that would allow it to confirm these domains as trackers according to the taxonomy presented earlier. However, this analysis cannot give us a sense of how many third-party requests are entirely absent from Wayback data due to cascading failures, nor a sense of any other data missing from the archive, such as

	2011	2013	2015	2016
Wayback (All Third Parties)	553	621	749	723
Wayback (Vanilla+Personal)	47	49	92	90
Live (Vanilla+Personal)	370	419	493	459
Wayback-to-Live Ratio (Vanilla+Personal)	0.13	0.12	0.19	0.20

Table 3: We compare the prevalence of the most common tracking types (Vanilla and Personal) over the four years for which we have data from the live web. Though the Wayback Machine provides only partial data on trackers, it nevertheless illuminates a general upward trend reflected in our ground truth data.

missing cookie headers on otherwise archived responses. For that, we must compare directly with live results.

We focus our attention on unique trackers: we attempt to identify which live trackers are missing in the 2015 Wayback dataset, and why. For each tracker we observe in our 2015 live measurement, Figure 3 identifies whether we (1) also observe that tracker in “Wayback mode,” (2) observe only a third-party request (but no confirmed cookie-based tracking behavior, i.e., we classify it only as a third-party domain), or (3) do not observe any requests to that tracker at all.

We conclude two things from this analysis. First, because the Wayback Machine may fail to provide sufficient data about responses or miss cookies even in archived responses, many trackers confirmed in the live dataset appear as simple third-party requests in the Wayback data (the second column in Figure 3). For example, `doubleclick.net`, one of the most popular trackers, appears as only a third party in Wayback data because of its `robots.txt` file. Thus, we learn that to study third-party web tracking in the past, due to missing data in the archive, *we must consider all third-party requests*, not only those confirmed as trackers according to the taxonomy. Though considering only third-party requests will overcount tracking in general (i.e., not all third parties on the web are trackers), we find that it broadens our view of tracking behaviors in the archive.

Second, we find that a non-trivial fraction of trackers are missing entirely from the archive (the third column in Figure 3). In the next subsection, we show that we can nevertheless draw conclusions about trends over time, despite the fact that the Wayback Machine under-represents the raw number of third parties contacted.

4.3 Lesson (Opportunity): The Wayback Machine’s data allows us to study trends over time

As revealed above, the Wayback Machine’s view of the past may miss the presence of some third parties entirely. Thus, one unfortunately cannot rely on the archive to shed light on the exact raw numbers of trackers and other third parties over time. Instead, we ask: does the Wayback Machine’s data reveal genuine historical *trends*?

To investigate trends, we compare all of our live

datasets (2011, 2013, 2015, and 2016) to their Wayback counterparts. Table 3 compares the number of Vanilla and Personal trackers (the most prevalent types) detected in each dataset. For the purposes of this comparison, we sum the two types, since their distinction depends only on the user’s browsing behaviors. We also include the number of all third parties in the Wayback datasets, based on the previous lesson. Though not all of these third parties represent trackers in live data, they help illuminate trends in third party prevalence over time.

We draw two conclusions from this comparison. First, we find that we *can* rely on the archive to illuminate general trends over time. Although confirmed trackers in “Wayback mode” (as expected from our earlier lessons) underrepresent the number of confirmed trackers found on the live web—and third parties in the archive overestimate confirmed trackers in the live data—we find that the trends we see over time are comparable in both sets of measurements. Critically, we see that *the upward trend in our archival view is not merely the result of improvements in archive quality over time or other factors—we indeed observe this trend reflected in ground truth data*. We gain further confidence in these trends in Section 5, where we see a rise in tracking behaviors since 1996 that corresponds with our intuition. The absence of any large vertical steps in the figures in Section 5 further suggests that the trends we identify are artifacts of the web evolving as opposed to any significant changes in the Wayback Machine archival process.

Second, however, we find that—although long-term trends appear to be meaningfully represented by the Wayback Machine—one should not place too much confidence into *small* variations in trends. For example, the Wayback Machine’s data in 2013 appears to be worse than in other years, under-representing the number of confirmed trackers more than average. Thus, in Section 5, we do not report on results that rely on small variations in trends unless we have other reasons to believe that these variations are meaningful.

4.4 Lesson (Opportunity): Popular trackers are represented in the Wayback Machine’s data

Because popular trackers, by definition, appear on many sites that users likely browse to, they have a strong effect on user privacy and are particularly important to examine. We find that although the Wayback Machine misses some trackers (for reasons discussed above), *it does capture a large fraction of the most popular trackers*—likely because the Wayback Machine is more likely to have correctly archived at least one of each popular tracker’s many appearances.

Specifically, when we examine the 2015 archival and live datasets, we find that 100% of the top 20 trackers from the live dataset are represented as either confirmed

trackers or other third parties in the Wayback data. In general, more popular trackers are better represented in Wayback data: 75% of the top 100 live trackers, compared to 53% of all live trackers. Tracker popularity drops quickly—the first live tracker missing in Wayback data is #22, which appears on only 22 of the top 500 websites; the 100th most popular tracker appears on only 4 sites. By contrast, the top tracker appears on 208 sites. In other words, those trackers that have the greatest impact on user privacy do appear in the archive.

Based on this lesson, we focus part of Section 5’s analysis on popular trackers, and we *manually label* those that the Wayback Machine only sees as third parties but that we know are confirmed trackers in live data.

4.5 Lesson (Opportunity): The Wayback Machine provides additional data beyond requests

Thus far, we have considered third-party requests and confirmed cookie-based trackers. However, the Wayback Machine provides, and TrackingExcavator collects, additional data related to web tracking behaviors, particularly the use of various JavaScript APIs that allow third parties to collect additional information about users and their machines (e.g., to re-identify users based on fingerprints). For JavaScript correctly archived by the Wayback Machine, TrackingExcavator observes accesses to the supported APIs (Appendix A). For example, we observe uses of `navigator.userAgent` as early as 1997.

4.6 Summary

In summary, we find that the Wayback Machine’s view of the past is incomplete, and that its weaknesses particularly affect the third-party requests critical for evaluating web tracking over time. We identified and quantified those weaknesses in Section 4.1, and then introduced findings and strategies for mitigating these weaknesses in Sections 4.2-4.5, including considering third-party requests as well as confirmed trackers, manually labeling known popular trackers, and studying general trends over time instead of raw numbers. We leverage these strategies in our own measurements. By surfacing and evaluating these lessons, we also intend to help guide future researchers relying on data from the Wayback Machine.

We focus on the Wayback Machine since it is to our knowledge the most comprehensive web archive. Applying our approach to other, more specialized archives [58], if relevant for other research goals, would necessitate a new evaluation of the form we presented here.

5 Historical Web Tracking Measurements

We now turn to our longitudinal study of third-party cookie-based web tracking from 1996-2016.

Datasets. We focus our investigation on the most popular websites each year, for two reasons: first, trackers

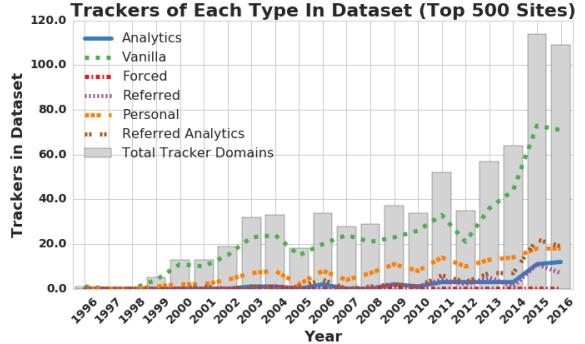

Figure 4: Evolution of tracker types over time. The grey bars show the total number of tracking domains present in each dataset, and the colored lines show the numbers of trackers with each type of tracking behavior. A single tracker may have more than one behavior in the dataset (e.g., both Vanilla and Analytics), so the sum of the lines might be greater than the bar.

on these sites are (or were) able to collect information about the greatest number of users; second, popular sites are crawled more frequently by the Wayback Machine (if permitted by `robots.txt`). We thus need historical lists of the top sites globally on the web.

2003-2016: Alexa. For 2010-2016, we use Wayback Machine archives of Alexa’s top million sites list (a csv file). For 2003-2009, we approximate the top 500 by scraping Alexa’s own historical API (when available) and archives of individual Alexa top 100 pages. Because of inconsistencies in those sources, our final lists contain 459-500 top sites for those years.

1996-2002: Popular Links from Homepages. In 2002, only the Alexa top 100 are available; before 2002, we only have ComScore’s list of 20 top sites [69]. Thus, to build a list of 500 popular sites for the years 1996-2002, we took advantage of the standard practice at the time of publishing links to popular domains on personal websites. Specifically, we located archives of the People pages of the Computer Science or similar department at the top 10 U.S. CS research universities as of 1999, as reported in that year by U.S. News Online [2]. We identified the top 500 domains linked to from the homepages accessible from those People pages, and added any ComScore domains that were not found by this process. We ran this process using People pages archived in 1996 and 1999; these personal pages were not updated or archived frequently enough to get finer granularity. We used the 1996 list as input to our 1996, 1997 and 1998 measurements, and the 1999 list as input for 1999-2002.

5.1 Prevalence of Tracking Behaviors over Time

We begin by studying the prevalence of tracking behaviors over time: how many unique trackers do we observe, what types of tracking behaviors do those trackers exhibit, and how many trackers appear on sites over time?

Prevalence and Behaviors of Unique Trackers. Figure 4 shows the total number of unique trackers observed over time (the grey bars) and the prevalence of different tracking behavior types (the lines) for the top 500 sites from 1996-2016. Note that trackers may exhibit more than one behavior across sites or on a single site, so the sum of the lines may be greater than the height of the bar. We note that the particularly large bars in 2015 and 2016 may reflect not only a change in tracking prevalence but also changes in the way the Wayback Machine archived the web. See Table 3 for validation against live data which suggest that actual growth may have been smaller and more linear, similar to past years.

We make several observations. First, we see the emergence of different tracking behaviors: the first cookie-based tracker in our data is from 1996: `microsoft.com` as a Vanilla tracker on `digital.net`. The first Personal tracker to appear in our dataset is in 1999: `go.com` shows up on 5 different sites that year, all also owned by Disney: `disney.com`, `espn.com`, `sportszone.com`, `wbs.net`, and `infoseek.com` (acquired by Disney mid-1999 [1], before the date of our measurement). The existence of a Personal tracker that only appeared on sites owned by the same company differs from today’s Personal tracking ecosystem, in which social media widgets like the Facebook “Like” button appear on many popular sites unaffiliated with that tracker (Facebook, in this case) [60].

More generally, we see a marked increase in quantities of trackers over time, with rises in all types of tracking behavior. One exception is Forced trackers — those relying on popups — which are rare and peaked in the early 2000s before popup blockers became default (e.g., in 2004 for Internet Explorer [54]). Indeed, we see third-party popups peak significantly in 2003 and 2004 (17 and 30 popups, respectively, compared to an annual mean of about 4), though we could not confirm all as trackers for Figure 4. Additionally, we see an increasing variety of tracking behavior over time, with early trackers nearly all simply Vanilla, but more recent rises in Personal, Analytics, and Referred tracking.

We can also consider the complexity of individual trackers, i.e., how many distinct tracking behaviors they exhibit over each year’s dataset. (Note that some behaviors are exclusive, e.g., a tracker cannot be both Personal and Vanilla, but others are nonexclusive.) Table 4 suggests that there has been some increase in complexity in recent years, with more trackers exhibiting two or even three behaviors. Much of this increase is due to the rise in Referred or Referred Analytics trackers, which receive cookie values shared explicitly by other trackers in addition to using their own cookies in Vanilla behavior.

Fingerprint-Related APIs. We measured the use of Javascript APIs which can be used to fingerprint

Year	1Type	2Type	3Type	4Type
1996	100.00% (1)	0	0	0
1998	0	0	0	0
2000	100.00% (13)	0	0	0
2002	100.00% (19)	0	0	0
2004	96.97% (32)	3.03% (1)	0	0
2006	100.00% (34)	0	0	0
2008	100.00% (29)	0	0	0
2010	94.12% (32)	2.94% (1)	2.94% (1)	0
2012	88.57% (31)	11.43% (4)	0	0
2014	93.75% (60)	4.69% (3)	1.56% (1)	0
2016	86.24% (94)	11.01% (12)	2.75% (3)	0

Table 4: Complexity of trackers, in terms of the percentage (and number) of trackers displaying one or more types of tracking behaviors across the top 500 sites.

Year	Most Prolific API-user	Num APIs Used	Coverage
1998	realhollywood.com	2	1
1999	go2net.com	2	1
2000	go.com	6	2

2016	aolcdn.com	25	3

Table 5: Most prolific API-users, with ties broken by coverage (number of sites on which they appear) for each year. The maximum number of APIs used increases over time, but the max API users are not necessarily the most popular trackers.

browsers and persist identifiers even across cookie deletion. Though the use of these APIs does not necessarily imply that they are used for tracking (and we know of no published heuristic for correlating API use with genuine fingerprinting behaviors), the use of these APIs nevertheless allows third parties to gather potentially rich information about users and their machines. The full list of 37 fingerprint-related APIs we measure (based on prior work [3, 4, 15, 56, 57]) is in Appendix A.

We now consider third parties that are prolific users of fingerprint-related APIs, calling many APIs on each site. Table 5 shows the tracker in each year that calls the most APIs on a single site. Ties are broken by the choosing the third party that appears on the largest number of sites. Maximum usage of APIs has increased over time, but we observe that the most prolific API users are not the most popular cookie-based trackers. Although we only identify API uses within JavaScript, and not how their results are used, we note that increasing use

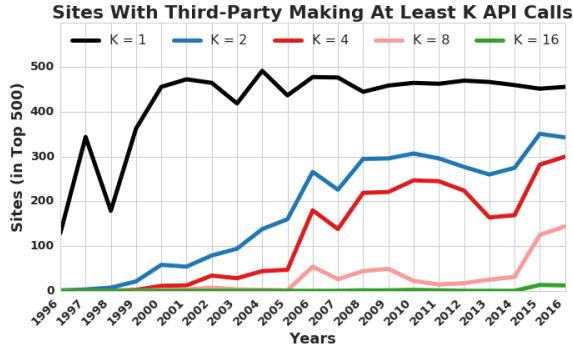

Figure 5: Number of sites in each year with a tracker that calls (on that site) at least K (of our 37) fingerprint-related APIs.

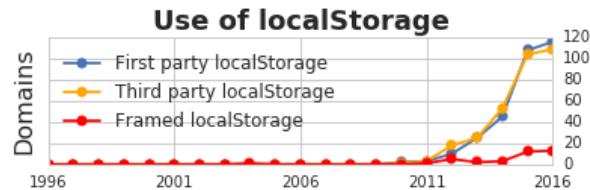

Figure 6: Domains using `window.localStorage`. First party usages are uses in the top frame of a web page by a script loaded from the web page’s own domain. Third party usages are those also in the top frame of a page but by a script loaded from a third party. Framed usages are those inside of an iframe.

of these APIs implies increased power to fingerprint, especially when combined with non-Javascript signals such as HTTP headers and plugin behavior. For example, Panopticlick derived 18 bits of entropy about remote browsers from a subset of these APIs plus HTTP headers and information from plugins [15].

Beyond the power of the most prolific fingerprint-related API users growing, we also find that more sites include more trackers using these APIs over time. Figure 5 shows the number of sites in each year containing a tracker that calls, on that site, at least K of the 37 fingerprinting APIs. Although many sites contain and have contained trackers that use at least 1 API (typically `navigator.userAgent`, common in browser compatibility checks), the number of sites containing trackers that call 2 or more APIs has risen significantly over time.

In addition to fingerprint-related APIs, we also examine the use of HTML5 LocalStorage, a per-site persistent storage mechanism standardized in 2009 in addition to cookies. Figure 6 shows that the use of the `localStorage` API rises rapidly since its introduction in 2009, indicating that tracking defenses should increasingly consider storage mechanisms beyond cookies.

Third Parties Contacted. We now turn our attention to the number of third parties that users encounter as they browse the web. Even third parties not confirmed as trackers have the *potential* to track users across the web, and as we discovered in Section 4, many third par-

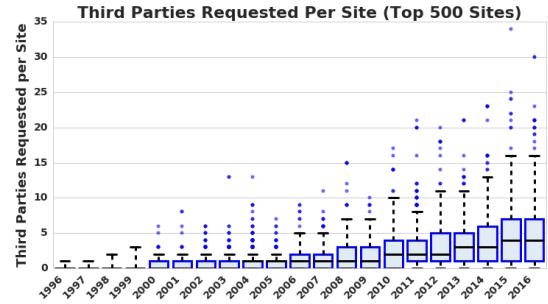

Figure 7: Distributions of third-party requests for the top 500 sites 1996–2016. Center box lines are medians, whiskers end at $1.5 \times \text{IQR}$. The increase in both medians and distributions of the data show that more third-parties are being contacted by popular sites in both the common and extreme cases.

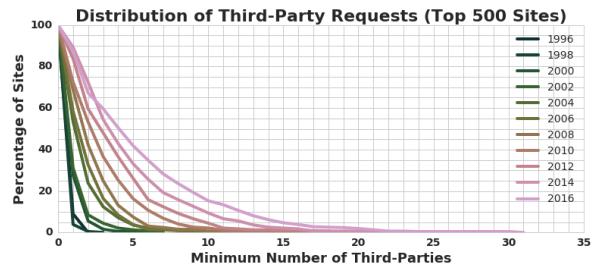

Figure 8: Distribution of top sites for each year by number of unique third-parties (tracking-capable domains) they contact. In later years, more sites appear to contact more third parties.

ties in archived data may in fact be confirmed trackers for which the Wayback Machine simply archived insufficient information. Figure 7 thus shows the distributions of how many third parties the top 500 sites contacted in each year. We see a rise in the median number of third parties contacted—in other words, more sites are giving more third parties the opportunity to track users.

Figure 8 provides a different view of similar data, showing the distribution of the top sites for each year by number of distinct third parties contacted. In the early 2000s, only about 5% of sites contacted at least 5 third parties, while in 2016 nearly 40% of sites did so. We see a maximum in 2015, when one site contacted 34 separate third-parties (a raw number that is likely underestimated by the Wayback Machine’s data)!

5.2 Top Trackers over Time

We now turn to an investigation of the top trackers each year: who are the top players in the ecosystem, and how wide is their view of users’ browsing behaviors?

Coverage of Top Trackers. We define the *coverage* of a set of trackers as the percentage of total sites from the dataset for which at least one of those trackers appears. For a single tracker, its coverage is the percentage of sites on which it appears. Intuitively, coverage suggests the concentration of tracking ability—greater coverage al-

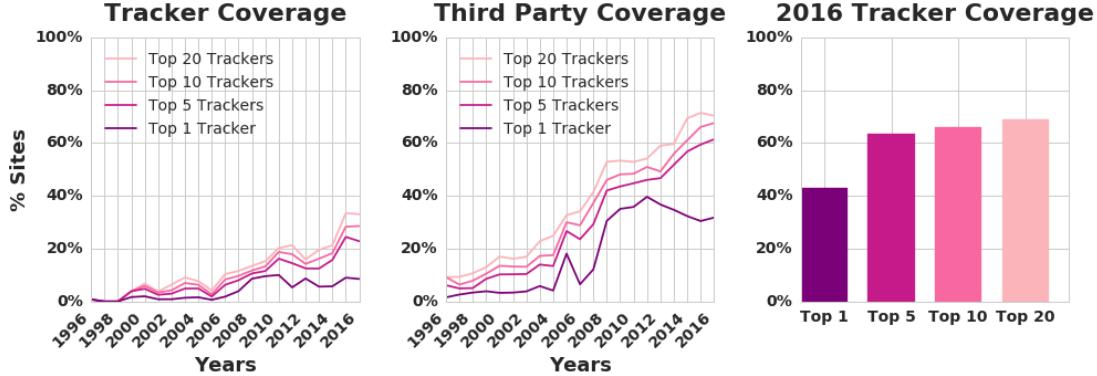

Figure 9: The growth in the coverage (percentage of top 500 sites tracked) of the top 1/5/10/20 trackers for each year is shown in the first and second panels, for all confirmed trackers and for all third parties respectively. The right hand panel shows the values on the live web for confirmed trackers, with the top 5 trackers covering about 70% of all sites in the dataset. Note that top third party coverage in the archive is an excellent proxy for modern confirmed tracker coverage today.

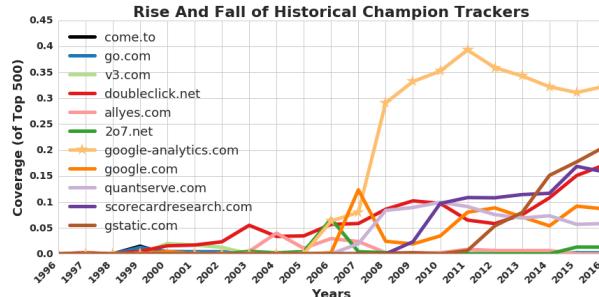

Figure 10: This figure depicts variations in site coverage for a number of the most popular confirmed trackers from years across the studied period. We call the two trackers embedded on the most sites in a given year the “champions” of that year, filtered by manual classification as described in the text.

lows trackers to build larger browsing profiles. This metric reaches toward the core privacy concern of tracking, that certain entities may know nearly everything a person does on the web. We consider trackers by domain name, even though some trackers are in fact owned by the same company (e.g., Google owns `google-analytics.com`, `doubleclick.net`, and the “+1” button served from `google.com`), because a business relationship does not imply that the entities share data, though some trackers may indeed share information out of public view.

Figure 9 illustrates the growth of tracker coverage over time. It considers both the single domain with the highest coverage for each year (Top 1 Tracker) as well as the combined coverage of the union of the top 5, 10 and 20 trackers. Confirming the lesson from Section 4.2, the coverage rates we see for third party domains in the archive are similar to live coverage of *confirmed* Vanilla cookie-based trackers.

Clearly, the coverage of top trackers has risen over time, suggesting that a small number of third parties can observe an increasing portion of user browsing histories.

Popular Trackers over Time. Who are these top track-

ers? Figure 10 shows the rise and fall of the top two trackers (“champions”) for each year. To create this figure, we make use of the lesson in Section 4.4 to manually label known popular confirmed trackers. We identified the two domains with the highest third-party request coverage for each year, omitting cases where the most popular tracker in a year appeared on only one site. We manually verified that 12/19 of these domains were in fact trackers by researching the domain, owning company, archived behavior and context, and modern behaviors (if applicable). Based on this analysis, we are able to assess the change in tracking behaviors even of domains for whom cookies are lost in the archive (e.g., `doubleclick.net`). In particular, this analysis reveals trends in the trackers with the most power to capture profiles of user behavior across many sites.

We find that in the early 2000s, no single tracker was present on more than 10% of top sites, but in recent years, `google-analytics.com` has been present on nearly a third of top sites and 2-4 others have been present on more than 10% and growing. Some, such as `doubleclick.net` (acquired by Google in 2008) have been popular throughout the entire time period of the graph, while others, such as `scorecardresearch.com`, have seen a much more recent rise.

We note that `google-analytics.com` is a remarkable outlier with nearly 35% coverage in 2011. Google Analytics is also an outlier in that it is one of only two non-cross-site trackers among the champions (`gstatic.com`, a Referred Analytics tracker, is the other). As an Analytics type tracker, Google Analytics tracks users only within a single site, meaning that its “coverage” is arguably less meaningful than that of a cross-site tracker. However, we observe that Google Analytics *could* track users across sites via fingerprinting or by changing its behavior to store tracking cookies. This observation highlights the need for repeated

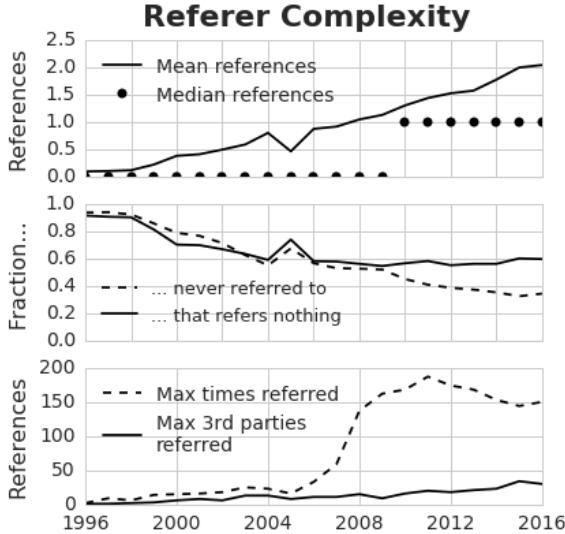

Figure 11: Changes in the frequency with which domains are referred to or refer to other domains (based on HTTP Referer).

measurements studies that provide transparency on the web: with a simple change to its tracking infrastructure, Google Analytics could begin to track users across 40% of the most popular sites on the web overnight. Thus, Google’s decision not to structure Google Analytics in this way has a tremendous impact on user privacy.

5.3 Evolution of the Tracking Ecosystem

Finally, we consider the tracking ecosystem as a whole, focusing on relationships between different trackers. We find a remarkable increase in the complexity of these relationships over time. Again we consider only relationships observable using TrackingExcavator, not external information about business relationships.

To study these relationships, we construct the graph of referring relationships between elements on pages. For example, if we observe a third-party request from `example.com` to `tracker.com`, or from `tracker.com` referring to `tracker2.com`, the nodes for those domains in the graph will be connected by edges.

We find a significant increase in complexity over time by examining several properties of this graph (Figure 11). Over time, the mean number of referrals outward from domains increases (top of Figure 11), while the number of domains that are never referred to by other domains or never refer outward steadily decreases (middle of Figure 11). Meanwhile, the maximum number of domains that refer to a single domain increases dramatically, suggesting that individual third parties in the web ecosystem have gradually gained increasing prominence and coverage. This reflects and confirms trends shown by other aspects of our data (Figures 10 and 9). These trends illuminate an ecosystem of generally increasingly connected relationships and players growing in size and influence.

Appendix B shows this evolution in graph form; the increase in complexity over time is quite striking.

5.4 Summary and Discussion

We have uncovered trends suggesting that tracking has become more prevalent and complex in the 20 years since 1996: there are now more unique trackers exhibiting more types of behaviors; websites contact increasing numbers of third parties, giving them the opportunity to track users; the scope of top trackers has increased, providing them with a broader view of user browsing behaviors; and the complexity and interconnectedness of the tracking ecosystem has increased markedly.

From a privacy perspective, our findings show that over time, more third parties are in a position to gather and utilize increasing amounts of information about users and their browsing behaviors. This increase comes despite recent academic, policy, and media attention on these privacy concerns and suggests that these discussions are far from resolved. As researchers continue to conduct longitudinal measurements of web tracking going forward, our work provides the necessary historical context in which to situate future developments.

6 Additional Related Work

Tracking and Defenses. Third-party tracking has been studied extensively in recent years, particularly through analysis and measurements from 2005 to present [18, 19, 24, 30, 32–34, 40–43, 60]. A few studies have considered mobile, rather than desktop, browser tracking [20, 27]. Beyond explicit stateful (e.g., cookie-based) tracking, recent work has studied the use of browser and machine fingerprinting techniques to re-identify and track users [3, 4, 15, 37, 57, 71]. Others have studied the possible results of tracking, including targeted ads [45, 70], personalized search [29], and price discrimination [66].

User-facing defenses against tracking range from browser extensions like Ghostery [23] and Privacy Badger [16] to research proposals (e.g. [8, 28]). Researchers have also designed privacy-preserving alternatives including privacy-preserving ads [22, 25, 59, 64], social media widgets [14, 39, 61], and analytics [6]. Others have studied user attitudes towards tracking and targeted advertising (e.g., [46, 51, 65]). Our study shows the increased prevalence of tracking over time, suggesting that designing and supporting these defenses for privacy-sensitive users is as important as ever.

Wayback Machine and other Longitudinal Measurements. Others have used the Wayback Machine for historical measurements to predict whether websites will become malicious [62] and to study JavaScript inclusion [55] and website accessibility [26]; to recover medical references [67]; to analyze social trends [35]; and as evidence in legal cases [17]. Others [53] found that

websites are accurately reflected in the archive. These studies noted similar limitations as we did, as well as ways it has changed over time [38]. Finally, researchers have studied other aspects of the web and Internet longitudinally without the use of archives, including IPv6 adoption [12], search-engine poisoning [47], privacy notices [52], and botnets [68].

7 Conclusion

Though third-party web tracking and its associated privacy concerns have received attention in recent years, the practice long predates the first academic measurements studies of tracking (begun in 2005). Indeed, in our measurements we find tracking behaviors as early as 1996. We introduce TrackingExcavator, a measurement infrastructure for third-party web tracking behaviors that leverages `archive.org`'s Wayback Machine to conduct historical studies. We rigorously evaluate the Wayback Machine's view of past third-party requests and develop strategies for overcoming its limitations.

We then use TrackingExcavator to conduct the most extensive longitudinal study of the third-party web tracking ecosystem to date, retrospectively from 1996 to present (2016). We find that the web tracking ecosystem has expanded in scope and complexity over time: today's users browsing the web's popular sites encounter more trackers, with more complex behaviors, with wider coverage, and with more connections to other trackers, than at any point in the past 20 years. We argue that understanding the trends in the web tracking ecosystem over time—provided for the first time at this scale by our work—is important to future discussions surrounding web tracking, both technical and political.

Beyond web tracking, there are many questions about the history and evolution of the web. We believe our evaluation of the Wayback Machine's view of the past, as well as TrackingExcavator, which we plan to release with this paper, will aid future study of these questions.

Acknowledgements

We thank individuals who generously offered their time and resources, and organizations and grants that support us and this work. Jason Howe of UW CSE offered invaluable technical help. Camille Cobb, Peter Ney, Will Scott, Lucy Simko, and Paul Vines read our drafts thoroughly and gave insightful feedback. We thank our colleagues from the UW Tech Policy Lab, particularly Ryan Calo and Emily McReynolds, for their thoughts and advice. This work was supported in part by NSF Grants CNS-0846065 and IIS-1302709, an NSF Graduate Research Fellowship under Grant No. DGE-1256082, and the Short-Dooley Professorship.

B Ecosystem Complexity

Figure 12 (on the next page) visually depicts the connections between entities in the tracking ecosystem that we observe in our datasets for 1996, 2000, 2004, 2008, 2012, and 2016: domains as nodes, and referral relationships as edges. Note that the visual organization of these graphs (with nodes in multiple tiers) is not meaningful and simply an artifact of the graph visualization software. Over time, the complexity and interconnectedness of relationships between third-party domains on the top 450 websites has increased dramatically.

A Fingerprint-Related JavaScript APIs

As described in Section 3, TrackingExcavator hooks a number of JavaScript APIs that may be used in fingerprint-based tracking and drawn from prior work [3, 4, 15, 56, 57]. The complete list:

- navigator.appCodeName
- navigator.appName
- navigator.appVersion

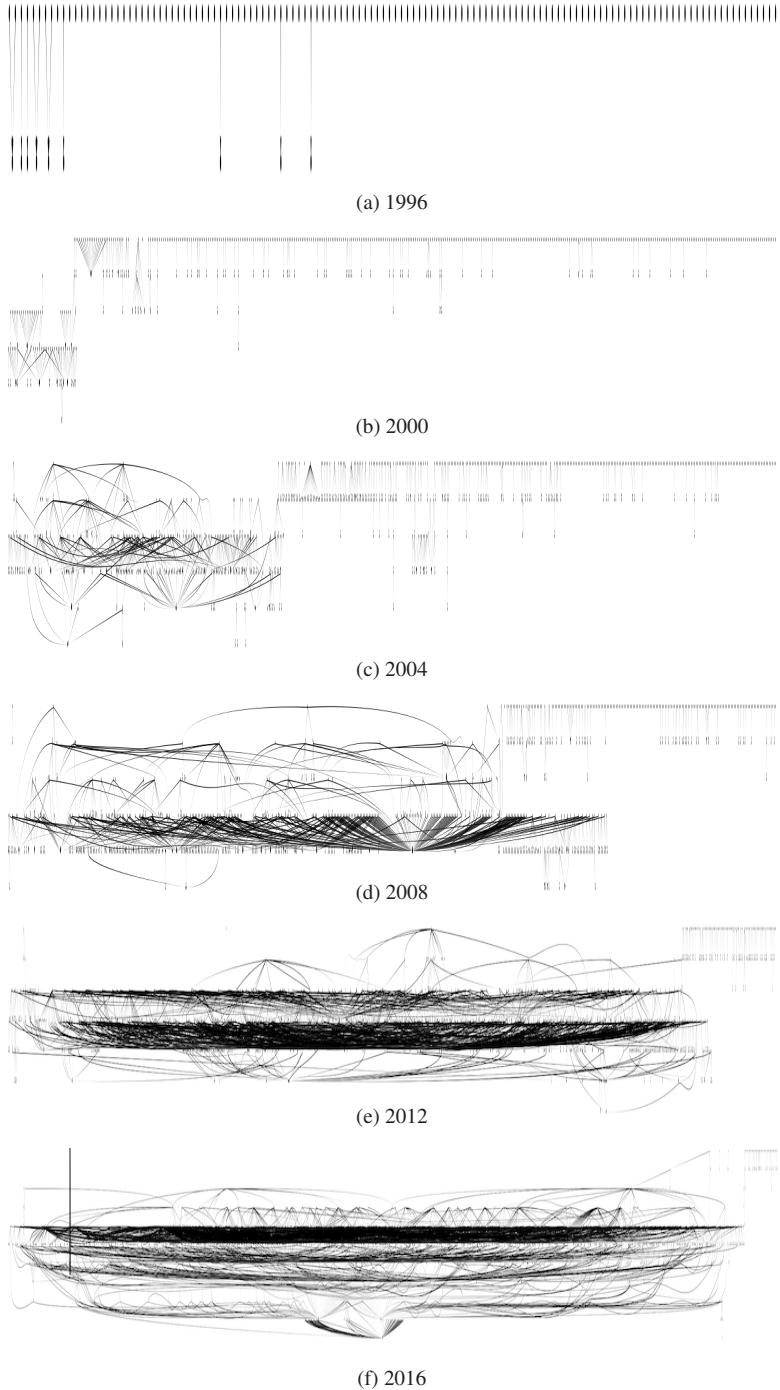

Figure 12: Referrer graphs for the top 450 sites in 1996, 2000, 2004, 2008, 2012 and 2016 as seen in the Wayback Machine’s archive. An edge from a domain `referrer.com` to another domain `referred.com` is included if any URL from `referrer.com` is seen to be the referrer for any request to `referred.com`. Note the increasing complexity of the graph over time.

Hey, You Have a Problem: On the Feasibility of Large-Scale Web Vulnerability Notification

Abstract

Large-scale discovery of thousands of vulnerable Web sites has become a frequent event, thanks to recent advances in security research and the rise in maturity of Internet-wide scanning tools. The issues related to disclosing the vulnerability information to the affected parties, however, have only been treated as a side note in prior research.

In this paper, we systematically examine the feasibility and efficacy of large-scale notification campaigns. For this, we comprehensively survey existing communication channels and evaluate their usability in an automated notification process. Using a data set of over 44,000 vulnerable Web sites, we measure success rates, both with respect to the total number of fixed vulnerabilities and to reaching responsible parties, with the following high-level results: Although our campaign had a statistically significant impact compared to a control group, the increase in the fix rate of notified domains is marginal.

If a notification report is read by the owner of the vulnerable application, the likelihood of a subsequent resolution of the issues is sufficiently high: about 40%. But, out of 35,832 transmitted vulnerability reports, only 2,064 (5.8%) were actually received successfully, resulting in an unsatisfactory overall fix rate, leaving 74.5% of Web applications exploitable after our month-long experiment. Thus, we conclude that currently no reliable notification channels exist, which significantly inhibits the success and impact of large-scale notification.

1 Introduction

The large-scale detection of vulnerabilities in Web applications has become significantly more common over the course of the last years. This can be attributed to two concurrent developments: The ever-growing adoption of open-source Web frameworks and the recent advances in automated vulnerability detection.

Open-source Web application frameworks, such as Joomla, Drupal, or WordPress, nowadays constitute the technological basis for a vast number of Web sites. Thus, a single vulnerability in any of these frameworks makes tens of thousands of Web applications attackable at once. Previously disclosed vulnerabilities range from Cross-Site Scripting attacks [20], to more severe attacks like SQL injections [10] or object deserialization flaws [19]. Given the rise in maturity and efficiency of Internet-wide scanning tools, such as ZMap [12], such flaws can effectively be identified on affected Web sites.

Furthermore, a recent stream of security research has demonstrated automated approaches that are capable of discovering Web vulnerabilities on a large scale. Examples of such research results include the discovery of high numbers of Client-Side Cross-Site Scripting problems [22], server-side application logic flaws [9], and instances of vulnerable server-side infrastructure [13].

However, as soon as a researcher has discovered security-critical vulnerabilities that affect thousands of Web sites, she has an ethical dilemma: On the one hand, with the awareness of a vulnerability comes the implicit responsibility of disclosing it to the affected parties. On the other hand, large-scale Web vulnerability disclosure is non-trivial, has not been well-studied, and there are no guidelines or suggestions on how to proceed.

Thus, in this paper, we explore the following questions: *Is it actually feasible to disseminate vulnerability information on a large scale? What are suitable communication channels to reach out to the affected parties? And does such a large-scale notification campaign affect the prevalence of vulnerabilities in the wild?*

To answer these questions, we conduct the first in-depth study on the feasibility and efficacy of large-scale Web vulnerability notification campaigns. To this end, we establish a large body of vulnerable Web sites, suffering from different types of vulnerabilities such as Reflected or Client-Side Cross-Site Scripting bugs. We then review communication channels to notify affected par-

ties at scale, including direct contacts (such as generic email aliases and WHOIS contacts) and indirect channels (such as hosting providers or CERTs). We notify the Web site administrators via these communication channels and compare how the vulnerabilities in the monitored Web sites evolve over time compared to a control group of vulnerable Web sites that we do not notify.

Our large-scale experiments reveal important take-away messages for fellow researchers. First, we show that while large-scale notifications can have a statistically significant impact on the fix rate of vulnerable Web applications, the long-term impact is marginal. Second, we therefore analyze the efficacy of direct and indirect communication channels, both with respect to reaching the (initial) recipient of the notification as well as the impact of the channel on the vulnerability landscape. Third, from our results, we derive the core challenges of notification campaigns and find that failures to reach out to contact persons cause the most severe degradation of success rates. Finally, we cover the lessons we learned during our pioneering efforts in order to assist researchers in future large-scale notification campaigns.

To sum up, we make the following contributions:

- We systematically evaluate the suitability of different communication channels for large-scale vulnerability disclosure and present a methodology to measure the feasibility and efficacy of such a disclosure process (§3).
- We document the results of a large-scale notification campaign, discussing the data set of vulnerable domains (§4) and the impact our campaign of notifying 35,832 vulnerable domains had (§5).
- Based on the observed (low) impact on the global landscape, we analyze factors inhibiting the success of large-scale disclosure campaigns (§6).
- We highlight key insights gathered in our study and present directions for future work in this space (§7).

2 Problem Statement

In this section, we outline the research questions we aim to answer. Secondly, we follow up with information on the actual vulnerabilities we consider for our work.

2.1 Research Questions

The ad-hoc process of reporting individual Web-related vulnerabilities to a single vendor is fairly well understood. Given its small scale, such a notification can be conducted with some manual, site-specific effort. However, detecting large numbers of vulnerabilities spanning several parties has become the norm rather than

the exception. Examples in the recent past include the identification of high numbers of vulnerable SSL implementations [13], Client-Side XSS vulnerabilities [22], or execute-after-redirect flaws in Ruby on Rails applications [9]. With higher numbers of affected parties, manual effort becomes unfeasible, and hence responsible disclosure transforms into a distinctly different problem. Therefore, it is necessary to investigate notification processes that function with little to no human involvement.

Taking this overarching motivation into consideration, we reach a set of distinct research questions: For one, given a large number of vulnerabilities that affect a similarly large set of disjoint site owners: *How can a scalable responsible vulnerability notification process be conducted?* As manual effort is not a realistic option, an automated vulnerability disclosure process is required.

Furthermore: *What are suitable communication channels to report vulnerabilities?* Not all methods to communicate vulnerability information can be easily used in automated processes. Once suitable channels are selected, it is necessary to examine *how successful a large-scale Web vulnerability disclosure process can be*. Even in an automated fashion, a large-scale notification campaign results in considerable effort: The notification process has to be set up, executed, and monitored. Moreover, even automated initial notification will in many cases lead to personal, non-automated communication with a subset of recipients of the vulnerability reports. Thus, it is reasonable to examine how significant the positive effect of our campaign was. Based on the results of such a study, another question arises: *Which methods were most successful in delivering notification, and what might inhibiting factors be?*

An increasing number of security researchers (professional and academic) spend significant time and effort to discover and fix security-critical software bugs, often wondering about how to proceed with large-scale disclosure processes. With the aforementioned research questions, we aim to shed light on the under-explored issue of *whether, how and with what chance of success* researchers can notify affected parties.

2.2 Vulnerability Information

To answer these research questions, we leverage a data set with concrete instances of Web sites that contain security-critical flaws. We can use this data set to notify affected parties and monitor their reactions. In the following, we outline the Web-related vulnerabilities we consider for our work, separated into *well-known* and *previously-unknown* vulnerabilities.

We establish the data set on well-known vulnerabilities by inspecting WordPress-based Web sites. We selected WordPress since it is the most frequently used

PHP-based web application, deployed by about 25% of the most popular Web sites [35]. To find WordPress vulnerabilities, we systematically searched the CVE (Common Vulnerabilities and Exposures) database [27] for vulnerabilities which could be verified with (i) non-intrusive proof-of-concept (*PoC*) tests and (ii) without requiring valid user credentials for the tested site. We chose two vulnerabilities: one reflected XSS from 2013 (CVE-2013-0237) and one Client-Side XSS discovered in 2015 (CVE-2015-3429).

In addition, we selected a recent vulnerability discovered by security researchers at Sucuri. This third vulnerability, which targets the XML-RPC service of WordPress prior to version 4.4, allows an attacker to perform brute-force amplification attacks [6]. The flaw is in the behavior of the XML-RPC service which accepts *multiple* remote procedure calls (RPCs) with *different* user credentials within a single HTTP request. As a result, an attacker can forge a request in which she tries several user passwords at once. In the remainder of this paper, we refer to this vulnerability as Multicall. All these vulnerabilities were already known and patched in current versions of WordPress when we started our experiments. In the following, we refer to these domains as Dwp.

Our data set on previously-unknown vulnerabilities contains Web sites from the Alexa Top 10,000 suffering from one or more Client-Side Cross-Site Scripting (*Client-Side XSS*) vulnerabilities. To detect these flaws, we used a methodology presented in our previous work (see Lekies et al. [22]) which is based on a taint-aware browsing engine and an exploit generator to gather verified exploitable vulnerabilities. To the best of our knowledge, these flaws were not shared with the site operators before our notification. The second data set thus represents a situation researchers face when discovering a previously unknown type or instance of Web flaws. We denote these domains as Dcxss.

3 Methodology

In this section we cover fundamental aspects of our methodology on large-scale notifications. We first discuss which communication channels can be used to reach out to affected parties. Subsequently, we outline how we prepared the notification messages. Third, we present the metrics that help to answer our research questions. Finally, we discuss ethical aspects of our methodology.

3.1 Communication Channels

The first key challenge when disclosing a Web vulnerability is to *reach out to an appropriate contact person*, e.g., to the administrator of a vulnerable Web site. In the

following, we review potential communication channels and discuss which of them are suitable in our context.

3.1.1 Direct Channels

We first consider and assess direct communication channels that lead to the responsible contact.

Web contacts (*discarded*) — One option would be to browse the Web site and search for contact email addresses, phone numbers, or contact forms. Naturally, calling affected parties or interacting with custom Web forms is not a viable option in a large-scale scenario. Alternatively, we could crawl the domain to extract email addresses. This process, however, is an unreliable and error-prone undertaking, and is complicated by anti-scraping mechanisms such as CAPTCHAs or obfuscated email addresses. Hence, such contacts are not viable for large-scale notifications and we do not consider them.

Generic email aliases — Standardized email aliases for each domain should ideally redirect to appropriate mailboxes and are “*to be used when contacting personnel of an organization*” (RFC 2142 [7]). The RFC also proposes alias categories suitable for our goal. Besides the security-related aliases, security@ and abuse@, we chose to contact the support mailbox for the HTTP service, i.e., webmaster@. In addition, we include the generic info@ alias.

Domain WHOIS information — The Domain WHOIS protocol can be used to query information about registered domain names. Depending on the providing server, however, the structure and content of the provided information varies. WHOIS data is optimized for readability to humans [8] and thus does not have a consistent document format [25]. While a human can easily use WHOIS to retrieve contact information for a *single* domain, it does not scale to large-scale disclosure. WHOIS providers also rate-limit requests and partially employ CAPTCHAs to protect contact addresses [17]. Hence, querying WHOIS at large scale is not feasible. Instead, to retrieve the WHOIS domain contact, we purchased a machine-readable WHOIS data set for the Alexa top one million Web sites as of September, 29th, 2015¹ and augmented the data with additional, on-demand queries. To select the contact person, first priority was given to the registrant’s email address. In cases where this did not exist, we selected the technical contact address instead.

3.1.2 Indirect Channels

Apart from direct channels, we can ask intermediaries to forward information about vulnerabilities on our behalf:

¹We bought the data set from <http://whoisxmlapi.com>

VRPs (*discarded*) — In recent years, vulnerability reward programs (VRPs) have gained traction and their success has been studied by researchers [14]. VRPs incentivize researchers to responsibly disclose flaws either directly to the vendor or to a VRP organization. Companies such as Google run their own in-house programs, whereas others outsource the coordination to organizations like HackerOne or BugCrowd. Naturally, in-house programs focus on vulnerabilities that are specific to the company, and hence, cannot be used for large-scale disclosure. Moreover, VRP organizations usually only accept and forward reports for their customers. Given a large body of vulnerable sites from several domains, VRPs are not a viable option for large-scale notifications. We thus exclude VRPs from our study.

Hosting providers — Hosting providers may already have an infrastructure in place to receive and react to security complaints. The provider likely has an incentive to use its direct customer contacts to forward the vulnerability information. While there is no specific security-related contact for providers, each provider typically has an abuse mailbox, which is used to notify operators about malicious activities originating from their networks. Abuse contacts can be found in Regional Internet Registries (RIRs) contact databases or queried via the IP WHOIS protocol. Both systems rate-limit requests and return proprietary formats. To work around this limitation, we query the Abusix Contact IP WHOIS proxy service [1] to obtain contacts of providers hosting the vulnerable Web sites.

TTPs — Trusted Third-Party Coordinators (hereafter TTPs) such as CERTs (Computer Emergency Response Teams) can act as intermediaries to report software vulnerabilities to operators. TTPs either operate on a regional level, i.e., within countries, or on a global scale, e.g., FIRST (Forum of Incident Response and Security Teams) [15]. Typically, TTPs already have technical infrastructure and procedures to forward vulnerability information to the administrators within their authority. To select CERTs, we determined the countries in which the vulnerable Web applications are hosted. We selected the top-20 countries in our data set and looked up their national CERTs. As global coordinators, we chose FIRST [15], and Ops-T [29] (Operations Security Trust), a closed community of security professionals.

3.2 Notification Procedure

In this section, we outline our notification procedure. Our campaign consisted of sending emails to the four notification groups on a bi-weekly basis, i.e., an initial notification and subsequent reminders every two weeks. In each round, we only notified Web sites which were

exploitable at least once in the previous 72 hours².

We split our overall data set of vulnerable Web sites into five disjoint groups of equal size, i.e., each domain is part of exactly one group. We use four notification groups and assign 1/5th of the domains to each of them: (i) generic email aliases, (ii) domain WHOIS contacts, (iii) abuse contacts of network providers, and (iv) TTPs. To reduce possible bias, we did not inform TTPs and network providers that they received only an excerpt of all affected sites in their constituency (since the rest were in the other groups). In addition, to set a baseline, we assign the fifth group to the *control group*, to which we did not send notifications.

3.2.1 Notification Types

To notify contacts, we carefully aggregated information to avoid a single contact receiving multiple notification emails, as discussed in the following.

Individual Disclosure — For the Generic and the WHOIS contact groups, we sent individual emails that contained a list of discovered flaws for their domain, as well as instructions to retrieve the technical report. We left it to the recipient to either view the technical report on our vulnerability disclosure Web interface, or to use our mailbot to retrieve the reports. Each domain therefore had a unique token assigned to it which could be used to retrieve the report. Additionally, the email informed the recipient that they could opt out of the experiments or get in touch with us via a dedicated mailbox. An example of the email is shown in Appendix A.

Aggregated Disclosure — For the network provider and TTP contact groups, the email contained a message similar to the one used for the individual disclosure, kindly asking the recipient to forward the information to the responsible domain admin. However, we aggregated vulnerability information per authority and prepared a single message to disclose multiple vulnerabilities affecting Web sites within the authority of TTPs and network providers. Specifically, we attached a CSV file specifying the domain, IP address, vulnerability types, Web interface link, and unique token for each site. The email also contained a note regarding opt-out and reaching us.

3.2.2 Mail Delivery and Anti-Spam Filters

To send out a large number of such notification emails, we opted to set up our own email server. Operating our own email infrastructure prevents side-effects that may have arisen when using existing email infrastructure of the university, e.g., in case an IP-based blacklist starts blocking our server due to the notification emails.

²See Section 3.3.1 for details on these exploitability checks

One of the key challenges for benign email campaigns is to avoid the emails being flagged as spam, based either on a bad sender reputation, or the message content. To minimize this risk, we implemented both Sender Policy Framework (SPF) [31] and, starting from the first reminder, DomainKeys Identified Mail (DKIM) [28]. For each email template, we used SpamAssassin to ensure that the message content would not be flagged as spam. Finally, throughout the mail sending process, we periodically monitored the reputation of our mail server by repeatedly querying IP-based blacklists, such as Spamhaus.org and SpamCop. In addition, as email providers may implement custom spam filters, we also tested our messages against the filters of the two most popular mail providers, i.e., Google Mail and Outlook, registering new email accounts on both services. In addition, we signed up for Microsoft’s Junk Mail Reporting Program (*JMRP*), which provides feedback on the spam check for mail from a given host [26].

3.2.3 Report Interface

During the experiment design time, one of the main concerns was the manual effort of our staff to address the quantity of possible questions that Web site owners might have. To help us with this type of activity, we built a web-based system, composed of a back end component for our staff and a front end for the Web site owner.

We wanted to provide users with as much detail as possible on the vulnerability, its impact, and ways of fixing it. Therefore, we created report templates for each vulnerability. For WordPress, we provided the details and hints on updating the installation. For Client-Side XSS, we provided the proof-of-concept URL which would open an alert box, as well as information on all the files which were involved in the exploitable data flow. Depending on the type of flaw, one of the customized templates would be presented to users of the front end.

The back end allowed us to retrieve current Web site statuses and statistics. Additionally, we automatically assigned emails to each domain. This allowed us to easily find all emails associated with a domain to give the best possible information on questions from domain admins.

3.3 Measurements

We broke down our research questions into a number of measurements that we perform throughout our notification campaign. These measurements are:

Global and Per-Group Vulnerable Web Sites — To measure the number of Web sites that are still exploitable, we set up a monitoring system which periodically verifies the exploitability of flaws using PoC tests.

In addition, as groups are mutually disjoint, our monitor naturally provides per-group results. The monitoring system is presented in Section 3.3.1.

Reachability of Recipients, Viewed Reports, and Time to Fix — We can directly measure the success of mail delivery by looking at both email responses and report interface access logs. The logs help to infer that a message has reached the recipient. We present this reachability analysis in Section 3.3.2.

3.3.1 Web Site Monitoring

Throughout our experiments, we periodically monitored Web sites to establish the point in time when they were no longer vulnerable. In the following, we discuss the different types and frequency of tests, as well as the approach used to determine that a site was fixed.

WordPress Vulnerabilities Tests — To test for the three WordPress vulnerabilities, we implemented the following vulnerability-specific probes.

XSS Vulnerabilities — The CVE-2013-0237 vulnerability affects a specific version of a Flash file which is part of the PIUpload component included in default WordPress installations. Our test retrieves the Flash file and compares its checksum against the checksum of the known vulnerable version. If the checksums match, the test returns *Exploitable*. In all other cases, it returns *Non-Exploitable*. Similarly, the presence of the CVE-2015-3429 vulnerability can be verified by comparing the checksum of a specific HTML page. If the checksum values match, the Web site is considered *Exploitable*; otherwise it is *Non-Exploitable*. Both these files have the same content regardless of Web site language, i.e., we did not have to implement a checker per site language.

Multicall — The detection of the Multicall vulnerability requires further care. In a vulnerable installation, the XML-RPC API checks all user-provided credentials per request. In the patched variant, it skips all credential checks if one has failed, but still returns a list of *invalid credential* error messages. As a result, the output of the service cannot be used to deduce exploitability. However, as vulnerable services process all calls—including the ones with invalid credentials—the processing time is longer than for the patched version. Based on this observation, we developed a test which uses this timing side channel to deduce if a site is vulnerable or not. For the technical details, we refer the interested reader to Appendix B. As side channels are susceptible to false positives, we correlate the results with the deployed version of WordPress, which we extract by using the testing tool *plecost* [18]. If both timing analysis and version reflect a vulnerable service, the site is *Exploitable*. In all other cases the Web site is *Non-Exploitable*.

Web Site Time-Series Analysis — Since the exploitability relies on core components of WordPress, it can be reliably triggered. To keep server loads to the necessary minimum, we only checked for these vulnerabilities once per day. Given the variety and number of Web sites that we monitor, however, our point-wise observations are susceptible to temporal errors, such as Web applications that are temporarily inaccessible or are otherwise unresponsive at the time of our check. To decide whether a Web site is no longer exploitable, or just temporarily unavailable, we calculate the confidence of our tests. The confidence is the complement of the number of unlikely events (i.e., number of observed transitions from *Non-Exploitable* to *Exploitable*). A site is only marked as fixed if the confidence is greater than 0.99. For a precise definition of our confidence function, we refer the interested reader to Appendix C.

Client-Side XSS Test — To test for this vulnerability, we used the set of per-domain exploits discovered with our methodology from previous work. Each exploit is a URL including the XSS payload. For more details on this aspect, we refer the reader to our paper [22]. The exploits are grouped according to the vulnerability they trigger. To keep the load on the target server low, we initially only check one exploit URL. If the exploit works, we consider the site still vulnerable. If the exploit fails, we do not consider the Web site as fixed yet. In fact, as our previous work has shown, a vulnerable page may no longer exist or the flaw may be caused by rotating advertisements [32]. To rule out such volatility, we re-check the exploit every three hours. Additionally, if the page no longer exists, we check other exploits from the same exploit group and update the PoC if any of them succeeds. A flaw is only marked as fixed if it was not exploitable for at least three consecutive days.

3.3.2 Mailbox and Report Access Log Analysis

One of our core research questions is to study the effectiveness of each notification group. To measure if we actually *reached* someone, we analyzed our mailbox and the logs of the front end. Our front end allows notified parties to retrieve a detailed technical report by clicking on a link, or, if the owner distrusts URLs in emails, via our mailbot. In both cases, the recipient has to submit a unique token. We kept track of all actions by logging the tokens and access times. This allowed us to perform fine-grained analyses regarding the access to our vulnerability reports. In addition, the mailbox we used to disseminate emails received a variety of automated replies that provided insights on the status of the email delivery. We use all this information to classify each contact point into one of the following categories.

Reached — For individual disclosure, we state that we *reached* a contact point when the response message is, for example, an auto-responder message acknowledging the receipt of our email, a response by a tracking system (e.g., a new ticket), and other messages in which the recipient unequivocally states that the message was received. We say that we reached a contact point also when we observe an access to corresponding domain’s technical report. In case of aggregated disclosure, if the email recipient, i.e., TTP or provider, is reached, then each of the domains within their constituency is also marked as reached. Similarly for individual disclosure, if a technical report for any domain within a constituency is accessed, we mark all associated domains as reached.

Bounced — Bounce messages are messages sent by a mail transfer agent to notify the sender that an error occurred and the message could not be delivered. Such errors might stem from the mailbox not existing or being full. If *all* emails we sent for a particular domain bounce, we classify the domain as *bounced*.

Unreachable — A contact point is unreachable when the response message indicates that no human will process our request. Examples of these cases are messages stating that the mailbox is unattended, or emails asking to contact Web site personnel only via a web form. Another example of an unreachable contact point is domains for which we could not retrieve any email address, e.g., if such information is missing in the WHOIS data.

Unknown — When we cannot establish whether a message was received, bounced, or the contact point was unreachable, we mark the contact point as *Unknown*.

While the identification of bounce messages is quite straightforward based on their content (e.g., SMTP error codes), automatically assigning emails to the aforementioned categories is prone to errors. Hence, we manually assigned incoming emails to one of the categories.

3.4 Ethical Considerations

We addressed ethical concerns from the early stages of our methodology design. In general, we design our experiments to be *unobtrusive*. This is, e.g., reflected on both the WordPress vulnerabilities selection criteria and the monitoring frequency. Despite that, our regular checks may still be undesired by network providers and Web site owners. For this reason, in our emails, we included instructions to *opt out* of our study. Moreover, we configured descriptive reverse DNS names for our infrastructure and hosted a website that described our initiative, again detailing contact information (postal address, email address, phone numbers) and an opt-out procedure.

The second ethical consideration of our experiments was fairness towards Web site administrators. As a result

of our methodology, there are administrators that were not made aware of vulnerabilities affecting their sites, i.e., were contained in the control group. After the end of our notification campaign, we informed them using the discussed direct channels and shared the list of vulnerable domains with the TTPs.

Our experiments are in part related to human operators on the receiving end of our notification emails. Our organizations, however, neither mandate nor provide an IRB approval before conducting such experiments.

4 Data Set

In this section, we explain the details of our experiments such as the time period, data sets of vulnerable applications, and composition of our notification groups.

Vulnerable Domains — In total, our data set included 44,790 Web sites of which 43,865 are WordPress-based Web sites suffering from at least one vulnerability discussed in Section 2.2 (D_{WP}). The remaining 925 Web sites were susceptible to site-specific Client-Side XSS exploits (D_{CXSS}).

Notification Groups — We randomly split the data sets of vulnerable Web sites into five equally-sized groups of 185 D_{CXSS} and 8,773 D_{WP} domains. During the lookup process, we could not retrieve contact points for several domains. For the domain group, the WHOIS database did not contain email addresses for 34 (18.4%) and 1,665 Web sites (19.0%) for D_{CXSS} and D_{WP}, respectively. For the network provider group, queries to the Abusix servers did not return a contact for 18 (9.7%) and 254 domains (2.9%) of D_{CXSS} and D_{WP}, respectively. In all these cases, we marked these Web sites as *unreachable* within their contact group.

For the TTP group, we followed a different approach. To select regional coordinators, we extracted the country code of the ASN hosting each domain, using the IP-to-ASN database of Team Cymru [33]. Finally, we selected coordinators for the 20 most frequent country codes from the list maintained by CERT-CC [4]. These regional CERTs account for 90.8% of the domains in the TTP contact group, the remaining 9.2% were hosted in a country outside of the top 20. To close this gap, we augmented the set of coordinators with the two global coordinators FIRST and Ops-T.

Notification Campaign — We notified the affected parties on Jan 14th, 2016. We sent two reminders, one after two weeks (Jan 28th), and one after four weeks (Feb 11th). For FIRST, we accidentally delayed the initial mail delivery by two days due to a misunderstanding, but made sure they received the vulnerability information as soon as the issue was resolved. In total, our server delivered 17,819 emails as the initial notification, 15,110 as

primary reminders, and 13,588 as secondary reminders. In each round, the number of emails sent decreased because administrators fixed the vulnerability, they explicitly asked to be excluded from the experiments, or email addresses were invalidated due to bounces.

Unsubscribed Domains — As discussed in Section 3.4, we enabled domains to opt out of our analysis. Throughout the duration of our experiments, we received five requests to exclude a total of 187 domains, of which 149 were in a notification group and 38 in the control group. We received an email from a hosting provider on the second day of our campaign, threatening to sue our university if we did not immediately stop the analysis on this network. Additionally, we received messages from domain owners that were contacted by their hosting providers, stating that their Web sites would be taken down if the vulnerabilities were not fixed within a short timeframe. In these cases, we not only excluded the domains from any further analysis, but also reached out to the providers to clarify the obvious misunderstanding.

5 Site Vulnerability Evolution

Using the methodology described before, we now instantiate our large-scale notification experiment and assess whether we can affect the prevalence of vulnerabilities in the wild. We answer this question by looking at the observed trends of fixed vulnerabilities and the significance of our campaign. Finally, we have a closer look at each data set and discuss the impact in isolation.

5.1 Trend of Fixed Vulnerabilities

Table 1 shows the total number of non-exploitable domains at the end of our measurements (February 16th). The fraction of non-exploitable Web sites ranges from about 25.1% (*Generic*) to 26.5% (*WHOIS*) for D_{WP}. For D_{CXSS}, the fraction of domains has a greater variety and ranges from 8.6% (*Provider*) to 16.8% (*TTP*). We observe a distinctive difference in the fix rates for the control group for D_{WP} (23.3%) and D_{CXSS} (2.4%). We discuss the reasons for this in Sections 5.2.1 and 5.2.2.

	D _{WP}	D _{CXSS}
Generic	2,201	25.1%
WHOIS	2,325	26.5%
Provider	2,261	25.8%
TTP	2,268	25.9%
Control	2,043	23.3%
	25	13.5%
	21	11.4%
	16	8.6%
	31	16.8%
	4	2.2%

Table 1: Non-exploitable domains per group by 02/16

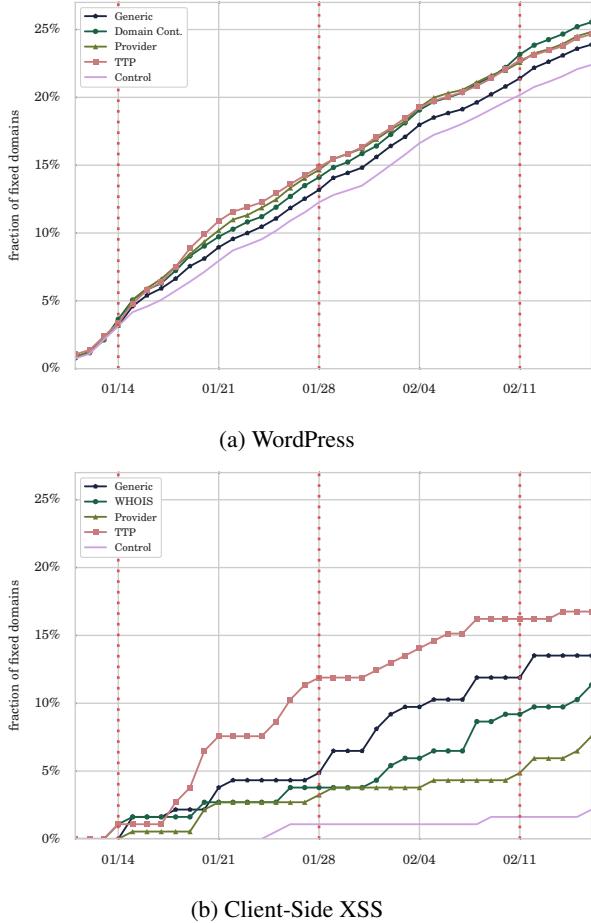

Figure 1: Fixed vulnerabilities over time

Figures 1a and 1b show the timeline and reveal when the vulnerabilities were fixed. For D_{WP}, we observe that all groups (including the control group) have a steady increase in non-exploitable domains. Each group progresses to the maximum, following a slight “wave” shape. This shape correlates to a weekly pattern. The weeks following a notification round (denoted as the horizontal lines) are characterized by a slightly steeper increase than the weeks before a notification round. For each of the groups, more than 2,000 of the 8,773 domains were no longer vulnerable at the end of our study. Overall, all notification groups performed better than the control group.

In contrast to the steady increase we observed for D_{WP}, no such pattern can be found for D_{CXSS}. Generally speaking, the difference between control and notified groups is much larger for D_{CXSS}. We discuss the results in Section 5.2.

Result Significance — During our experiments, we witnessed an increase in the fix rate for notified domains in comparison to the control group for both D_{WP} and

	D _{WP}	D _{CXSS}	
Generic	0.0053449	7.76	0.0000486
WHOIS	0.0000009	24.24	0.0004299
Provider	0.0001308	14.63	0.0058000
TTP	0.0000796	15.57	0.0000016
Overall Campaign	0.0000012	23.51	0.0000360
			17.07

Table 2: *p*-values and raw values from χ^2 tests

D_{CXSS}. In order to ascertain whether this is due to chance or an effect of our campaign, we analyze the gathered data in more detail. To that end, we state the hypothesis H_0 that the difference in the results originates purely from chance and is not an effect of our notification. For both D_{CXSS} and D_{WP}, we use Pearson’s χ^2 [30] test to calculate the *p*-values for each notification group in comparison to the control group. This test allows us to determine whether the differences between the results arose by chance. Both the resulting *p*-values and the raw χ^2 values for both D_{WP} and D_{CXSS} are shown in Table 2.

In our case, however, we need to account for the comparison of the control group to several other groups. Hence, an error in the control group would bias all comparisons. Applying the Holm-Bonferroni method ($\alpha = 0.05$) [16], we observe that every value p_i is below $\frac{\alpha}{5-i+1}$, i.e., H_0 does not hold. Hence, we find that the notified groups all differ significantly from the control group.

For the sake of completeness, in addition to the comparison to the control group, Tables 7 and 8 in the appendix show the *p*-values when comparing the notified groups against each other. While direct comparison between two groups sometimes reveals significant differences (e.g., D_{WP} WHOIS and Generic), no group performed significantly better than *all* other groups.

5.2 Impact Analysis

In this section, we analyze the collected data in more depth. More precisely, we discuss the changes for D_{WP} over time, showing how long-lasting the effect of our notification was. Moreover, we explain why the number of fixed domains in the control group is high, at almost one fifth. Subsequently, we discuss the impact of our notification on D_{CXSS}.

5.2.1 WordPress

Our notification campaign increased the number of domains that fixed the WordPress vulnerabilities by 11.2%. All notification groups outperformed the control group. The WHOIS group was the communication channel with the highest fix ratio (+15.4%). Next, the TTPs (+12.1%)

and providers (+10.9%) were second and third, respectively. The least effective channel was Generic, which still showed a 5.9% increase over the control group.

Besides the overall impact, we analyzed our collected data on a per-week basis, starting on the first day of our campaign. The results of this analysis are shown in Table 3. Next to the absolute number, the table also shows the fraction of domains fixed in each week. Note that this is relative to the number of domains that was still vulnerable at the beginning of that week for that group. In the first week, all channels performed better than the control group. In the second week, only providers still showed an observable increase in fixed domains. After the reminders, only the Generic and WHOIS contact groups had slightly increased fix numbers. All in all, however, the most drastic change occurred in the first week. Based on our definition of *fixed* domains (see Section 3.3.1), conclusive results can only be given at least three days back. As we stopped our experiments on January, 17th, we can only provide information on the first four weeks.

We observe that a substantial fraction of about one fifth of the control group was fixed during the duration of our study. This observation can be explained by analyzing the evolution of WordPress installations. We require version information to make a decision about the Multicall flaw, i.e., we had this information readily available for all days of the experiment. Indeed, out of the 8,773 domains in the control group, 1,134 moved from a version prior to 4.4 to an updated variant (not susceptible to Multicall) in the timeframe of our experiments. In addition, we observed that 360 domains no longer used WordPress or were offline at the end of our study. Throughout the remainder of the paper, we refer to these fixes as the *natural decay* of vulnerable domains.

It is also clear from Table 3 that in the first week of our campaign, a comparatively higher number of domains in the control group was marked first. While we cannot conclusively say why this occurred, we have anecdotal evidence from emails we received from one administrator who was responsible for multiple domains. Even though we had only notified him about one do-

main, he fixed several domains at once. Similarly, the WHOIS data set we purchased shows that different domains (spread across notified and control groups) contained the same contact email, i.e., had the same owner.

5.2.2 Client-Side XSS

Contrary to what we observed for DWP, there is no evidence for a natural decay of Client-Side XSS vulnerabilities. This stems from the fact that updates for the WordPress flaws are readily available and that sites are constantly being upgraded. For DCXSS, however, to the best of our knowledge, developers were not aware of the flaws and no automated update existed to patch the flaws. Therefore, the impact of our campaign is much higher in comparison to DWP.

In total, our campaign on average increased the number of fixed domains by a factor of almost 6, compared to the negligible number of *three* fixed domains in the control group. The highest fix rate was achieved by Trusted Third-Parties (16.8%), followed by the Generic channel with 13.5%. Additionally, 11.4% of the WHOIS and 8.7% of the provider group domains were fixed.

Important to note in this instance is one specific feature of Client-Side XSS: such issues are often caused by third-party scripts [32], which are out of the control of the administrator of the vulnerable domain. If a vulnerable third-party component is used across multiple domains, it is sufficient if *one* affected party reports this to the third-party vendor. In one particular case, we found that nine domains suffered from the same flaw. The vulnerability was fixed on February 8th, and its effect is visible in Figure 1b in the increase of fixed domains for Generic (three domains), WHOIS (four domains), and TTP (two domains) on that day. Since by chance, none of the domains was in the control group, this anomaly had a heavy impact on the overall notification campaign.

6 Communication Channel Analysis

In the previous section, we outlined the global picture on the vulnerability landscape and how much our campaign impacted it. Although the notifications for both DWP and DCXSS showed significant improvements over the control group, the number of domains which were fixed is unsatisfactory (25.8% and 12.6%, respectively). This raises the question whether we succeeded in reaching out to administrators. Therefore, in this section, we analyze how both direct and indirect communication channels performed in terms of successfully reporting the flaws to the responsible administrators.

	Control	Generic	WHOIS	Prov.	TTP
14/1-20/1	438 (5.1%)	521 (6.1%)	610 (7.2%)	631 (7.4%)	664 (7.8%)
21/1-27/1	387 (4.8%)	387 (4.8%)	397 (5.1%)	416 (5.3%)	395 (5.0%)
28/1-03/2	382 (5.0%)	416 (5.5%)	418 (5.6%)	380 (5.1%)	380 (5.1%)
04/2-10/2	386 (5.3%)	389 (5.4%)	402 (5.7%)	368 (5.2%)	365 (5.2%)

Table 3: WordPress flaws fixed per week

6.1 Direct Channels

In this section, we analyze the direct channels, first determining whether we reached the intended recipient. We then assess how many reports were accessed and how quickly flaws were fixed after report view.

6.1.1 Reachability Analysis

For the direct channels, i.e., Generic email addresses and WHOIS contacts, we sent a single email per domain. As outlined in Section 3.3.2, we then classified each domain as to its *reachability state*. The results of the classification are shown in Table 4. Based on the numbers we observe, several characteristics for the direct channels become apparent. First and foremost, more than half of all domains are marked as *unknown*, either because the emails were silently bounced, delivered to an unmonitored mailbox, or ignored by the recipient. Apart from this, we observe that the groups have distinct differences, which we discuss separately in the following.

For the Generic group, we received a large number of email bounces. More precisely, for 50% and 28% of DWP and DCXSS domains, respectively, *all* emails we sent bounced. The difference in number of bounces between DCXSS and DWP likely originates from the higher popularity of DCXSS Web sites (Alexa Top 10,000) in comparison to DWP (Alexa Top 1 million). As popular Web sites may have a more structured staff, they may tend to adhere to standards like RFC-2142 [7], thus reducing the number of bounces. Nevertheless, even for the high-ranked DCXSS Web sites, only 41 (22.2%) were actually reached. Moreover, for 90 DCXSS domains (48.6%) we neither received emails acknowledging our reports, nor saw any hits on our Web site. Similarly, we observe that more than 45% of the DWP domains are *unknown*.

The situation for the WHOIS group is slightly different: the fraction of bounces is significantly lower than for the Generic channels. This appears natural based on the fact that a valid email address is typically necessary to register a domain. However, apart from the large body of unknown domains, we see that the second-biggest fraction of domains belong to the *unreachable* bucket. This

is caused by the fact that for 1,699 domains (both DWP and DCXSS), we could not retrieve a contact address from the WHOIS information. Additionally, for 37 domains, our messages were not delivered to the domain owner because the emails from the WHOIS database are of organizations that hide email addresses. The remaining 31 domains in that bucket were marked as unreachable since we received emails redirecting us to a Web-based form.

Given the large volume of emails we sent out for direct notifications (four on Generic, one on WHOIS), anti-spam filters also interfered with reaching out to Web site administrators. Despite our careful preparation of infrastructure and email content, our messages were partially labeled as spam. Even though our mailserver was never listed in any well-known blacklist, Microsoft’s JMRP reported that the emails of the first two rounds were in parts flagged as spam. Interestingly, none of the emails of the second round of reminders were labeled as spam.

Additionally, provider-specific anti-spam filters mislabeled our emails. For 562 domains, we received bounces stating that our mails were classified as spam and thus rejected. In addition, in a handful of cases, we received feedback from contact points stating that they had only received our reminders and not the initial notification. This was either caused by *silent bounces* (the mail server accepted the email, but dropped it without notifying the sender), or by our email ending up in the spam folder, and then being automatically deleted after a few days.

6.1.2 Report Access

As we have seen in the previous section, the number of reached domains for the direct channels is low, amounting to only 357 and 714 DWP domains for Generic and WHOIS, respectively. The increase in fixed DWP domains compared to the control group, however, is even smaller: 158 and 282, respectively (see Table 1). We observe a similar trend for DCXSS. To investigate this discrepancy, in the following we analyze for how many of the *reached* domains a report was accessed on our Web interface or via the mailbot.

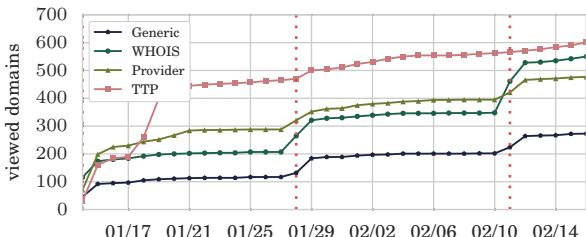

Table 5 shows the number of domains which accessed a report at least once. In addition, Figures 2a and 2b

	Generic		WHOIS		
	DWP	DCXSS	DWP	DCXSS	Total
Reached	357	41	714	38	1,150
Bounced	4,395	52	771	14	5,232
Unreach.	10	2	1,731	36	1,779
Unknown	4,011	90	5,557	97	9,755
Total	8,773	185	8,773	185	17,916

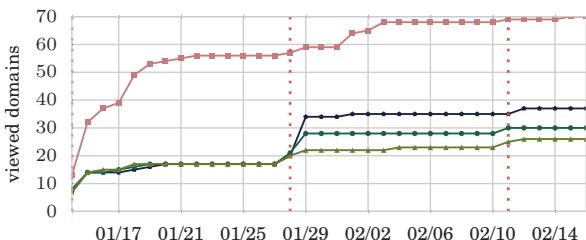

Table 4: Success of direct channels

	DWP	DCXSS
Generic	273	3.1%
WHOIS	550	6.3%

Provider	477	5.4%
TTP	601	6.9%
sum indirect	1,078	6.1%
	37	20%
	30	16.2%
	67	18.1%
	26	14.1%
	70	37.8%
	96	25.9%

Table 5: Viewed reports for all channels up to 02/16

(a) WordPress

(b) Client-Side XSS

Figure 2: Accessed reports for different channels

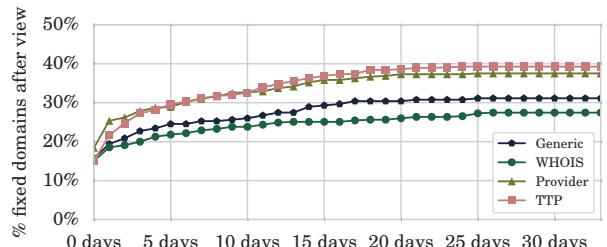

plot the temporal evolution of the viewed reports for DWP and DCXSS, respectively. We observe that within a few days of the initial notification, the number of accessed domain reports stabilizes for both DWP and DCXSS. Both reminders increased the number of viewed domains, but interestingly the effect for DWP was larger for the second reminder, whereas for DCXSS this held true for the first.

In total, only 823 of the DWP domains had reports viewed for the direct channels. For DCXSS, the ratio of viewed reports was much higher, but still adds up to only 67 (18.1%) of the notified domains, whereas Generic was slightly better than WHOIS with 37 viewed reports.

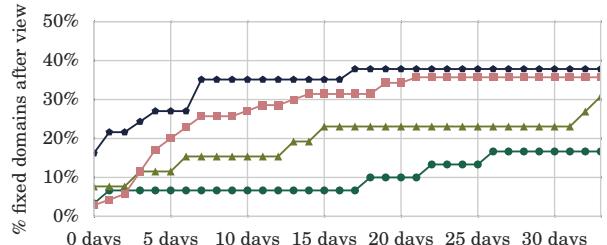

6.1.3 From Report Access to Fix

Even though not all *reached* domains had a report view, the number of domains for which a report was viewed is still larger than the increase in fixed domains. This is due to the fact that instead of only viewing a report, the final step towards ensuring that the domain is no longer vulnerable is to understand the specific issue and patch it accordingly. In this section, we therefore analyze how many domains from the direct channels were fixed after a report was viewed and how long it took.

Figures 3a and 3b show the time between a report being viewed and the fix of the underlying flaw. For DWP we observe on the Generic channel about 30% of the *viewed* domains are fixed within 5 days. Similarly, for WHOIS we observe a slightly higher rate of 32.5% within that timeframe. After this, the increase in fixed

(a) WordPress

(b) Client-Side XSS

Figure 3: Time from first report view to flaws fixed

domains aligns with what we observed for domains in the control group (roughly 0.5-0.7% per day). In essence, domains are either fixed within a very short time after initial report view or become non-exploitable just based on the natural decay of vulnerable domains.

For the DCXSS domains, this pattern differs, showing significant increases in the fix rates even after more than a week. These flaws, in contrast to WordPress, are mostly site-specific and, more importantly, a fix has to be developed first. Hence, a longer timeframe for the fix is somewhat expected. Of all channels, the Generic channel had the highest rate of fixed domains after having viewed a report with about 38%. Noteworthy in this instance is the poor conversion rate for the WHOIS group. One possible explanation for this is the fact that the domain owner for high-ranked sites might be disconnected from the engineering team. Hence, the information might have been viewed by this person, but not properly forwarded to the actual administrator of the site. In contrast, for DWP, we argue that such installations are mostly used by either small companies or single persons, and hence no such disconnect exists.

6.2 Indirect Communication Channels

After the discussion of direct channels, we now follow up with an in-depth analysis on the indirect channels.

	Provider		TTP		total
	DWP	Dcxss	DWP	Dcxss	
Reached	3,992	75	7,567	138	11,772
Bounced	2	0	0	0	2
Unreach.	271	20	0	0	291
Unknown	4,508	90	1,206	47	5,851
Total	8,773	185	8,773	185	17,916

Table 6: Success of indirect channels

6.2.1 Reachability Analysis

Similarly to direct channels, we also classified all domains based on their reachability. In this case, however, reaching the end point does not entail that we reached the administrator of the site. Instead, since we rely on intermediaries, we can only measure whether they received the email and not whether they forwarded it to the responsible party. This is also reflected in Table 6 in the large number of *reached* domains. As discussed in Section 3.3.2, a domain is marked as *reached* once the intermediary was reached, i.e., either confirmed our email or viewed at least one report disclosed to them.

In total, we reached 592 network providers responsible for 3,992 and 75 domains, respectively. Unreachable domains for the indirect channels were providers for which no contact existed in the Abusix database. In contrast to the high number of reached providers, about 50% for both DWP and Dcxss remain unknown.

For TTPs, such as CERTs or Ops-T, the numbers seem even more promising. Here, the *unknown* domains correspond to such domains for which we received no feedback from the hosting country’s CERT, or those which were not located in any of the top 20 countries. Since a relatively small number of TTPs is responsible for a large body of vulnerable domains, the fraction of *reached* domains is comparatively high.

6.2.2 Report Access

The large number of reached domains appears to be a positive sign for a successful vulnerability notification. However, looking at the number of accessed reports shown in Table 5, we find that the improvement over the direct channels is less significant.

In general, the report access pattern for the provider group (depicted in Figures 2a and 2b) is similar to what we observed for direct channels: an initial increment of access to our reports after each notification round followed by long intervals of a quasi-constant number of accesses. For the provider group, the percentage of viewed reports remains low at 5.4% and 14.1% for DWP and Dcxss, respectively. For the most part, this is caused by unhelpful providers: the top 5 providers accounted for

2,082 domains, but none of them reviewed any report, thus effectively stopping the notification process dead in its tracks for more than half of the *reached* domains.

Compared to the providers, TTPs show a significantly different access pattern. First of all, after the first notification round, we observe an increase of access after four days. This can in part be attributed to FIRST receiving our initial email two days late. Additionally, from feedback received from the third-largest active regional CERT, we learned that they follow their own dates to distribute notifications. While we sent notifications every other Thursday, this CERT sent their notifications on Mondays. In addition, we argue that the CERTs did not simply forward our messages, but rather vetted them first. Therefore, it is highly likely that the information was vetted on Friday, and only forwarded to responsible parties on Monday. This can be observed in Figures 2a and 2b as the steep increase starting from the fourth day of our campaign (i.e., Monday, January 18th).

For TTPs, we have a large number of reached domains, but cannot observe an analogous increase in number of viewed reports. The fractions of viewed reports are 37.8% for Dcxss and 6.9% for DWP. In contrast to the direct channels, our measurements could not reveal direct causes for these low numbers such as bounces or unreachable contacts. An explanation may be that TTPs did not forward our notification emails to Web site administrators. Among the 20 regional CERTs, 18 reacted to our email. Since we did not receive bounces for the two non-reactive CERTs, we marked the domains in their constituency as *unknown*. 10 CERTs that reacted to our email did not view a single report. This could happen for two reasons. First, rather than vetting the information, these TTPs could have directly forwarded the information, but the Web site administrators did not receive them, or did not act upon them. Second, the CERT might not have forwarded the information at all. Given the assumption that a TTP would first vet the information originating from an untrusted source, the lack of accesses to the report favors the second explanation, i.e., our notification messages were not forwarded by half of the CERTs.

In total, the combination of indirect channels performed better in terms of accessed reports than the combination of direct channels. However, providers performed worst of all channels for Dcxss and ranked third for DWP. In contrast, TTPs were most successful for report access on both types of vulnerable domains. This result, however, is greatly influenced by Ops-T: this TTP alone was exclusively responsible for 135 report accesses for DWP and 36 for Dcxss. Let us consider a scenario in which we could have relied only on regional CERTs and FIRST. In this case, the number of viewed reports for TTPs would have gone down to 466 and 34 for DWP and Dcxss, respectively. These numbers are similar to

or even lower than the other groups. Hence, although the TTPs were of great help in our campaign, a researcher without access to the vetted Ops-T community could not have achieved a comparable report access rate.

6.2.3 From Report Access to Fix

For the indirect channels, we also measured the time between first access of a report and fix for the disclosed vulnerability. The results are depicted in Figures 3a and 3b. For DWP, although TTPs perform similar to the direct channels, they have a distinct lag. More precisely, only 15.4% of domains were fixed within one day of report access, whereas this number ranged between 20.8% and 22.4% for direct channels. This underlines our hypothesis that TTPs would first vet the information we presented them. Hence, the first access to a domain report would have originated from the TTP, which subsequently forwarded the information to the responsible party.

As discussed before, there is less of a natural decay for DCXSS vulnerabilities, hence any fix is more likely to be caused by our notifications. However, due to the specifics of Client-Side XSS, where a single third-party script may be the cause for multiple flaws, it is hard to detect a distinct trend for the vulnerabilities. Similar to the DWP flaws, we observe a lag for both providers and TTPs between the initial view of the report and the time to fix, especially compared to the Generic group. This again highlights the vetting process of the intermediaries.

6.3 Discussion

As this section highlighted, the most significant issue we were faced with during our notification campaign was reaching the administrators in the first place. The issues depend on both communication channels and characteristics for the vulnerable domains. Naturally, reaching the intermediaries was quite straightforward: the email addresses were well-known and we only needed to send a comparatively small number of emails to them. In contrast, on the direct communication channels, especially for domains from DWP, we had a large number of bounces or unreachable contacts to begin with.

While the results for reachability suggest that using intermediaries greatly improves the chances of successful notifications, the benefit was not carried on to the number of viewed reports. Although TTPs performed best for both DWP and DCXSS report views, this was mostly caused by the closed Ops-T community. Additionally, our reminders improved on the number of accessed reports, especially for the direct channels.

Once a report was viewed, fix rates for DWP were similar across all groups, while the providers had a slightly higher fix rate. Moreover, we found that with a chance

of approximately 30%, domains were fixed within 5 days of a report view. After this period, the fraction of fixed domains only increased by what we observed to be the natural decay of flaws. For DCXSS, differences between communication channels were more drastic, with a much lower performance by the WHOIS channel. Although the number of fixes is subject to side-effects from vulnerabilities caused by third-party scripts, we note that the Generic channel worked best when considering the fix rate within the first 5 days.

7 Key Insights and Follow-Up Questions

In our work, we not only wanted to measure how successful a large-scale vulnerability notification campaign could be, but also aimed at determining what issues researchers would face. In the following, we discuss the key insights gained in our efforts, and present a number of follow-up questions which arise out of our findings.

Establishing Communication Channels — First and foremost, establishing a direct communication channel is remarkably challenging. For direct channels, we observe three main problems: (i) standardized addresses perform poorly with less popular Web sites; (ii) WHOIS contacts are a valid alternative for less popular Web sites, but the WHOIS database is not complete (about 20% domains lack contact points); and (iii) sending a large number of emails can be considered a spam campaign. All these reasons contribute to the low fraction of viewed reports.

Relying on indirect channels may reduce the workload for disclosure, as it *de facto* outsources the effort to an external organization. We found that for a large fraction of the domains such an intermediary could be reached. Although judging from the number of viewed reports, TTPs have the highest success rate, the overall results are still unsatisfactory. Moreover, we cannot ascertain how many TTPs forwarded the information or simply discarded them. We also found that reminders do not cause significant changes for TTPs, but have a slight impact on providers. Given all these facts, we find that establishing a communication channel to Web site administrators remains a hard problem even in the presence of intermediaries. Thus, the first question that arises for future work is: *How can the security community come up with reliable means of establishing communication channels between researchers and affected parties?*

User Distrust — For our experiments it was imperative that we were able to keep track of delivered and viewed reports. Therefore, we embedded a link to our web interface into the email. This naturally increases the risk of improper spam classification. Moreover, the security community trains users not to click on untrusted links or respond to suspicious emails, i.e., a significant fraction

of all reached administrators might not have followed our link or accessed the report via email. To investigate to what extent such behavior might have influenced our findings, we sent emails containing the full vulnerability details to all domains of the control group that were still vulnerable at the end of our experiments, using only the direct notification channels. While for Dcxss, no significant difference could be observed, Dwp domains notified this way show significant differences. Contrary to the intuition that a report only accessible via a link would hinder the campaign, however, these domains performed *worse* in terms of fix rates. This curious fact might be caused by the fact that the emails contained multiple links (e.g., to the vulnerable site, the description on mitre.org, and the information on updating WordPress), hence triggering more spam filters. Alternatively, such long emails might have aroused more suspicions by the recipients. Hence, this rises another question: *To what extent does the message tone, content, and length influence the success of notification campaigns?*

Sender Reputation — When looking at the results for TTPs in more detail, we find that the trusted Ops-T community was responsible for a large portion of successful notification deliveries, even up to 50% of Dcxss viewed reports for the TTPs. Thus, we argue that although studies have shown otherwise [5], trust in the sender of a notification message may be important factor to a campaign’s success. This also holds true for the German CERT, which (according to our data) was more inclined to forward our messages. In this case, the cause is most likely the fact that we originate from a German university and have had interactions with the CERT before. This brings up another question for future work: *What is the impact of the sender reputation, especially when using intermediaries, on the success of a notification campaign?*

Time to Fix and Need for Reminders — Once a report was viewed, the fix rate for Dwp was around 30% within five days, regardless of the channel that was used to originally transmit the report. After that, the fix rate approximates what we observe for the control group, i.e., is most likely not an effect of our notification. For Dcxss, the fix ratio for Generic, Provider, and TTP channel was between 30% and 40%, while the WHOIS group achieved a fix rate of less than 20%. In total, fixing these vulnerabilities typically took longer, which stems from the lack of a readily available patch for the custom flaws.

Additionally, as indicated by the increase in viewed reports right after our reminders, we find that they are necessary and useful. Moreover, considering that a patch typically only occurred within the first five days of a report being viewed, *future work should select a shorter interval for such reminders*.

Results Generality — Our work was a first glimpse into the landscape of vulnerability notifications. We explicitly studied the effects of such a campaign in the context of Web vulnerabilities which could be verified without interfering with the server’s normal operation, i.e., we did not consider high-impact flaws such as SQL injections or remote code execution. The impact of our notification campaign was statistically significant, but smaller than in other related experiments (e.g., [13, 21]). Judging from their results, the criticality of the discovered flaws may also effect the impact of a notification campaign.

While in principle we could have applied our methodology to other types of flaws, we limited our study specifically to Web vulnerabilities. Contrary to other works in this space, our methodology to find Client-Side XSS gave us the opportunity to notify domain owners of site-specific flaws rather than vulnerabilities which are the same across multiple installations. Also, to the best of our knowledge, no other parties had access to such a data set, and hence, the site administrators were not aware of the flaws before our notification. This data set gave us the opportunity to study the behavior of administrators when notified of previously-unknown vulnerabilities, and to perform a comparative analysis with a data set of known vulnerabilities.

Web vulnerabilities can be attributed to a *domain*, therefore allowing us to use additional anchors to reach administrators, e.g., in comparison to physical devices such as home routers. We nevertheless believe the methodology can be applied to other types of flaws, to determine whether the vulnerability type influences the impact of notifications. Hence, comparing different means of notifying parties for different types of vulnerabilities is an interesting direction for future research.

Even though the WordPress flaws were publicly known beforehand, they had not received media attention such as, e.g., Heartbleed or NTP amplification attacks. The vulnerabilities we disclosed also concerned the application layer rather than the network layer, i.e., needed to be fixed by a large number of disjunct site owners rather than significantly fewer network providers. Investigating these factors therefore is an interesting direction for future research. This opens new research questions such as: *Are campaigns more successful if the vulnerabilities gained attention in the media (such as Heartbleed)? Does it matter who needs to fix the vulnerability, be it a Web site developer, network admins, or end-users?*

8 Related Work

In this section, we relate our study to prior work, reviewing works on vulnerability notifications, large-scale security analysis and an emerging area of disclosing security-relevant information.

Large-Scale Vulnerability Notification — In concurrent work, Li et al. [23] investigated the feasibility of vulnerability notifications for networked systems, i.e., industry control systems, misconfigured IPv6 firewalls, and DDoS amplifiers. Similarly to our work, they discovered that notifications have a positive impact, but the global effect is low and thus unsatisfactory. Contrary to our work, they did not use links to track the reachability of recipients. They did, however, gain insights into how message content influences fix rates. Moreover, from messages received in a survey they handed out to the notified parties, they found that such notifications generally are welcomed by affected parties, underlining the need for future work in this problem space.

Prior to this work, Li et al. [24] investigated how notification of compromised Web sites can improve the time to clean-up from malware infestation. They find that directly communicating with administrators via the Google Webmaster Console increases likelihood of clean-up by 50% and decreases infection lengths by 62%.

Prior to these closely related works, Durumeric et al. [13] conducted a large-scale analysis of the Heartbleed bug. This work showed that large-scale notification may increase the number of patched servers by about 50%. The main differences between this work and our study are in the composition of the data set. The first, important one is the type of flaw: the Heartbleed bug was a very popular, high-impact flaw with outstanding media coverage and its own website. Our data set does not contain flaws of this type, however it contains previously undisclosed XSS vulnerabilities that, to the best of our knowledge, were unknown to the Web site administrator prior to our disclosure. As a result, our data set allows us to study the problem without bias due to popularity. Second, the authors used the network operator abuse contact (retrieved from the IP WHOIS), whereas we use multiple channels. Finally, our study focuses on Web vulnerabilities, and does not target flaws in the Internet infrastructure, e.g., SSL/TLS.

Similarly to the previous work, Kührer et al. [21] reported on the vulnerability disclosure process on a data set of 9 million servers susceptible to becoming unwitting attackers in NTP amplification attacks. The authors reported all flaws using *en masse* well-established channels. This allowed them to remove 90% of the vulnerable servers within 7 weeks. As opposed to our paper, they relied only on two channels, i.e., TTPs and vendors, and they did not consider other possible ones such as domain WHOIS. More importantly, the authors did not perform a comparative analysis between channels, leaving the research questions of our paper unanswered.

Large-Scale Security Analyses — Recently, we have witnessed an increasing number of large-scale security analyses ranging from validation of security testing tech-

niques (e.g., Balduzzi et al. [2], Lekies et al. [22], Doupé et al. [9]) to Internet-wide analyses of insecure behavior (e.g., Durumeric et al. [11], Kührer et al. [21]), which can spot a large number of security issues. While most of the efforts have been expended on tools and analysis techniques, little has been done to address the problem of reporting the discovered issues. For example, Balduzzi et al. [2] tested 5,000 Web sites for HTTP parameter pollution (HPP), discovering a vulnerability in 30% of them. With reference to the disclosure, the authors left the problem unaddressed, only mentioning that they could not reach all Web site owners. (For other examples in the Web domain, please refer to Doupé et al. [9]).

To better support large-scale analysis, new tools have been developed. For example, ZMap [12] can scan the entire IPv4 address space in 45 minutes. ZMap has already been used for Internet-wide analysis. For example, Durumeric et al. [11] used ZMap to study the HTTPS ecosystem, uncovering a variety of issues including certificates with invalid domains and certificate misuse. Similarly, this paper does not address the problem of reaching operators to solve the problem.

Notification of Security-Relevant Information — This paper can be seen as part of an emerging line of research that develops the idea of using notifications of security-relevant information as a security measure. Works in this area studied the distribution of security-relevant information from different angles and with a major focus on malware reports. For example, Cetin et al. [5] studied the role of sender reputation in abuse reports by sending 480 reports to network providers and Web site owners from senders with different reputations. Their study found no evidence that reputation improves cleanup rates, but they observed that, after accessing an online technical report, network providers performed better than Web site owners.

Vasek and Moore [34] looked at the problem from the angle of the quality of the reports, concluding that detailed reports increase the number of cleanups, while reports with minimal details perform better than not sending reports at all. Our paper builds on the results of these works: we did not consider sender reputation as a variable, and we prepare detailed reports.

Canali et al. [3] studied provider diligence by setting up compromised Web sites and notifying them about ongoing malicious activities. Their experiments showed that 64% of complaints were ignored. While this work shows an alarming attitude towards these problems, the size of their data set, 22 providers, makes it hard to generalize to a larger scale. From this point of view, our paper provides a broader view on the issue, including other notification channels and comparative analysis using a control group as a baseline.

9 Conclusion

With the increase of inter-connectivity on the Internet, the magnitude and diversity of large-scale vulnerability incidents will likely rise. We presented our experiences with a large-scale notification process to inform Web site owners about vulnerable Web apps. While our notifications have had a statistically significant impact on the vulnerability remediation, the overall fix rate is unsatisfactory, leaving 74.5% of Web sites exploitable after our month-long experiment.

This naturally begs the question for the potential reasons for the large fraction of unfixed sites. The major cause is the unsolved challenge to reach out to persons who can deploy a fix, such as developers or administrators. Of all contacts that we notified, only 5.8% viewed our vulnerability report. Out of these, 40% fixed the vulnerability within a week. This, but also the ease of fixing the vulnerabilities (in most cases just update WordPress), indicates that the main problem is actually to *disseminate* the vulnerability information.

How do we inform affected parties about vulnerabilities on large scale? Identifying contact points remains the main challenge that has to be addressed by the Internet society, including network providers, CERTs, and registrars. We imagine that this problem could, for example, be tackled by centralized contact databases, more efficient dissemination strategies within hosters/CERTs, or even a new notification channel or trusted party responsible for such notifications. Until we find solutions to the reachability problem, the effects of large-scale notifications are likely to remain low in the future.

Acknowledgements

The authors would like to thank Thomas Schreck and the Spanish CERT for providing insights into the inner workings of CERT organizations. Also, we would like to thank the anonymous reviewers for their helpful comments. In addition, we thank our shepherd Leyla Bilge for her support in improving the paper for the camera-ready version. This work was supported by the German Ministry for Education and Research (BMBF) through funding for the Center for IT-Security, Privacy and Accountability (CISPA).

A Notification Email

Subject: Vulnerability Notification for your domain
...com

Hello,

Primer: All information in and attached to this email is confidential and should be passed on to individuals and organizations on a need-to-know principle only.

We are security researchers from Saarland University, Germany. In our research, we have been scanning several web sites for critical vulnerabilities. We would like to inform you that your website is susceptible to the following vulnerability(ies):

- XMLRPC Multicall Vulnerability

The XMLRPC API of Wordpress can be abused to execute numerous commands on the server-side, thereby allowing an attacker to bruteforce passwords or perform a Denial-of-Service attack against the server.

You can review more detailed information using our web interface at [https://notify.mmcii.uni-saarland.de/....](https://notify.mmcii.uni-saarland.de/). Alternatively, you can retrieve more information via email. To do so, please respond to this email and set the subject line to *only* contain the token 72cf.... We will automatically respond with the vulnerability report via email.

Since this notification is part of an ongoing research project, we will re-scan your web site to see if the vulnerability has been fixed. If you wish us to stop scanning your web site, please contact us at contact@notify.mmcii.uni-saarland.de. Should you need further information or have any other questions, please do not hesitate to contact us using the same email address.

Best Regards,
Ben Stock, Researcher at CISPA

Center for IT-Security, Privacy, and Accountability
Saarland University, Building E9 1

B Multicall Checker

The Multicall checker uses a timing side-channel to determine whether a WordPress XMLRPC service is vulnerable or not. First, we estimate network latency with a probe request. We use the round-trip time of the probe to rule out network transmission time from the measurement of the multicall request. The resulting value is an estimation of the CPU time. However, as this value may be sensitive to fluctuations of the network latency estimation, we increase the execution time with inefficient user credentials. These strings trigger WordPress sanitization procedures, resulting in longer execution time,

and guarantee to always fail at login attempts to prevent accidental unauthorized access to a WordPress installation. Our test estimates CPU time of two multicall requests with 40 and 80 calls per request. We measured that our servers take 1,600 ms and 3,300 ms of CPU time on an Intel i7 processor for 40 and 80 multicalls, respectively, which we use as indicators for vulnerable services. Finally, we correlate the time analysis with the version of the deployed WordPress, which can be extracted from several sources. If both timing analysis and version indicate a vulnerable service, then we mark the Web site as *Exploitable*, otherwise as *Non-Exploitable*.

C Confidence Function

The monitoring system for WordPress returns a collection of time series $T_{ws}^v = s_1 \cdot s_2 \cdot \dots \cdot s_n$ where ws is the Web site, v a vulnerability, and s_i is the result of the checker in a point of time i with $1 \leq i \leq n$. The value s_i can be E if the checker found the vulnerability *Exploitable*; N for *Non-Exploitable*. In our experiments, we need to establish whether a Web site ws has fixed v . To do that, we take into account the rate of unlikely events within a time series in order to establish a confidence level, i.e., the number of substrings $N \cdot E$ in the longer prefix of the time series. We define the confidence that the Web site is not vulnerable as the complement of this rate. We define a Web site as not vulnerable if the confidence is greater than 0.99. If no errors occur in a time series, we define a conservative error of 0.1, i.e., a domain is marked fixed if it was *Non-Exploitable* for three consecutive days.

D Comparison of Notified Groups

Abstract

Security researchers can send vulnerability notifications to take proactive measures in securing systems at scale. However, the factors affecting a notification's efficacy have not been deeply explored. In this paper, we report on an extensive study of notifying thousands of parties of security issues present within their networks, with an aim of illuminating which fundamental aspects of notifications have the greatest impact on efficacy. The vulnerabilities used to drive our study span a range of protocols and considerations: exposure of industrial control systems; apparent firewall omissions for IPv6-based services; and exploitation of local systems in DDoS amplification attacks. We monitored vulnerable systems for several weeks to determine their rate of remediation. By comparing with experimental controls, we analyze the impact of a number of variables: choice of party to contact (WHOIS abuse contacts versus national CERTs versus US-CERT), message verbosity, hosting an information website linked to in the message, and translating the message into the notified party's local language. We also assess the outcome of the emailing process itself (bounces, automated replies, human replies, silence) and characterize the sentiments and perspectives expressed in both the human replies and an optional anonymous survey that accompanied our notifications.

We find that various notification regimens do result in different outcomes. The best observed process was directly notifying WHOIS contacts with detailed information in the message itself. These notifications had a statistically significant impact on improving remediation, and human replies were largely positive. However, the majority of notified contacts did not take action, and even when they did, remediation was often only partial. Repeat notifications did not further patching. These results are promising but ultimately modest, behooving the security community to more deeply investigate ways to improve the effectiveness of vulnerability notifications.

1 Introduction

A secure Internet ecosystem requires continual discovery and remediation of software vulnerabilities and critical misconfigurations. Security researchers discover thousands of such issues each year, across a myriad of platforms [1]. This process consists of four key phases: (1) discovering new security problems, (2) identifying remedies, (3) determining affected parties, and (4) reaching out to promote remediation among those affected.

The security community has decades of experience with the first two phases, and developments in high-speed scanning [10, 11] and network monitoring [23, 25] have significantly advanced the ease of the third phase for many security issues. However, the process of outreach remains today at best ad hoc. Unlike the public health community, which has carefully studied and developed best practices for patient notification (e.g., [4, 19]), the security community lacks significant insight into the kinds of notification procedures that produce the best outcomes.¹ Instead, for most software, the modern practice of vulnerability notification remains broadcasting messages via well-known mailing lists or websites that administrators must periodically poll and triage.

Given the relative ease with which investigators can today often determine the affected parties, the question then arises of how they should best utilize that information. In the past, performing large-scale notifications was often seen as both ineffective and impractical [2, 7, 12, 18]. However, several recent case studies have provided clear evidence to the contrary. For example, to promote patching of the 2014 OpenSSL Heartbleed vulnerability, Durumeric et al. emailed notices to operators of hosts detected as vulnerable via scanning

¹An exception concerns the development of online software update systems that explicitly tie together notification and remediation, allowing precise and automated updating targeting the affected parties. Unfortunately, the vast majority of software lacks such systems; even for those that do, operators may disable it in some contexts (critical servers, embedded systems) to avoid unplanned downtime.

and found that notified operators patched at a rate almost 50% greater than a control group [9]. Similarly, Li et al. analyzed the efforts of Google Safe Browsing and Search Quality in reaching out to operators of compromised websites, and found that direct communication with webmasters increased the likelihood of cleanup by over 50%, and reduced infection durations by more than 60% [14].

With these clear indications that notifications *can* drive positive security outcomes, it behooves the security community to determine how to best conduct the outreach efforts. At the same time, we must balance the benefits to the ecosystem (and the associated ethical responsibilities to notify) against the burden this imposes on the reporter, which calls for determining notification regimens that will not prove unduly taxing.

In this work, we strive to lay the foundations for systematically determining the most effective notification regimens, seeking to inform and drive the development of “best practices” for the community. The solution space has many more dimensions than we can hope to methodically explore in a single study. Here, we aim to develop soundly supported results for the most salient basic issues, with an eye towards then facilitating follow-on work that builds on these findings to further map out additional considerations. The issues we address include (1) who to notify (e.g., WHOIS contacts versus national CERTs versus US-CERT), (2) the role of notification content (e.g., do reporters need to devise detailed messages or do short ones suffice), (3) the importance of localization (e.g., what role does native language play in notification response rates), and (4) how these considerations vary with the nature of the vulnerability (including whether for some vulnerabilities notification appears hopeless).

We evaluate these questions empirically in the context of notification campaigns spanning three different vulnerability categories: publicly accessible industrial control systems, misconfigured IPv6 firewalls, and DDoS amplifiers. Using large-scale Internet scanning to identify vulnerable hosts and then monitor their behavior over time post-notification, we infer the effects of different notification regimes as revealed by the proportion and timeliness of contacts remediating their vulnerable hosts.

Our results indicate that notifications can have a significant positive effect on patching, with the best messaging regimen being directly notifying WHOIS contacts with detailed information within the message itself. An additional 11% of contacts addressed the security issue when notified in this fashion, compared to a control. However, we failed to push the majority of contacts to take action, and even when they did, remediation was often only partial. Repeat notifications did not further patching. We additionally characterize the responses we

received through our notification campaigns, of which 96% of human-sent responses were positive or neutral. Given these promising yet modest findings, it behooves the security community to more deeply investigate vulnerability notifications and ways to improve their efficacy. Our methodology and results form the basis for establishing initial guidelines to help drive future efforts.

2 Related Work

Several recent studies have found that large-scale security notifications increase patching and remediation—particularly for infected websites.

Vasek et al. notified 161 infected websites [24] and found that after 16 days, 55% of notified sites cleaned up compared to 45% of unnotified sites. They further note that more detailed notifications outperformed reports with minimal information by 13%, resulting in a 62% cleanup rate. Cetin et al. performed a similar study, measuring the role of sender reputation when notifying the owners of hijacked websites [5]. They emailed the WHOIS contacts of 240 infected sites from email addresses belonging to an individual independent researcher (low reputation), a university research group (medium reputation), and an anti-malware organization (high reputation). While nearly twice as many notified sites cleaned up within 16 days compared to unnotified ones, they found no significant differences across the various senders.

On a larger scale, Li et al. investigated the life cycles of 761 K website hijacking incidents identified by Google Safe Browsing and Search Quality [14]. They found that direct notifications to webmasters increased the likelihood of cleanup by over 50% and reduced infection lengths by 60% on average. Absent this communication, they observed that browser interstitials—while intended to protect browser users—correlated with faster remediation.

Most similar to the vulnerabilities we investigate, Durumeric et al. used Internet-wide scanning to track the Heartbleed vulnerability and notified system owners two weeks after public disclosure [9]. Their notifications drove a nearly 50% increase in patching compared to a control: 39.5% versus 26.8%.

Concurrent to this work, Stock et al. investigated the feasibility of large-scale notifications for web vulnerabilities [22]. Similar to our study, they experimentally evaluated the effectiveness of different communication channels, including WHOIS email contacts and CERTs. Additionally, they analyzed the reachability and viewing behavior of their messages. Their results largely accord with ours, providing a complementary study of notifications in a separate context (namely, vulnerable websites). Notably, they likewise observed that while notifications

Dataset	Hosts	WHOIS Abuse Contacts	Hosts with WHOIS Contacts
ICS	45,770	2,563	79.7%
IPv6	180,611	3,536	99.8%
Ampl.	83,846	5,960	92.4%

Table 1: Vulnerable Hosts—We notified network operators about three classes of vulnerabilities found in recent studies: publicly accessible industrial control systems (ICS), hosts with misaligned IPv4 and IPv6 firewall policies, and DDoS amplifiers (NTP, DNS, and Chargen).

could induce a statistically significant increase in patching, the raw impact was small. In the best case, only an additional 15% of the population patched compared with a control group.

Each of these studies has established that notifications can increase vulnerability patching and cleanup. We build on these works and explore the next critical step: understanding what factors influence patching and how to construct effective vulnerability notifications.

3 Methodology

To measure notification efficacy and to understand how to construct effective notifications, we notified network operators while varying aspects of the notification process. In this section, we detail the datasets of vulnerable hosts, the variables we tested, and how we tracked remediation.

3.1 Vulnerable Hosts

We notified operators about the three classes of vulnerabilities listed below. We show the population of vulnerable hosts in Table 1.

Publicly Accessible Industrial Control Systems Industrial control systems (ICS) are pervasive and control physical infrastructure ranging from manufacturing plants to environmental monitoring systems in commercial buildings. These systems communicate over a myriad of domain and manufacturer specific protocols, which were later layered on Ethernet and TCP/IP to facilitate long distance communication. Never designed to be publicly accessible on the Internet, these protocols lack important security features, such as basic authentication and encryption, but nonetheless are frequently found unsecured on the public Internet. To identify vulnerable ICS devices, Mirian et al. extended ZMap [10] and Censys [8] to complete full IPv4 scans for several ICS protocols: DNP3, Modbus, BACnet, Tridium Fox, and Siemens S7 [17]. In total, they found upwards of

46 K ICS hosts that were publicly accessible and inherently vulnerable.

We coordinated with Mirian et al. to complete daily scans for each protocol against the public IPv4 address space from January 22–24, 2016. We limited our study to the 45.8 K hosts that were present all three days to reduce the noise due to IP churn. To track the impact of our notifications, we continued the daily scans of these hosts using the same methodology.

Misconfigured IPv6 Firewall Policies Czyz et al. found that 26% of IPv4/IPv6 dual-stack servers and routers have more permissive IPv6 firewall policies compared to IPv4, including for BGP, DNS, FTP, HTTP, HTTPS, ICMP, MySQL, NTP, RDP, SMB, SNMPv2, SSH, and Telnet access [6]. For example, twice as many routers have SSH accessible over IPv6 compared to IPv4. Given the presumed rarity of IPv6-only services, this likely indicates a misconfiguration and potential security issue.

To identify dual-stack servers, Czyz et al. looked for hostnames in the Rapid7 DNS ANY dataset [20] that had both A and AAAA records. After filtering out automatically generated hostnames, they identified 520 K dual-stack servers. To find routers, the team performed reverse DNS lookups and subsequent A and AAAA lookups for hosts in the CAIDA Ark dataset [3], identifying 25 K routers. Czyz et al. then scanned these hosts using Scamper [15] to identify firewall inconsistencies.

We scanned the hosts that Czyz et al. identified over a 25 day period from December 31, 2015 to January 24, 2016. We limited our study to the 8.4 K routers and 172.2 K servers that were consistently available during that period. Similar to the ICS measurements, we continued to perform daily scans using the same methodology to track the impact of our notifications.

DDoS Amplifiers Several UDP protocols allow attackers to launch distributed denial of service attacks when improperly configured [21]. In this scenario, an attacker spoofs a small request to a misconfigured server, which then sends a large response to the victim. For example, an attacker can spoof a DNS lookup to a recursive DNS resolver, which will then send the full recursive lookup to the victim’s machine. We identified 152 K misconfigured hosts that were actively being used to launch DDoS attacks over NTP, DNS, and Chargen by monitoring the sources of DDoS attacks against a university network between December 11–20, 2015.

We restricted our notifications to the vulnerable hosts that were consistently available during our daily scans from December 21, 2015 to January 26, 2016. In total, we discovered 5.9 K Chargen amplifiers, 6.4 K NTP amplifiers, and 71.5 K DNS amplifiers on 83.8 K distinct IP addresses. We continued to track these hosts by performing

ing daily protocol scans (e.g., Chargen requests, NTP monlist commands, and DNS recursive lookups).

In each case, we coordinated with the studies’ authors to ensure that they did not simultaneously notify operators. However, we do note that groups have previously sent notifications to DDoS amplifiers [13].

3.2 Experiment Variables

To understand how to best construct and route notification messages, we performed notifications using several methodologies and measured the differences in remediation. We specifically aimed to answer the following questions:

Who should researchers contact? Researchers have several options when deciding where they should report vulnerabilities, including directly contacting network operators, notifying national CERTs, and asking their own country’s CERT to disseminate the data to other CERT groups. We tested three options: (1) notifying the abuse contact from the corresponding WHOIS record, (2) geolocating the host and contacting the associated national CERT, and (3) asking our regional CERT (US-CERT) to propagate the information.

How verbose do messages need to be? It is not clear how much information researchers need to include when notifying operators. For example, are notifications more effective if researchers include detailed remediation steps or will such instructions go unheeded? We sent three types of messages: (1) a terse message that briefly explained that we discovered the vulnerability with Internet-wide scanning, and the impact of the vulnerability (e.g., for ICS notifications, we wrote “These devices frequently have no built-in security and their public exposure may place physical equipment at risk for attack.”), (2) a terse message with a link to a website with detailed information, and (3) a verbose email that included text on how we detected the problem, vulnerability details, and potential remediation steps. We provide the full text of our different messages in Appendix B–G.

Do messages need to be translated? We tested sending messages in English as well as messages translated by native technical speakers to several local languages.

3.3 Group Assignment

To test the impact of our experiment variables, we randomly formed experiment groups that received different notification regimens. Here we describe our process for constructing these groups.

For each IP address, we extracted the abuse contact from the most specific network allocation’s WHOIS

Group	ICS	IPv6	Ampl.
Control	657	3,527	1,484
National CERTs	174	650	379
US-CERT	493	578	1,128
WHOIS: English Terse	413	633	777
WHOIS: English Terse w/ Link	413	633	777
WHOIS: EnglishVerbose	413	632	777
WHOIS: Language – Terse

Table 2: Notification Groups—We aggregated vulnerable hosts by WHOIS abuse contacts and randomly assigned these contacts to notification groups. Here, we show the number of contacts notified in each group. Note that for the language experiments, we tested terse and verbose messages for several countries, both translated and in English.

record. For the 16.7% of dual-stack hosts with different contacts extracted from IPv4 and IPv6 WHOIS records, we used the contact with the deepest level of allocation, and preferred IPv6 contacts when all else was equal (4.3% of dual-stack hosts).

To test each variable, we split the abuse contacts from each vulnerability into treatment groups (Table 2). For the ICS and amplifier experiments, we randomly allocated one quarter of abuse contacts to the control group (Group 1), one quarter to the CERT groups (half US-CERT, half national CERTs), and the remaining half to the WHOIS groups. For IPv6, to act in a responsible manner we needed to complete *some* form of notification for all hosts to ensure adequate disclosure prior to the release of the corresponding study [6] in February 2016. This prevented us from using a true control group. Instead, we approximate the behavior of the control group using the 25 days of daily scans prior to our notifications. We allocated a third of the IPv6 contacts to the CERT groups, and the remainder to the WHOIS groups.

For the vulnerable hosts assigned to the CERT groups,

we geolocated each IP using MaxMind [16] and identified the associated CERT. We note that not all countries have an established CERT organization. This was the case for 2,151 (17%) IPv6 hosts, 175 (8%) ICS devices, and 2,156 (19%) DDoS amplifiers. These hosts were located in 16 countries for IPv6, 26 countries for ICS, and 63 countries for DDoS. Many of these countries are in Africa or Central America (e.g., Botswana, Ethiopia, and Belize), or are smaller island states (e.g., American Samoa, Antigua and Barbuda, and the Bahamas). We did not include hosts without a CERT organization in the CERT experiment (although we later passed them along to US-CERT).

In total, 64 CERTs were responsible for IPv6 hosts, 57 for ICS, and 86 for amplifiers. To compare directly contacting national CERTs versus having US-CERT distribute information to them, we randomly divided the affected national CERTs into two halves. For national CERTs in the first half, we contacted them directly with vulnerable hosts in their region (Group 2). We sent the remaining hosts for CERTs in the second half to US-CERT (Group 3).

We obtained native translations of our WHOIS messages for several countries. We allocated contacts in the WHOIS groups that were in those countries (based on the WHOIS records) for our language experiment, further detailed in Section 4.3. The remaining contacts were randomly split into three groups based on message verbosity: terse (Group 4), terse with a link (Group 5), and verbose (Group 6).

3.4 Notification Process

We sent notification emails with the FROM and REPLY-TO header set to an institutional mailing list: *security-notifications@berkeley.edu*. In each message, we attached a CSV file that contained the list of vulnerable hosts along with the latest scan timestamp and the list of vulnerable protocols. We also included a link to an anonymous survey, which asked for the organization’s perspective on the reported security issue and whether they found our detection and notification acceptable. The messages were sent from a server in UC Berkeley’s network, which was listed as a valid mail server by UC Berkeley’s SPF policy. We note that we also included a randomly generated identifier in each email subject that enabled us to match a reply to the original notification.

3.5 Tracking Remediation

We tracked the impact of different notification methodologies by scanning all hosts for several weeks following our notifications. As our scanning methods tested the reachability of several services, we may have falsely

identified a host as patched due to random packet loss or temporary network disruptions. To account for this, we only designated a host as patched if it did not appear vulnerable in any subsequent scans. We leveraged the last day’s scan data for this correction, but did not otherwise use it in our analysis as it lacked subsequent data for validation.

One limitation in our tracking is the inability to distinguish true patching from network churn, where the host went offline or changed its IP address. While we can still conduct a comparative analysis against our control group, we acknowledge that our definition of patching is a mixture of true patching and churn. We investigated whether we could better approximate true remediation by distinguishing between RST packets and dropped packets. We compared the proportion of RSTs and drops between our control group and our notified groups two days after notification and two weeks after notification. At both times, we observed nearly identical proportions between the control and notified groups—in all cases less than 20% of hosts sent RST packets. This indicates that RST packets are not a reliable signal for remediation, as most hosts did not send RST packets even when truly fixed.

Unless stated otherwise, we consider a host as having taken remediation steps for a particular vulnerability if any of its affected protocols were detected as fixed. Likewise, we say a notification contact has taken remediation steps if any of its hosts have patched. We define the remediation rate as the percentage of notification contacts that have taken remediation steps. This definition is over contacts rather than hosts as we are measuring the impact of notifying these contacts, and contacts differ in the number of affected hosts.

3.6 Ethical Considerations

We followed the guidelines for ethical scanning behavior outlined by Durumeric et al. [10]: we signaled the benign intent of our scans through WHOIS entries and DNS records, and provided project details on a website on each scanning host. We respected scanning opt-out requests and extensively tested scanning methods prior to their deployment.

The ethics of performing vulnerability notifications have not been widely discussed in the security community. We argue that the potential good from informing vulnerable hosts outweighs the risks. To minimize potential harm, we only contacted abuse emails using addresses available in public databases. Additionally, we messaged all unnotified contacts at the conclusion of the study. We offered a channel for feedback through an anonymous survey with questions about the notified organization (described in Appendix A). We note that be-

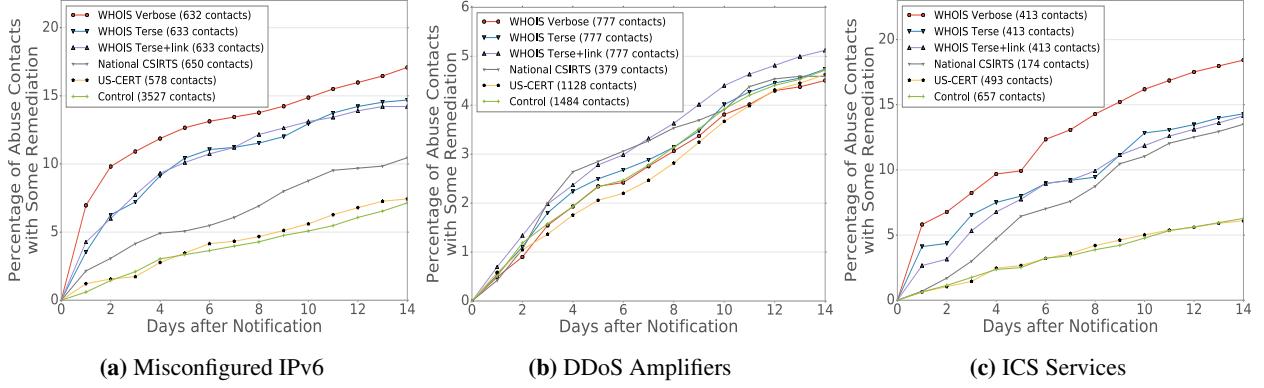

Figure 1: Remediation Rates—We show the remediation rate for each variable we tested. We find that verbose English notifications sent to network operators were most effective for IPv6 and ICS. Note the varying Y axes.

cause we only collected data about organizational decisions and not individuals, our study did not constitute human subjects research (confirmed by consulting the UC Berkeley IRB committee). Nevertheless, we followed best practices, e.g., our survey was anonymous and optional.

4 Results

For both ICS and IPv6, our notifications had a significant impact on patch rates. In our most successful trial—verbose English messages sent directly to operators—the patch rate for IPv6 contacts was 140% higher than in the control group after two weeks. For ICS, the patch rate was 200% higher. However, as can be seen in Figure 1b, none of our notifications had significant impact on DDoS amplifiers. This is likely due to the extensive attention DDoS amplifiers have already received in the network operator community, including several prior notification efforts [21]. In addition, these amplifiers were already previously abused in DDoS attacks without administrative responses, potentially indicating a population with poor security stances. It is also important to note that our best notification regimen resulted in at most 18% of the population remediating. Thus, while notifications can significantly improve patching, the raw impact is limited. In the remainder of this section, we discuss the impact of each experiment variable and how this informs how we should construct future notifications.

To characterize the performance of our trial groups, we measure the area under the survival curve for each group, which captures the cumulative effect of each treatment. To determine if observed differences have statistical significance, we perform permutation tests with 10,000 rounds. In each round of a permutation test, we randomly reassign group labels and recompute the area differences under the new assignments. The intuition is

that if the null hypothesis is true and there is no significant difference between two groups, then this random reassignment will only reflect stochastic fluctuation in the area difference. We assess the empirical probability distribution of this measure after completing the permutation rounds, allowing us to determine the probability (and significance) of our observed values.

All reported p -values are computed via this permutation test. We use a significance threshold of $\alpha = 0.05$, corrected during multiple testing using the simple (although conservative) Bonferroni correction, where each test in a family of m tests is compared to a significance threshold of $\frac{\alpha}{m}$.

Ideally, we would have selected this procedure as part of our original experimental design. Unfortunately, we only identified its aptness *post facto*; thus, its selection could introduce a selection bias, a possible effect that we lack any practical means to assess.

4.1 Notification Contact

For both IPv6 and ICS notifications, directly notifying WHOIS abuse contacts was most effective—particularly early on. Two days after IPv6 disclosure, direct verbose notifications resulted in 9.8% of the population remediating, compared to 3.1% when contacting national CERTs and 1.4% by contacting US-CERT. For ICS, direct notifications promoted 6.8% of the population to patch, more than national CERTs (1.7%) and US-CERT (1.0%). In both cases, direct notifications were notably better than no notifications. As can be seen in Figures 1a and 1c, this gain was persistent. After two weeks, the patch rate of directly notified IPv6 contacts was 2.4 times as high as the control, and three times as high for ICS contacts.

To determine if these observations are statistically significant, we perform permutation tests using the Bonferroni correction. With six treatment groups, the family of

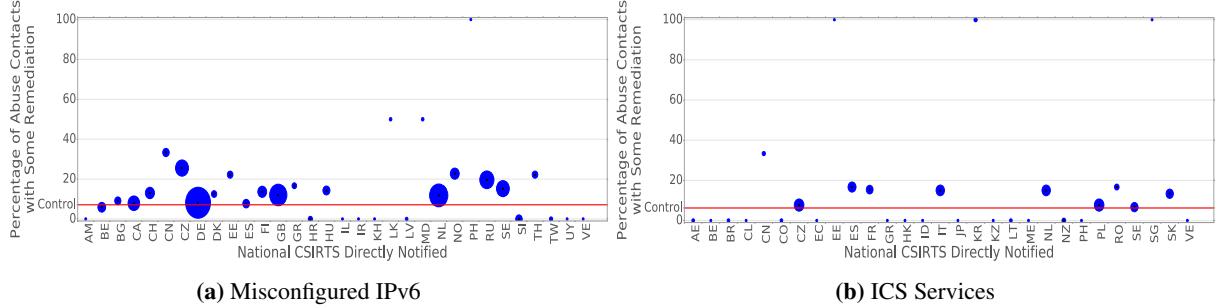

Figure 2: Differences between National CERTs—We show the remediation rate for each directly notified national CERT after two weeks. The size of a data point is proportional to the number of abuse contacts in the country. We directly contacted 32 CERTs for IPv6, and 29 CERTs for ICS. We observe notable differences between CERT groups. However, none are statistically significantly different than the control group. This may be because there are too few hosts for some countries, and that the Bonferroni correction is conservative.

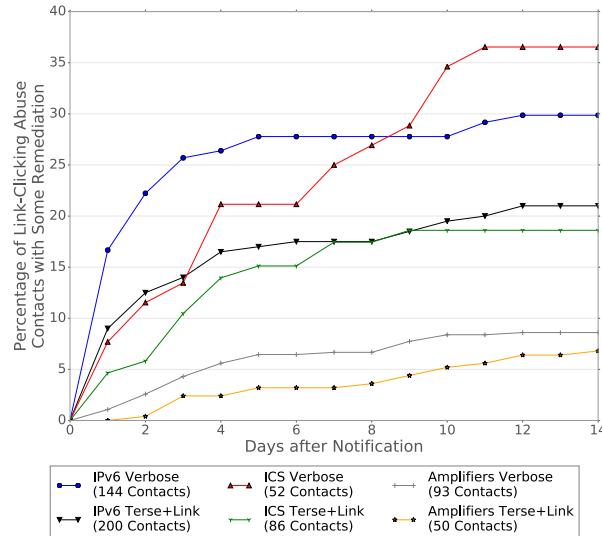

Figure 3: Remediation Rates for Website Visitors—The contacts who viewed our informational website remediated at a higher rate than those who received a verbose message. However, despite this, less than 40% of the contacts who visited the site fixed the vulnerability.

pairwise comparisons includes 15 tests, giving an individual test threshold of $\alpha = 0.0033$. Under the permutation test, the gains that direct verbose notifications had on the CERTs and the control group are statistically significant for both IPv6 and ICS, with all p -values less than 0.0001 except when comparing ICS verbose notifications with national CERTs ($p = 0.0027$).

Notably, US-CERT—our local CERT who we asked to disseminate data to other CERT groups—had the lowest patch rate, which is statistically indistinguishable from the control group that had no notifications. We suspect that US-CERT did not disseminate the data to any other

CERT groups or notify any US operators. One national CERT included in the report to US-CERT informed us they had not received any notices from US-CERT. As seen in Figure 2, there were stark differences between CERT groups—some duly notified operators, while others appear to have ignored our disclosures.

Overall, this suggests that the most effective approach—in terms of both the number of hosts patched and the rate of patching—is to directly notify network operators rather than contact CERT groups.

4.2 Message Verbosity

To determine what information needs to be included in notification messages, we sent three types of emails: (1) verbose, (2) terse, and (3) terse with a link to a website with additional details. We observed the best remediation by contacts who received verbose messages. For IPv6, verbose messages were 56.5% more effective than either terse messages after two days and 55.5% more effective for ICS. However, as can be seen in Figure 1, the differences between verbose and terse messages decreased over time.

Using permutation testing and the Bonferroni correction, we find that the differences between the message types are not statistically significant for IPv6 and ICS. However, given the earlier benefits that verbose messages had for both data sets, we argue notifiers may still want to prefer verbose messages over terse ones. We discuss this effect further in Section 4.4 and note that further investigation of this variable is warranted.

We tracked the remediation rate of contacts who visited the linked website, as shown in Figure 3. We note that all of the information included in the verbose message was available on the linked website and that 16.8% of users who received an email with a link visited the site. This indicates that a sizable population of users engaged

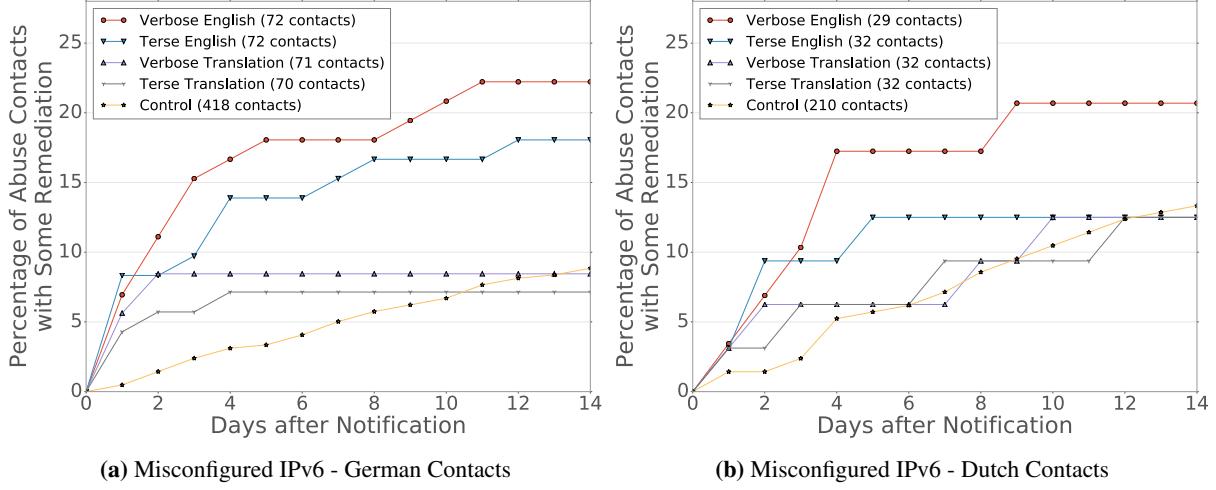

Figure 4: Remediation Rates for Translated Messages—We find that sending verbose English messages was more effective than translating notifications into the language of the recipient. Note, though, that this observation is limited to the small set of languages we were able to evaluate.

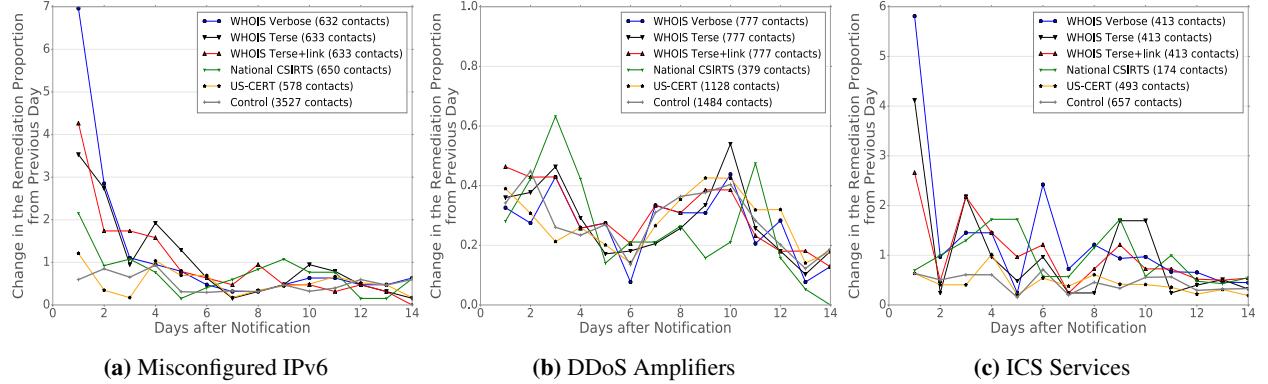

Figure 5: Daily Changes in Remediation Proportions—We show the differences in the proportions of remediated contacts from one day to the next. We find that most contacts that remediated fixed the problem immediately after disclosure. After a few days, contacts returned to remediating at the same rate as the control group.

with our site, but many would not patch even after visiting the link. Specifically, no more than 40% of website visitors patched. Thus, even when our messages successfully reached contacts, the majority did not take action.

4.3 Message Language

To investigate whether notifications need to be translated into recipients’ local languages or can be sent in English, we distributed translated messages for two countries for DDoS and IPv6 notifications. For DDoS amplifiers, we obtained native Russian and Polish translations—for the countries with the third and fourth largest number of vulnerable organizations. For IPv6, we translated messages into German and Dutch, for the second and third largest countries. The population of contacts in non-English

speaking countries for the ICS dataset was too low to provide significant meaning. We randomly split the WHOIS contacts in each country into four groups that vary language and verbosity.

We observe no significant effect from language for DDoS notifications. This is unsurprising given our notifications’ overall lack of effect on DDoS amplifiers. For IPv6, as seen in Figure 4, we observe that translated messages resulted in worse patching than when left in English. Several survey respondents were surprised at receiving translated messages from United States institutions and initially suspected our notifications were phishing messages or spam, which may explain the lower patch rate. The additional overhead of translating messages paired with less successful disclosure suggests that it may be most effective to send notifications in English.

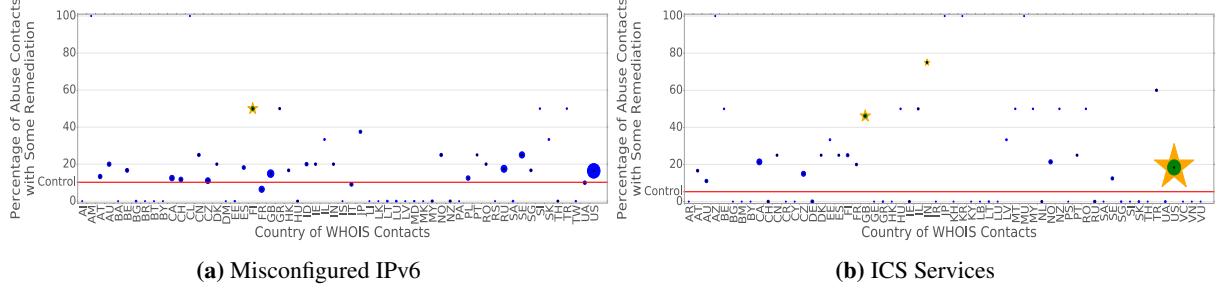

Figure 6: Contact Remediation per Country—We show the percentage of contacts who remediated per country after two weeks. The data sizes are proportional to the number of contacts. Green data points surrounded by an orange star signify countries with a remediation rate statistically better than the control group's, under the permutation test using the Bonferroni correction.

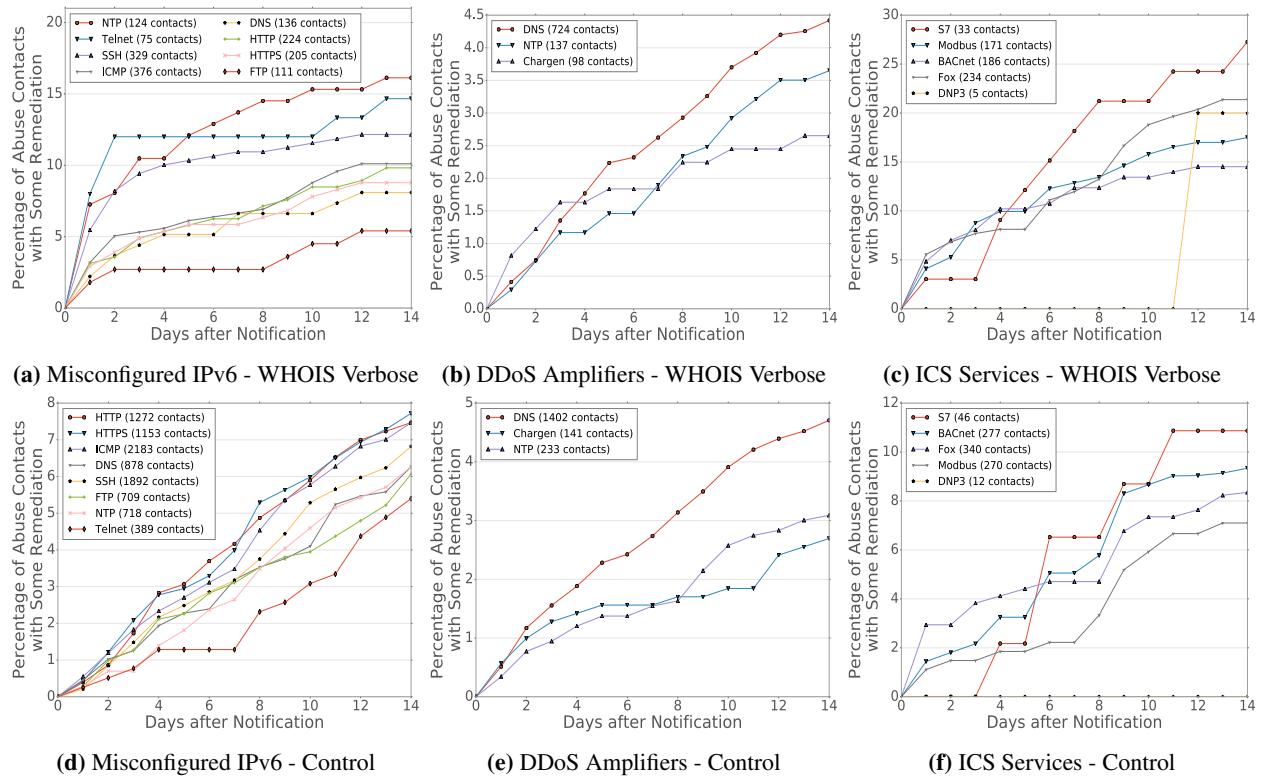

Figure 7: Protocol Remediation Rates—We track the remediation rate for each specific protocol within the WHOIS verbose group and the control group. We note that operators patched some protocols significantly faster than others (e.g., Telnet versus FTP).

However, we note that our results are limited to the small set of languages we were able to obtain reliable translations for, and deeper investigation into the effects of message language is warranted.

4.4 Staying Power of Notification's Effect

As can be seen in Figure 5, our notifications caused a near immediate increase in patching. However, this

increased patching velocity did not persist. In other words, we find that the effects of notifications were short-lived—on the order of several days. The day after notifications were sent, we observe large increases in the remediation proportions for IPv6 and ICS notified groups, as operators responded to our reports. However, we also see that the daily changes in remediation proportions drastically dropped by the second day.

For IPv6, the daily changes in remediation proportions

for all notified groups leveled off and matched that of the control group from the fifth day onward. We also witness a drop off in the daily remediation proportion changes for ICS, although a non-trivial amount of change continued throughout the first 10 days. Notably, the national CERTs first began accelerating remediation after two days, a delay compared to WHOIS experiment groups. For amplifiers, there was little change in the remediation rate over time, which is unsurprising given the limited effect of our notifications.

4.5 Geographic Variation

As with the national CERTs, we note variation in the patching rates between countries. This suggests that the geographic distribution of vulnerable contacts may influence a notification’s outcome. As visible in Figure 6, the United States, Great Britain, India, and Finland were the only countries that patched significantly better than the control group. However, we note that some countries had too few hosts to be statistically significant, given the conservative nature of the Bonferroni correction.

4.6 Variation over Protocols

In Figure 7, we observe variation in the patch rates for different protocols within each vulnerability (e.g., Modbus versus S7 for ICS). As seen in Figure 7a, network administrators reacted most to open IPv6 NTP, Telnet, and SSH services, and least to FTP, with over a 200% difference in the remediation proportions. This variation is not reflected in the control group (Figure 7d), where all protocols exhibited similar behavior. This may reflect an increased likelihood that certain services were unintentionally left accessible, or that operators assessed different levels of risk for allowing different protocols to be reachable.

Operators also responded differently for the multiple ICS protocols (Figure 7c), but the variation is also reflected for contacts in the control group (Figure 7f). BACnet, Fox, and Modbus devices were fixed at similar rates. While the remediation of S7 systems initially lagged behind, there was a significant upswing in action after three days, with nearly 18% of contacts with vulnerable S7 systems patching after 8 days.

Surprisingly, no DNP3 systems had been patched within 10 days of notification (out of 5 contacts). We note that these five contact groups belonged to Internet service providers—not individual organizations. We similarly note that DNP3 differs from the other protocols and is specifically intended for power grid automation. These devices may be remote power stations which require more complex changes than local devices

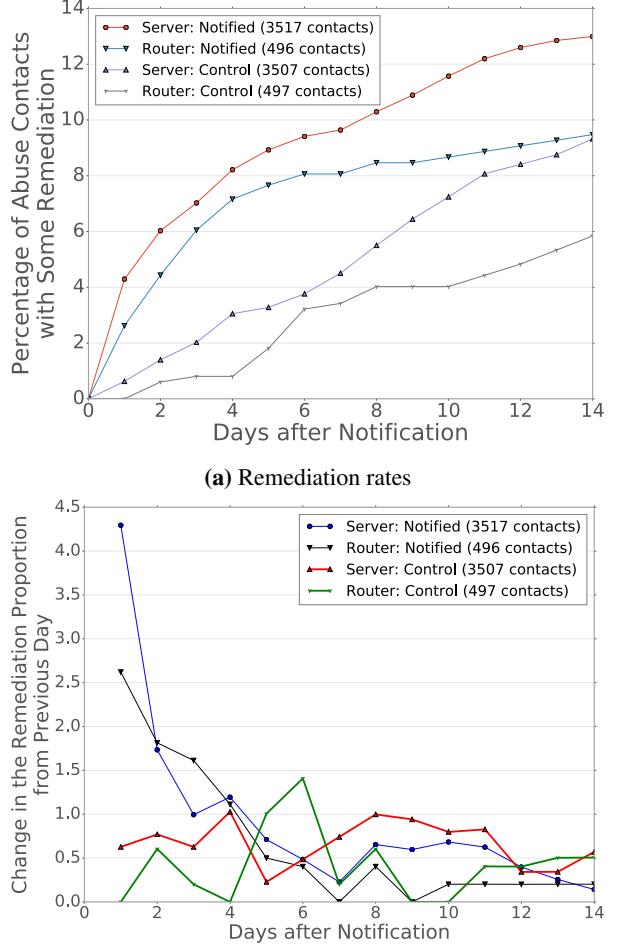

Figure 8: Remediation Rates by Host Type—We find no significant difference in the remediation rate between servers and routers.

(e.g., installation of new hardware versus a configuration change).

While we observe variation between amplifier protocols, these fluctuations are similar in both the notified and control group. Given the limited effect of our DDoS amplifier notifications, these differences likely reflect the varying natural churn rates of these hosts.

4.7 Host Type

When notifying IPv6 operators, we were able to distinguish between servers and routers. To assess the difference between device types, for each type, we only consider contacts with a vulnerable host of that type. We count a contact as having performed some remediation if that contact fixed at least one host of that type.

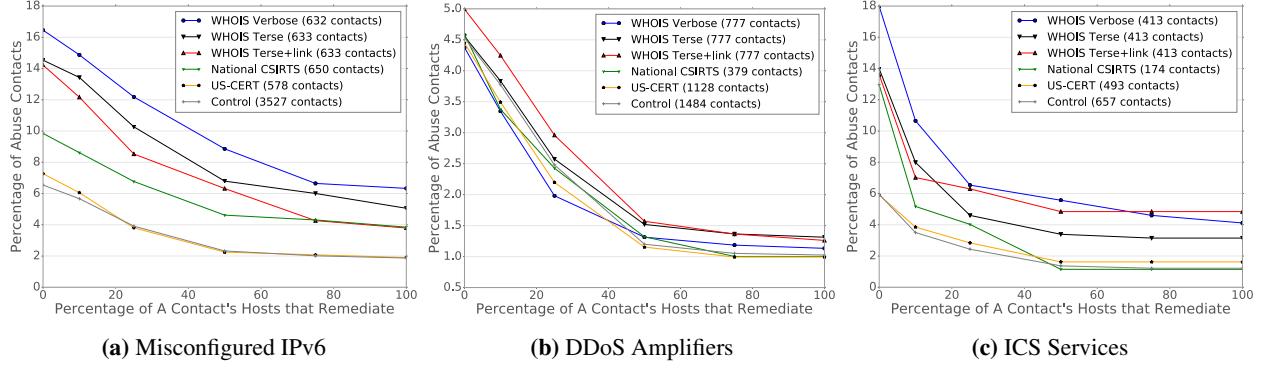

Figure 9: Remediation Completeness—We find that most operators only fixed a subset of their vulnerable hosts. For example, only 40% of the operators that fixed a single host fixed all hosts in their purview.

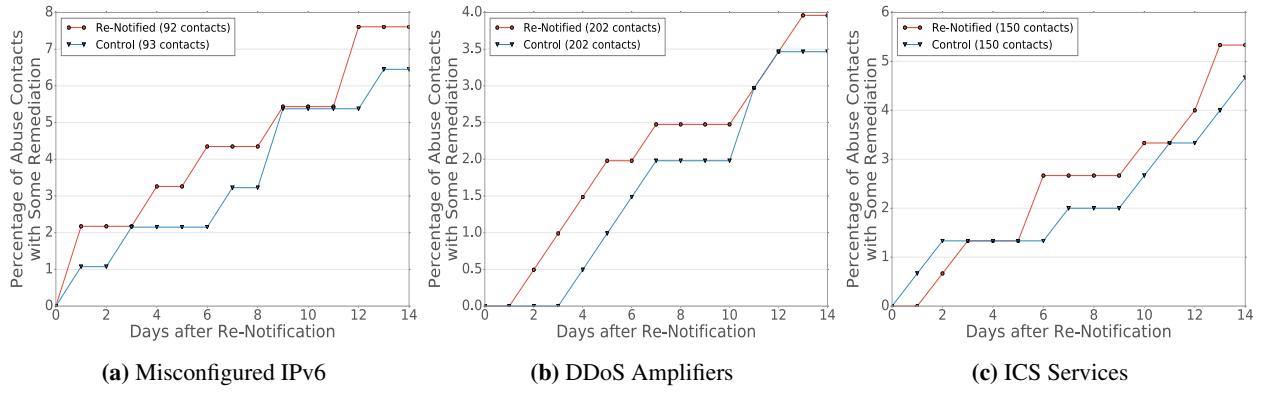

Figure 10: Re-Notifications—We find that a second round of notifications did not result in increased remediation.

We observe that servers and routers remediated at similar rates for the first four days, after which router remediation dropped off and fell significantly below that of servers (Figure 8a). However, servers also naturally patched at a higher rate than routers in the control group. This difference accounts for the gap between notified servers and routers after four days. This is also visible in Figure 8b, where the daily changes in the remediation proportions converged after four days. After 14 days, notified contacts with servers fixed at a rate 44% higher than notified contacts with routers. The divergence in the control group was similar at 48%. This indicates that overall, network administrators respond to vulnerabilities in servers and routers about equally.

4.8 Degree of Remediation

Up to this point, we designated a contact as having patched if any host under its purview was patched. We now consider how well operators patched their hosts.

As can be seen in Figure 9, the majority of contacts did not patch all of their servers. Less than 60% secured all hosts and we note that 30% of groups with 100% reme-

diation were only responsible for fixing one or two hosts. This highlights one of the challenges in the vulnerability notification process: even if our messages reach a designated contact, that contact may not have the capabilities or permissions to remediate all hosts. The multiple hops in a communication chain can be broken at any link.

4.9 Repeated Notifications

Given that our notifications resulted in improved patching, a natural question is whether repeat notifications promote further remediation. We conducted a second round of notifications for the contacts that were directly sent verbose messages in the first round since these proved to be the most effective. We randomly split contacts who had not remediated one month after our notifications into two groups, one as a control group and one to receive a second round of notifications.

As can be seen in Figure 10, the patch rates between the re-notified group and the control group were similar for all three vulnerabilities, indicating that repeat notifications are not effective. This suggests that contacts who did not remediate during the first round of notifications

either were not the appropriate points of contact, or chose (either intentionally or due to lack of capabilities) to not remediate. It is unlikely they simply missed or forgot about our original notification.

5 Notification Reactions

We included a link to an anonymous survey in all of our notification emails as well as monitored the email address from which we sent messages. In the two weeks following our disclosures, we received 57 survey submissions and 93 human email replies. In this section, we analyze these responses.

5.1 Email Responses

Of the 685 email responses we received, 530 (77%) were automated responses (e.g., acknowledgment of receipt), 62 (9%) were bounces, and 93 (14%) were human responses (Table 3). For all three vulnerabilities, over 70% of the human responses expressed positive sentiments. We received only four negative emails, all of which concerned IPv6. Two stated that we were incorrectly using the abuse contact; the other two noted that the open IPv6 services were intentional and asked to be excluded from notifications in the future. None of the emails were threatening. We detail the breakdown for each vulnerability type in Table 4.

Beyond expressing sentiments, 23 contacts requested additional information—primarily about how we detected the vulnerabilities; two requested remediation instructions. Of those 23 contacts, 15 (65%) received terse notifications without a link to additional information, while 3 contacts (13%) received verbose messages. We note that verbose messages both reduced follow-up communication and resulted in the highest patching rate.

Unexpectedly, all five contacts who requested information about DDoS amplifiers asked for evidence of DDoS attacks via network logs. This may be a result of the extensive attention amplifiers have received in the past, such that operators only respond to active abuse issues regarding amplifiers.

Twelve IPv6 contacts rebutted our claim of vulnerability. Six stated that the inconsistency was intentional; one was a honeypot; and five explained that the IP addresses we sent them no longer pointed to the same dual-stack host, likely due to network churn. Two amplifier contacts claimed we falsely notified, stating that their hosts were honeypots. However, we do note that these IPs were seen as part of an attack and were therefore likely misconfigured honeypots.

Most human responses were in English, with eight (9%) in other languages: 3 Russian, 1 German, 1 Czech, 1 Swedish, 1 French, and 1 Slovak. These non-English

Response Types	ICS	IPv6	Ampl.
Automated	143	214	173
Human	22	48	23
Bounces	10	34	18
Total	175	296	214
Contacts w/ No Reply	85.9%	87.2%	92.8%

Table 3: Email Responses—We received 685 email responses to our notifications, of which 14% were human replies.

Human Responses	ICS	IPv6	Ampl.
Positive Sentiments	17	35	19
Negative Sentiments	0	4	0
Neutral Sentiments	5	9	4
Request for Information	2	16	5
Taking Actions	12	17	15
False Positive Notification	0	12	2
Total	22	48	23

Table 4: Human Email Responses—We characterize the human email responses we received in reply to our notifications.

replies were in response to English notifications and expressed gratitude; none requested additional information.

We note that the level of feedback we received regarding DDoS notifications was commensurate with our other efforts, yet the patch response was minimal. This could indicate that operators struggle with actually resolving the issue after encountering and responding to our messages, or have become desensitized enough to DDoS issues to not take real action.

5.2 Anonymous Survey Responses

All of our notification messages contained a link to an anonymous seven question survey (Appendix A), to which we received 57 submissions. We summarize the results in Table 5.

Interestingly, 46% of respondents indicated that they were aware of the vulnerability prior to notification, and 16% indicated that they had previously attempted to resolve the problem. This contrasts with the survey results in the Heartbleed study [9], where all 17 respondents indicated they were aware of the Heartbleed vulnerability and had previously attempted to resolve the problem. The widespread media attention regarding the Heartbleed bug may account for this discrepancy, highlighting the differences in the nature of various vulnerabilities.

For DDoS amplifiers and ICS vulnerabilities, the ma-

Survey Responses	ICS	IPv6	Ampl.
Aware of Issue	2/4	20/45	4/8
Taken Prior Actions	1/4	5/43	3/8
Now Taking Action	4/4	24/43	6/8
Acceptable to Detect	3/4	35/45	7/8
Acceptable to Notify	2/4	34/45	7/8
Would want Future Notifications	2/4	30/43	7/8
Correct Contact	1/3	37/43	6/8
Total	4	45	8

Table 5: Survey Responses—We included a link to a short, anonymous survey in all of our notifications. We find that most respondents (54%) weren’t aware of the vulnerabilities, but found our scanning and notifications acceptable (over 75%). Further, 62% of respondents stated they were taking corrective actions and 71% of respondents requested future notifications.

jority of respondents expressed that they were now taking corrective action (75% for DDoS amplifiers, 100% for ICS). For IPv6, only 56% of respondents indicated they would fix the problem. Given the nature of the IPv6 notification, it is likely that some of the misaligned policies were intentional.

Over 80% of respondents indicated that we reached out to the correct contact, who found scanning and notifications acceptable and requested future vulnerability notifications. However, this is a population with whom we successfully established communication. The accuracy of the other contacts from whom we did not hear back could be lower.

Our survey also allowed respondents to enter free form comments. We received 17 IPv6 comments, 4 DDoS amplifier comments, and 1 ICS comment. Of the IPv6 respondents, 5 thanked us, 7 discussed how the misalignment could be intentional or that our detection was incorrect, 3 equated our messages to spam, and 2 noted that they initially thought our translated messages were phishing messages because they expected English messages from an institution in the United States. For amplifiers, we received four comments: two thanking us and two informing us not to notify unless there is a real attack. Finally, there was only one ICS commenter, who suggested contacting vendors instead of network operators, but thanked us for our notification.

The feedback we received from these survey answers and the email responses indicates an overall positive reception of our notifications. While it may be that those who provided feedback are more opinionated, these results suggest that further discourse on notifications is needed within our community.

6 Discussion

Here we summarize the main results developed during our study, and the primary avenues for further work that these suggest.

Effective Vulnerability Notifications Our results indicate that vulnerability notifications can improve remediation behavior and the feedback we received from network operators was largely positive. We conclude that notifications are most effective when detailed messages are sent directly to WHOIS abuse contacts. These notifications were most effective in our experiments and resulted in an additional 11% of contacts addressing a vulnerability in response to our message.

On the one hand, this result provides clear guidance on how to best notify network operators. On the other hand, the majority of organizations did not patch their hosts despite our notifications. Even among those who patched at least one host, most did not fix all of their vulnerable hosts. In the case of networks hosting DDoS amplifiers, *no* form of notification generated benefits statistically significant over the control.

The failures to remediate could signal a number of problems, including:

1. failure to contact the proper parties who could best instigate remediation;
2. a need for better education about the significance of the vulnerability;
3. a need for better education about the remediation process;
4. administrative or logistical hurdles that proved too difficult for those parties to overcome;
5. or a cost-benefit analysis by those parties that concluded remediation was not worth the effort.

Illuminating the role that each of these considerations plays, and the best steps to then address them, remains for future work.

In addition, we found the effects of our notification campaigns to be short-lived: if recipients did not act within the first couple days, they were unlikely to ever do so. Repeat notifications did not further improve remediation levels.

Thus, while we have developed initial guidance for conducting effective notifications, there remain many unanswered questions as to how to best encourage operators to patch vulnerable hosts.

Improving Centralized Notification Mechanisms We observed that relying on national and regional CERT organizations for vulnerability notifications had either a modest effect (compared to our direct notifications) or no effect (indistinguishable from our unnotified controls).

While certain national CERTs evinced improved levels of remediation, others either did not act upon the information we reported, or if they did so, recipients ignored their messages. Thus, the community should consider more effective mechanisms for facilitating centralized reporting, either within the existing CERT system, or using some separate organizational structure. This need is quite salient because the burden of locating and messaging thousands of individual contacts is high enough that many researchers will find it too burdensome to conduct notifications themselves.

Open Ethical Questions The process of notifying parties regarding security issues raises a number of ethical questions. The community has already discussed some of these in depth, as in the debates concerning “full disclosure.” Contacting individual sites suffering from vulnerabilities, likewise, raises questions regarding appropriate notification procedures.

For example, WHOIS abuse emails are a point-of-contact that multiple notification efforts have relied on [5, 9, 13, 14, 22, 24]. However, these contacts are technically designated for reports of abusive, malicious behavior (a point noted in the feedback we received as detailed in Section 5). While vulnerability reports have a somewhat similar flavor, they do not serve the same purpose. It behooves the security community to establish a standardized and reliable point-of-contact for communicating security issues.

Another question concerns whether the benefits of repeated notifications for the same vulnerability outweigh the costs imposed on recipients. Some may derive no benefits from the additional messages due to having no means to effectively remediate, yet must spend time ingesting the notifications. From our results, we observed that repeat notifications did not promote further patching, which argues against performing re-notifications.

More provocative, and related to the full-disclosure debate mentioned above, is the notion of *threatening* recipients with publicly revealing their vulnerabilities if unaddressed after a given amount of time. Likely, the research community would find this (quite) unpalatable in general; however, one can imagine specific situations where the community might conclude that spurring vital action justifies such a harsh step, just as some have concluded regarding full disclosure.

Future Abuse of Notifications In a future with widespread notifications, we would hope that security issues could be rectified more extensively and quickly. However, this would provide a new avenue for abuse, as attackers could potentially leverage the open communication channel to target network operators. As a simple example, a malicious actor could notify operators about a real security issue, and inform the operators to install

a malicious application to help hosts resolve the security gap. While existing techniques such as phishing detection and binary analysis can help limit these attacks, the problem domain likely will yield new challenges. It is important that the security community remain cognizant of these dangers as the state of security notifications evolves.

Effective Remediation Tools For contacts that do not remediate, our measurements cannot distinguish which of the underlying reasons sketched above came into play. However, while some operators may lack sufficient motivation to take action, it seems quite plausible that others wish to, but lack the technical capabilities, resources, or permissions to do. Accordingly, we see a need for investigation into the operational problems that operators encounter when considering or attempting remediation, as well as the development of effective and usable remediation tools that simplify the operators’ tasks. By reducing the effort and resources required to address a vulnerability, such tools could also increase the likelihood that an operator would take the steps to react to vulnerability reports. Ultimately, automated systems would be ideal, but these face significant challenges, such as heterogeneous platforms, potential abusive or malicious behavior, and inadvertent disruption of mission-critical systems.

7 Conclusion

We have undertaken an extensive study of notifying thousands of network operators of security issues present within their networks, with the goal of illuminating which fundamental aspects of notifications have the greatest impact on efficacy. Our study investigated vulnerabilities that span a range of protocols and considerations: exposure of industrial control systems; apparent firewall omissions for IPv6-based services; and exploitation of local systems in DDoS amplification attacks.

Through controlled multivariate experiments, we studied the impact of a number of variables: choice of party to contact (WHOIS abuse contacts versus national CERTs versus US-CERT), message verbosity, hosting a website linked to in the message, and translating the message into the notified party’s local language. We monitored the vulnerable systems for several weeks to determine their rate of remediation in response to changes to these variables.

We also assessed the outcome of the emailing process itself and characterized the sentiments and perspectives expressed in both the human replies and an optional anonymous survey that accompanied our notifications. The responses were largely positive, with 96% of human email responses expressing favorable or neutral sentiments.

Our findings indicate that notifications can have a significant positive effect on patching, with the best messaging regimen being directly notifying contacts with detailed information. An additional 11% of contacts addressed the security issue when notified in this fashion, compared to the control. However, we failed to prompt the majority of contacts to respond, and even when they did, remediation was often only partial. Repeat notifications did not further improve remediation. Given these positive yet unsatisfactory outcomes, we call on the security community to more deeply investigate notifications and establish standards and best practices that promote their effectiveness.

A Anonymous and Optional Security Notifications Survey

Help us better understand the factors surrounding security notifications by providing anonymous feedback in this survey. Each question is optional, so answer the ones you feel comfortable answering. Thank you!

1. Was your organization aware of the security issue prior to our notification?
2. Did your organization take prior actions to resolve the security issue before our notification?
3. Is your organization planning on resolving the security issue?
4. Do you feel it was acceptable for us to detect the security issue?
5. Do you feel it was acceptable for us to notify your organization?
6. Would your organization want to receive similar security vulnerability/misconfiguration notifications in the future?
7. Did we notify the correct contact?

B IPv6 Notification: Terse with Link

Subject: [RAND#] Potentially Misconfigured IPv6 Port Security Policies

Body: Computer scientists at the University of Michigan, the University of Illinois Urbana-Champaign, and the University of California Berkeley have been conducting Internet-wide scans to detect IPv4/IPv6 dual-stack hosts that allow access to services via IPv6, but not IPv4. This likely indicates a firewall misconfiguration and could be a security vulnerability if the services should not be publicly accessible. We have attached a list of hosts that are potentially vulnerable on your network.

C IPv6 Notification:Verbose

Subject: [RAND#] Potentially Misconfigured IPv6 Port Security Policies

Body: During a recent study on the network security policies of IPv4/IPv6 dual-stack hosts, computer scientists at the University of Michigan, the University of Illinois Urbana-Champaign, and the University of California Berkeley have been conducting Internet-wide scans to detect IPv4/IPv6 dual-stack hosts that allow access to services via IPv6, but not IPv4. This likely indicates a firewall misconfiguration and could be a security vulnerability if the services should not be publicly accessible. We have attached a list of hosts that are potentially vulnerable on your network (as determined by WHOIS information).

For each dual-stack host, we test whether popular services (e.g., SSH, Telnet, and NTP) are accessible via IPv4 and/or IPv6 using a standard protocol handshake. For ICMP this is an echo request, for TCP it is a SYN segment, and for UDP this is an application-specific request (e.g., DNS A query for ‘www.google.com’ or an NTP version query). We do not exploit any vulnerabilities, attempt to login, or access any non-public information.

The protocols we scanned are popular targets for attack and/or can be used to launch DDoS attacks when left publicly available to the Internet. We suspect they are misconfigured and are notifying you because hosts rarely offer services on IPv6 that are not offered on IPv4, and we believe these services may have been left exposed accidentally. This is a common occurrence when administrators forget to configure IPv6 firewall policies along with IPv4 policies.

If these IPv6-only accessible services should not be accessible to the public Internet, they can be restricted by updating your firewall or by disabling or removing the services. If none of your systems use IPv6, you can also disable IPv6 on your system. Make sure your changes are persistent and will not be undone by a system reboot.

Berkeley Security Notifications Team

Help us improve notifications with anonymous feedback at: <https://www.surveymonkey.com/r/ZC7BVW5>

E ICS Notification: Verbose

Subject: [RAND#] Vulnerable SCADA Devices

Body: During a recent study on the public exposure of industrial control systems, computer scientists at the University of Michigan and the University of California Berkeley have been conducting Internet-wide scans to detect publicly accessible industrial control (SCADA) devices. These devices frequently have no built-in security and their public exposure may place physical equipment at risk for attack. We have attached a list of SCADA devices on your network (as determined by WHOIS information) that are publicly accessible.

We scan for potentially vulnerable SCADA systems by scanning the full IPv4 address space and attempting protocol discovery handshakes (e.g., Modbus device ID query). We do not exploit any vulnerabilities or change any device state.

SCADA protocols including Modbus, S7, Bacnet, Tridium Fox, and DNP3 allow remote control and monitoring of physical infrastructure and equipment over IP. Unfortunately, these protocols lack critical security features, such as basic authentication and encryption, or have known security vulnerabilities. If left publicly accessible on the Internet, these protocols can be the target of attackers looking to monitor or damage physical equipment, such as power control, process automation, and HVAC control systems.

SCADA services are not designed to be publicly accessible on the Internet and should be maintained on an inter-

F DDoS Amplification Notification: Terse with Link

Subject: [RAND#] Vulnerable DDoS Amplifiers

Body: Computer scientists at George Mason University and the University of California Berkeley have been detecting open and misconfigured services that serve as amplifiers for distributed denial-of-service (DDoS) attacks. Attackers abuse these amplifiers to launch powerful DDoS attacks while hiding the true attack source. We have attached a list of hosts that are potentially vulnerable on your network.

[LINK: More information is available at [https://security-notifications.cs.berkeley.edu/\[RAND#\]/amplifiers.html](https://security-notifications.cs.berkeley.edu/[RAND#]/amplifiers.html).]

Berkeley Security Notifications Team

Help us improve notifications with anonymous feedback at: <https://www.surveymonkey.com/r/Y99J8K8>

G DDoS Amplification Notification: Verbose

Subject: [RAND#] Vulnerable DDoS Amplifiers

Body: During a recent study on distributed denial-of-service (DDoS) attacks, computer scientists at George Mason University and the University of California Berkeley have been conducting Internet-wide scans for open and misconfigured services that serve as amplifiers for DDoS attacks. Attackers abuse these amplifiers to launch powerful DDoS attacks while hiding the true at-

tack source. We have attached a list of hosts that are potentially vulnerable on your network (as determined by WHOIS information).

We detect amplifiers by monitoring hosts involved in recent DDoS attacks and checking whether these hosts support the features used for launching an attack (e.g., NTP monlist or recursive DNS resolution). We do not exploit any vulnerabilities or attempt to access any non-public data on these servers.

DDoS attacks are often conducted by directing an overwhelming amount of network traffic towards a target system, making it unresponsive. Amplifiers are services that send large amounts of data in response to small requests. Attackers leverage these in DDoS attacks by spoofing traffic to the amplifier, forging it to look as if it came from the attacker's target. Amplifiers then respond to the target with a large response that overwhelms the target. Publicly accessible amplifiers are constantly abused by attackers to conduct the DDoS attacks for them while hiding the tracks of the real attacker.

These amplifiers can be avoided by disabling the application or updating your firewall to block the application port or restrict the IP addresses that can access it. More specifically, Chargen should be closed as it is rarely useful and is inherently an amplifier. If left open, DNS should be configured to restrict who can make recursive requests, and NTP should be configured to disable the monlist functionality. Make sure your changes are persistent and will not be undone by a system reboot.

More information is available at [https://security-notifications.cs.berkeley.edu/\[RAND#\]/amplifiers.html](https://security-notifications.cs.berkeley.edu/[RAND#]/amplifiers.html).

Abstract

Proofs of Retrievability (POR) and Data Possession (PDP) are cryptographic protocols that enable a cloud provider to prove that data is correctly stored in the cloud. PDP have been recently extended to enable users to check in a single protocol that additional file replicas are stored as well. To conduct multi-replica PDP, users are however required to process, construct, and upload their data replicas by themselves. This incurs additional bandwidth overhead on both the service provider and the user and also poses new security risks for the provider. Namely, since uploaded files are typically encrypted, the provider cannot recognize if the uploaded content are indeed replicas. This limits the business models available to the provider, since e.g., reduced costs for storing replicas can be abused by users who upload different files—while claiming that they are replicas.

In this paper, we address this problem and propose a novel solution for proving data replication and retrievability in the cloud, **Mirror**, which allows to shift the burden of constructing replicas to the cloud provider itself—thus conforming with the current cloud model. We show that **Mirror** is secure against malicious users and a rational cloud provider. Finally, we implement a prototype based on **Mirror**, and evaluate its performance in a realistic cloud setting. Our evaluation results show that our proposal incurs tolerable overhead on the users and the cloud provider.

1 Introduction

The cloud promises a cost-effective alternative for small and medium enterprises to downscale/upscale their services without the need for huge upfront investments, e.g., to ensure high service availability.

Currently, most cloud storage services guarantee

service and data availability [4, 6] in their Service Level Agreements (SLAs). Availability is typically ensured by means of full replication [4, 23]. Replicas are stored onto different servers—thus ensuring data availability in spite of server failure. Storage services such as Amazon S3 and Google FS provide such resiliency against a maximum of two concurrent failures [30]; here, users are typically charged according to the required redundancy level [4].

Nevertheless, none of today’s cloud providers accept any liability for data loss in their SLAs. This makes users reluctant—and rightly so—when using cloud services due to concerns with respect to the integrity of their outsourced data [2, 7, 10]. These concerns have been recently fueled by a number of data loss incidents within large cloud service providers [5, 10]. For instance, Google recently admitted that a small fraction of their customers’ data was permanently lost due to lightning strikes which caused temporary electricity outages [10].

To remedy this, the literature features a number of solutions that enable users to remotely verify the availability and integrity of stored data [11, 15, 16, 25, 34]. Examples include Proofs of Retrievability (POR) [25, 34] which provide clients with the assurance that their data is available in its entirety, and Proofs of Data Possession (PDP) [12] which enable a client to verify that its stored data has not undergone any modifications. PDP schemes have been recently extended to verify the replication of files [18, 22, 30]. These extensions can provide guarantees for the users that the storage provider is replicating their data as agreed in the SLA, and that they are indeed getting the value for their money.

Notice, however, that existing solutions require the users themselves to create replicas of their files, appropriately pre-process the replicas (i.e., to create authentication tags for PDP), and finally upload all processed replicas in the cloud. Clearly, this in-

Table 1: Bandwidth cost in different regions as provided by CloudFlare [3]. “% Peered” refers to the percentage of traffic exchanged for free with other providers.

Region	% Peered	Effective price/Mbps/Month
Europe	50%	\$5
North America	20%	\$8
Asia	55%	\$32
Latin America	60%	\$32
Australia	50%	\$100

curs significant burden on the users. Moreover, this consumes considerable bandwidth from the provider, that might have to scale up its bandwidth to accommodate for such large upload requests. For example, in order to store a 10 GB file together with three replicas, users have to process and upload at least 40 GB of content. Recall that the provider’s bandwidth is a scarce resource; most providers, such as AWS and CloudFlare, currently buy bandwidth from a number of so-called Tier 1 providers to ensure global connectivity to their datacenters [3]. For example, CloudFlare pays for maximum utilization (i.e., maximum number of Mbps) used per month. This process is costly (cf. Table 3) and is considerably more expensive than acquiring storage and computing resources [24].

Besides consuming the provider’s bandwidth resources, this also limits the business models available to the provider, since e.g., reduced costs for storing replicas can be offered in the case where the replication process does not consume considerable bandwidth resources from the provider (e.g., when the replication is locally performed by the provider). Alternatively, providers can offer reduced costs by offering infrequent/limited access to stored replicas, etc. Amazon S3, for example, charges its users almost 25% of the underlying storage costs for additional replication [1,9]. Users therefore have considerable incentives to abuse this service, and to store their data at reduced costs as if they were replicas. Since the outsourced data is usually encrypted, the provider cannot recognize if the uploaded contents are indeed replicas.

In this paper, we address this problem, and propose a novel solution for proving data replication and retrievability in the cloud, **Mirror**, which goes beyond existing multi-replica PDP solutions and enables users to efficiently verify the retrievability of all their replicas without requiring them to replicate data by themselves. Notably, in **Mirror**, users need to process/upload their original files only once irrespective of the replication undergone by their data; here, conforming with the current cloud model [4],

the cloud provider appropriately constructs the replicas given the original user files. Nevertheless, **Mirror** allows users to efficiently verify the retrievability of all data replicas—including those constructed by the service provider.

To this end, **Mirror** leverages cryptographic puzzles to impose significant resource constraints—and thus an economic disincentive—on a cloud provider which creates the replicas on demand, i.e., whenever the client initiates the verification protocol. By doing so, **Mirror** incentivizes a rational cloud provider to correctly store and replicate the clients’ data—otherwise the provider risks detection with significant probability.

In summary, we make the following contributions in this work:

- We propose a novel formal model and a security model for proofs of replication and retrievability. Our proposed model, **PoR**², extends the POR model outlined in [34] and addresses security risks that have not been covered so far in existing multi-replica PDP models.
- We describe a concrete **PoR**² scheme, dubbed **Mirror** that is secure in our enhanced security model. **Mirror** leverages a tunable replication scheme based on the combination of Linear Feedback Shift Registers (LFSRs) with the RSA-based puzzle by Rivest [33]. By doing so, **Mirror** shifts the burden of constructing replicas to the cloud provider itself and is therefore likely to be appreciated by cloud providers since it allows them to trade their expensive bandwidth resources with relatively cheaper computing resources.
- We implement and evaluate a prototype based on **Mirror** in a realistic cloud setting, and we show that our proposal incurs tolerable overhead on both the users and the cloud provider when compared to existing multi-replica PDP schemes.

The remainder of this paper is organized as follows. In Section 2, we introduce a novel model for proofs of replication and retrievability. In Section 3, we propose **Mirror**, an efficient instantiation of our proposed model, and analyze its security in Section 4. In Section 5, we evaluate a prototype implementation of **Mirror** in realistic cloud settings and compare its performance to the multi-replica PDP scheme of [18]. In Section 6, we overview related work in the area, and we conclude the paper in Section 7.

2 PoR²: Proofs of Replication and Retrievability

In this section, we introduce a formal model for proofs of replication and retrievability, PoR².

2.1 System Model

We consider a setting where a user \mathcal{U} outsources a file D to a service provider \mathcal{S} who agrees to the following two conditions:

1. Store the file D in its entirety.
2. Additionally store r replicas of D in their entirety.

A PoR² protocol aims to ensure to the user that both conditions are kept without the need for users to download the files and the replicas. Hence, our model comprises a further party: the verifier \mathcal{V} who runs the PoR² scheme to validate that indeed the data and sufficient copies are stored by \mathcal{S} . In a privately-verifiable scheme, the user and the verifier consist of the same entity; these roles might be however different in publicly-verifiable schemes.

As one can see, Condition 1 indirectly implies that a PoR² scheme needs to comprise a PDP or POR scheme. Consequently, similar to the POR model, a PoR² involves a process for outsourcing the original data, referred to as **Store**, and an interactive verification protocol **Verify**.

However, Condition 2 goes beyond common POR/PDP requirements. Hence, one needs an additional (possibly interactive) process denoted by **Replicate** for generating the replicas and a second process, dubbed **CheckReplica**, which checks the correctness of the replicas (in case the replicas were created by the user). Moreover, the interactive verification protocol **Verify** needs to be extended such that it verifies the storage of the original file *and* the copies computed by the service provider. In what follows, we give a formal specification of the procedures and protocols involved in a PoR² scheme. Our model adapts and extends the original POR model introduced in [25, 34]. In Section 2.2, we summarize the relation between PoR² and previous POR models.

The Store Procedure: This randomized procedure is executed by the user once at the start. **Store** takes as input the security parameter κ and the file \tilde{D} to be outsourced, and produces a file tag τ that is required to run the verification procedure. Depending on whether the scheme is private or public verifiable, the verification tag needs to be kept secret or can be made public. The output of **Store** comprises the file D that the service provider should store. D may

be different from \tilde{D} , e.g., contain some additional information, but \tilde{D} should be efficiently recoverable from D . Finally, **Store** outputs public parameters Π which allow the generation of r replicas $D^{(i)}$ of the outsourced file. We assume that the number of copies is (implicitly) given in the copy parameters Π , possibly being specified in the SLA before. Summing up, the formal specification of **Store** is:

$$(D, \tau, \Pi) \leftarrow \text{Store}(\kappa, \tilde{D})$$

The Replicate Procedure: The **Replicate** procedure is a protocol executed between the verifier (who holds the verification tag τ) and the service provider to generate replicas of the original file. To this end, **Replicate** takes as inputs the copy parameters Π and the outsourced file D , and outputs the r copies $D^{(1)}, \dots, D^{(r)}$. In addition, the provider gets a *copy tag* τ^* which allows him to validate the correctness of the copies. Formally, we have:

$$\begin{aligned} \text{Replicate} : & \quad [\mathcal{V} : \tau, \Pi; \mathcal{S} : D, \Pi] \\ & \rightarrow [\mathcal{V} : \tau; \mathcal{S} : D^{(1)}, \dots, D^{(r)}, \tau^*] \end{aligned}$$

Recall that the verifier \mathcal{V} refers to the party that holds the verification tag and may not necessarily be a third party. This captures (i) the case where the user creates the copies on his own at the beginning (as discussed in [18]), and (ii) the case where this replication process is completely outsourced to the service provider (or even to a third party).

Observe that the output for the verifier includes again the verification tag. This is the case since we want to capture situations where the verification tag can be changed, depending on the protocol flow of **Replicate**. To keep the description simple, we denote both values (the verification tag as output of the **Store** procedure and the potentially updated verification tag after running **Replicate**) by τ .

The CheckReplica Procedure: The purpose of the **CheckReplica** procedure, which is used by the service provider, is to validate that the replicas have been correctly *generated*, i.e., are indeed copies of the original file. Notice that **CheckReplica** is mandatory for a comprehensive model but is not necessary in the case where the service provider replicates the data itself (in this case the service provider can ensure that the replication process is done correctly).

CheckReplica is executed between the verifier and the service provider. The verifier \mathcal{V} takes as input the copy parameters Π and verification tag τ , being his output of the **Replicate** procedure (see above), while the service provider \mathcal{S} takes as input the uploaded file D , a possible replica D^* (together with a replica

index $i \in \{1, \dots, r\}$), the copy parameters Π , and the copy tag τ^* . CheckReplica then outputs a binary decision expressing whether the service provider \mathcal{S} believes that D^* is a correct i -th replica of D according to the Replicate procedure and the copy parameters Π .

$\text{CheckReplica}: [\mathcal{V} : \tau, \Pi; \mathcal{S} : \tau^*, \Pi, D, D^*, i] \rightarrow [\mathcal{S} : \text{dec}]$

The Verify Protocol: A verifier \mathcal{V} , i.e., the user if the scheme is privately verifiable and possibly a third party if the scheme is publicly verifiable, and the provider \mathcal{S} execute an interactive protocol to convince the verifier that both the outsourced D and the r replicas $D^{(1)}, \dots, D^{(r)}$ are correctly stored. The input of \mathcal{V} is the tag τ given by Store and the copy parameters Π , while the input of the provider \mathcal{S} is the file D outsourced by the user and the r replicas generated by the Replicate procedure. The output $\text{dec} \in \{\text{accept}, \text{reject}\}$ of the verifier expresses his decision, i.e., whether he accepts or rejects. It holds that:

$\text{Verify}: [\mathcal{V} : \tau, \Pi; \mathcal{S} : D, D^{(1)}, \dots, D^{(r)}] \longrightarrow [\mathcal{V} : \text{dec}]$

Note that Verify and CheckReplica aim for completely different goals. The CheckReplica procedure allows the service provider \mathcal{S} to check if the replicas have been *correctly generated* and hence protects against a malicious customer who misuses the replicas for storing additional data at lower costs. On the other side, the Verify procedure enables a client or verifier \mathcal{V} to validate that the file and all copies are indeed *stored in their entirety* to provide security against a rational service provider. For instance, CheckReplica can be omitted if the replicas have been generated by the service provider directly while Verify would still be required.

2.2 Relation to Previous Models

Notice that the introduced PoR^2 model covers and extends both proofs of retrievability and proofs of multiple replicas. For example in case that no replicas are created at all, i.e., neither the Replicate nor the CheckReplica procedures are used, the scheme reduces to a standard POR according to the model given in [34]. Observe that in such cases storage allocation is a direct consequence of the incompressibility of the file. Moreover, the multi-replica schemes presented so far (see Section 6 for an overview) can be seen as PoR^2 schemes where the correct replication requirement is simply ignored. In fact, we argue that if existing multi-replica schemes are coupled with a proof that the replicas are honestly generated by the user, then the resulting scheme would be a secure PoR^2 scheme.

2.3 Attacker Model

Similar to existing work in the area [35, 36], we adapt the concept of the *rational attacker model*. Here, rational means that if the provider cannot save any costs by misbehaving, then he is likely to simply behave honestly. In our particular case, the advantage of the adversary clearly depends on the relation between storage costs and other resources (such as computation), and on the availability of these resources to the adversary. In the sequel, we capture such a rational adversary by restricting him to a bounded number of concurrent threads of execution. Given that the provisioning of computational resources would incur additional costs, our restriction is justified by the fact that a rational adversary would only invest in additional computing resources if such a strategy would result in lower total costs (including the underlying costs of storage).

Likewise, we assume that users are interested to misuse the replicas for storing more data than has been agreed upon. Recall that since replicas are typically charged less than original files [1, 9], a rational user may try to encode additional information or other files into the replicas.

2.4 Security Goals and Correctness

In this section, we formalize the security goals of a PoR^2 scheme and define the correctness requirements. Note that we do not consider confidentiality of the file \tilde{D} , since we assume that the user encrypts the file prior to the start the PoR^2 protocol. We start by defining three security notions that a PoR^2 scheme must guarantee:

Extractability: The user can recover the uploaded file D .

Storage Allocation: Provider uses *at least* as much storage as required to store the file and all replicas.

Correct Replication: The files $D^{(i)}$ are *correct* replicas of D .

The extractability notion protects the user against a malicious service provider who does not store the whole file. Similarly, the storage allocation notion aims to protect a user against a service provider who does not commit enough storage to store all replicas. Clearly, the first two conditions together imply that a rational provider \mathcal{S} indeed stores D and the replicas $D^{(1)}, \dots, D^{(r)}$ and therefore fulfills his part of providing redundancy to protect the data. In contrast to the two previous notions, correct replication aims to

protect the service provider against a malicious user who tries to encode additional data in the replicas. This is an important property, which is not satisfied by existing multi-replica PDP models, but which should cater to any practical deployment of PoR². In Section 3, we propose an instantiation of PoR² which allows the provider to run `Replicate` by itself—thus inherently satisfying this property. In the following paragraphs, we provide a formal description of the above defined notions.

Extractability. Extractability guarantees that an honest user is able to recover the data \tilde{D} . Adopting [25, 34], this is formalized as follows. If a service provider is able to convince a honest user with significant probability during the `Verify` procedure, then there exists an *extractor algorithm* that can interact with the service provider and extract the file. This is captured by a hypothetical game between an adversary and an environment where the latter simulates all honest users and an honest verifier. The adversary is allowed to request the environment to create new honest users (including respective public and private keys), to let them store chosen files, and to run the `Verify` and `Replicate` procedures. At the end, the adversary chooses a user \mathcal{U} with the corresponding outsourced file D and outputs a service provider \mathcal{S} who can execute the `Verify` protocol with \mathcal{U} with respect to the chosen file D . We say that a service provider is ϵ -admissible if the probability that the verifier does not abort is at least ϵ .

Definition 1 (Extractability) *We say that a PoR² scheme is ϵ -extractable if there exists an extraction algorithm such that for any PPT algorithm who plays the aforementioned game and outputs an ϵ -admissible service provider \mathcal{S} , the extraction algorithm recovers D with overwhelming probability.*

In addition, we say that correctness is provided with respect to the extractability if the following holds. If all parties are honest, i.e., the user, the verifier, and the provider, then the verifier accepts the output of the `Verify` protocol with probability 1. This should hold for any file $\tilde{D} \in \{0, 1\}^$.*

Storage Allocation. Let ST denote the storage of the service provider that has been allocated for storing the file D and the replicas $D^{(1)}, \dots, D^{(r)}$. We compute the storage allocation by the provider, ρ , as follows:

$$\rho := \frac{|ST|}{|D| + |D^{(1)}| + \dots + |D^{(r)}|} \quad (1)$$

Here, we consider the generic case where the sizes of the replicas can be different (e.g., due to different

metadata). Moreover, we assume that neither the file nor the replicas can be (further) compressed, e.g., because these have been encrypted first. Since the service provider aims to save storage, it holds in general that $0 \leq \rho \leq 1$. Storage allocation ensures that $\rho \geq \delta$ for a threshold $0 \leq \delta \leq 1$ chosen by the user.

Definition 2 (Binding) *We say that a PoR² scheme is (δ, ϵ) -binding if for any rational attacker who plays the aforementioned game, and outputs an ϵ -admissible service provider \mathcal{S} who invests only a fraction $\rho < \delta$ of memory, it holds that the verifier accepts only with negligible probability (in the security parameter).*

We say that the scheme is even strongly (δ, ϵ) -binding if it holds for any PPT attacker, i.e., also for non-rational attackers.

We stress that the distinction between binding and strongly binding is necessary in a comprehensive model. For instance, for schemes where the replicas are generated locally by the service provider \mathcal{S} himself, i.e., to save bandwidth, the strongly binding property is impossible to achieve for $\delta > |ST|/|D|$. The reason is that a non-rational service provider could always store D only and run the `Replicate` procedure over and over again when needed. On the other hand, if the user is generating and uploading the replicas, strong binding could be achieved when replicas are different encryptions of the original file, e.g., as done in [18]. In Fortress, we aim to outsource the replica generation to the service provider to save bandwidth and hence only aim for the binding property.

Correct Replication. Correct replication means essentially that both, `Replicate` and `CheckReplica`, are sound and correct. We detail this below.

We say that `Replicate` is sound if in the case where the user is involved in the replica generation, the service provider can get assurance that the additionally uploaded data represents indeed correctly built replicas that do not encode, for example, some additional data. That is, `Replicate` must not be able to encode a significant amount of additional data in the replicas. This is formally covered by the requirement that inputs of the verifier to the replicate procedure `Replicate`, namely the verification tag τ and the copy parameters Π , have a size that is independent of the file size.

On the other hand, we say that `Replicate` is correct if replicas represent indeed copies of the uploaded file D . This is formally captured by requiring that

D can be efficiently recovered from any replica $D^{(k)}$. More precisely, we say that **Replicate** is correct if there exists an efficient algorithm which given τ , Π , and any replica $D^{(k)}$ outputs D .

With respect to **CheckReplica**, we require that \mathcal{S} only accepts replicas which are valid output of **Replicate**. Let D and Π be the output of the **Store** procedure. Let \mathcal{E} be the event that τ^* and $D^{(1)}, \dots, D^{(r)}$ are the output of a **Replicate** run. Let dec be the decision of the service provider at the end of the **CheckReplica** protocol. We say that the scheme is ϵ^* -correctly building replicas if:

$$\forall i \in \{1, \dots, r\} : \Pr[\text{dec} = \text{Accept} | \mathcal{E}] = 1, \\ \max_{i \in \{1, \dots, r\}} \{\Pr[\text{dec} = \text{Accept} | \neg \mathcal{E}]\} \leq \epsilon^*.$$

Observe that the first and second condition express the correctness and soundness of **CheckReplica**, respectively.

3 Mirror: An Efficient PoR² Instantiation

3.1 Overview

The goal of **Mirror** is to provide a verifiable replication mechanism for storage providers. Note that straightforward approaches to construct PoR² would either be communication-expensive or would be insecure in the presence of a rational cloud provider.

For instance, the user could create and upload the required t replicas of his files, similar to [18]. Obviously, this alternative incurs considerable bandwidth overhead on the providers and users can abuse the replicas to outsource several, different files in encrypted form. An alternative solution would be to enable the cloud provider to create the replicas (and their tags) on his own given the original files. This would significantly reduce the provider's bandwidth consumption incurred in existing multi-replica schemes at the expense of investing additional (cheaper) computing resources [24]. This alternative might be, however, insecure since it gives considerable advantage for the provider to misbehave, e.g., store only one single replica and construct the replicas on the fly when needed.

To thwart the generic attacks described above, **Mirror** ensures that a malicious cloud provider can only reply correctly within the verification protocol by investing a minimum amount of resources, i.e., memory and/or time. However, to ensure the binding property (Definition 2), i.e., that the provider invests memory and not time, **Mirror** allows to scale the computational effort that a dishonest provider would

have to invest without increasing the memory effort of an honest provider. This allows to adjust the computational effort of a dishonest provider such that the costs of storing the replicas is cheaper than the costs of computing the response to the challenges on the fly—giving an economic incentive to a rational provider to behave honestly.

This is achieved in **Mirror** through the use of a tunable puzzle-based replication scheme. Namely, in **Mirror**, the user has to outsource only his original files and compact puzzles to the cloud provider; the solution of these puzzles will be then combined with the original file in order to construct the r required replicas. Puzzles are constructed such that (i) they require noticeable time to be solved by the cloud provider while the user is significantly more efficient by exploiting a trapdoor, (ii) storing their solution incurs storage costs that are at least as large as the required storage for replicas, (iii) their difficulty can be easily adjusted by the creator to cater for variable strengths (and different cost metrics), and (iv) they can be efficiently combined with the original file blocks in order to create r correct replicas of the file preserving the homomorphic properties needed for compact proofs¹.

To this end, **Mirror** combines the use of the RSA puzzle of Rivest [33] and Linear Feedback Shift Registers (LFSR) (cf. Section 3.3). A crucial aspect here is that the user creates two LFSRs: a short one which is kept secret, and a longer public LFSR. The service provider is only given the public LFSR to generate the exponent values. As we show later, this allows for high degrees of freedom with respect to security and performance of **Mirror**. In the following, we first explain the deployed main building blocks and give afterwards the full protocol specification.

3.2 Building Blocks

RSA-based Puzzles: **Mirror** ties each sector with a cryptographic puzzle that is inspired by the RSA puzzle of Rivest [33]. In a nutshell, the puzzle requires the repeated exponentiation of given values $X^a \bmod N$ where $N = p \cdot q$ is publicly known RSA modulus and a, p, q remain secret. Without knowing these secrets, this requires to perform modular exponentiation. Modular exponentiation is an inherently sequential process [33]. The running time of the fastest known algorithm for modular exponentiation is linear in the size of the exponent. Although the provider might try to parallelize the computation of

¹This condition restricts our choice of puzzles since e.g., hash-based puzzles cannot be efficiently combined with the authentication tag of each data block/sector.

the puzzle, the parallelization advantage is expected to be negligible [17, 26, 28, 33]. On the other hand, the computation can be efficiently verified by the puzzle generator through the trapdoor offered by Euler’s function in $O(\log(N))$ modular multiplications by computing $X^{a'} \bmod N \equiv X^{a' \bmod \phi(N)} \bmod N$.

Observe that this puzzle is likewise multiplicative homomorphic: given a and a' , the product of the solutions $X^{a'}$ and $X^{a''}$ represents a solution for $a' + a''$. This preserves the homomorphic properties of the underlying POR and allows for batch verification for all the replicas and hence enables compact proofs.

To further reduce the verification burden on users, **Mirror** generates the exponents using a Linear Feedback Shift Registers (LFSR) as follows.

Linear Feedback Shift Registers: A *Linear Feedback Shift Register (LFSR)* is a popular building block for designing stream ciphers as it enables the generation of long output streams based on a initial state. In **Mirror**, LFSRs will be used to generate the exponents for the RSA-based puzzle described above. In what follows, we briefly describe the concept of an LFSR sequence and refer the readers to [29] for further details.

Definition 3 (Linear Feedback Shift Register)
Let \mathbb{F} be some finite field, e.g., \mathbb{Z}_p for some prime p . A Linear Feedback Shift Register (LFSR) of length λ consists of an internal state of length λ and a linear feedback function $F : \mathbb{F}^\lambda \rightarrow \mathbb{F}$ with $F(x_1, \dots, x_\lambda) = \sum_{i=1}^{\lambda} c_i \cdot x_i$. Given an initial state $(s_1, \dots, s_\lambda) \in \mathbb{F}^\lambda$, it defines inductively an LFSR sequence $(s_t)_{t \geq 1}$ by $s_{t+\lambda} = F(s_t, \dots, s_{t+\lambda-1})$ for $t \geq 1$.

An important and related notion is that of a *feedback polynomial*. Given an LFSR with feedback function $F(x_1, \dots, x_\lambda) = \sum_{i=1}^{\lambda} c_i \cdot x_i$, the feedback polynomial $f(x) \in \mathbb{F}[x]$ is defined as:

$$f(x) = x^\lambda - \sum_{i=1}^{\lambda} c_i \cdot x^{i-1}. \quad (2)$$

It holds that any multiple of a feedback polynomial is again a feedback polynomial. That is, if $f^*(x) = x^{\lambda^*} - \sum_{i=1}^{\lambda^*} c_i^* \cdot x^{i-1}$ is a multiple of f , then it holds that $s_{t+\lambda^*} - \sum_{i=1}^{\lambda^*} c_i^* \cdot s_{t+i-1} = 0$ for each $t \geq 1$. **Mirror** exploits this feature in order to realize a gap between the puzzle solution created by provider and the verification done by the user.

3.3 Protocol Specification

We now start by detailing the procedures in **Mirror**.

Specification of the Store Procedure: In the store phase, the user is interested in uploading a file $D \in \{0, 1\}^*$. We assume that the file D is encrypted to protect its confidentiality and encoded with an erasure code (as required by the utilized POR in order to provide extractability guarantees) prior to being input to the **Store** protocol [25, 34]. First, the user generates an RSA modulus $N := p \cdot q$ where p and q are two safe primes² whose size is chosen according to the security parameter κ .

Similar to [34], the file is interpreted as n blocks, each is s sectors long. A sector is an element of \mathbb{Z}_N and is denoted by $d_{i,j}$ with $1 \leq i \leq n$, $1 \leq j \leq s$. That is, the overall number of sectors in the file is $n \cdot s$. To ensure unique extractability (see Section 4.1), we require that the bit representation of each sector $d_{i,j}$ contains a characteristic pattern, e.g., a sequence of zero bits. The length of this pattern depends on the file size and should be larger than $\log_2(n \cdot s)$.

Furthermore, the user samples a key k_{prf} per file, where the key length is determined by the security parameter, e.g., $k_{\text{prf}} \in \{0, 1\}^\kappa$. By invoking k_{prf} as a seed to a pseudo-random function (PRF), the user samples s non-zero elements of $\mathbb{Z}_{\phi(N)}$, i.e., $\varepsilon_1, \dots, \varepsilon_s \xleftarrow{\text{R}} \mathbb{Z}_{\phi(N)} \setminus \{0\}$. Finally, the user computes σ_i for each i , $1 \leq i \leq n$, as follows:

$$\sigma_i \leftarrow \prod_{j=1}^s d_{i,j} \varepsilon_j \in \mathbb{Z}_N. \quad (3)$$

These values are appended to the original file so that the user uploads $(D, \{\sigma_i\}_{1 \leq i \leq n})$. Unless specified otherwise, we note that all operations are performed in the multiplicative group \mathbb{Z}_N^* of invertible integers modulo N .³

Assuming that the user is interested in maintaining r replicas in addition to the original file D at the cloud, the user additionally constructs copy parameters Π which will also be sent to the server. To this end, the user first generates two elements $g, h \in \mathbb{Z}_N^*$ of order p' and q' , respectively. Recall that the order of \mathbb{Z}_N^* is $\phi(N) = (p-1)(q-1) = 4 \cdot p' \cdot q'$. The elements g and h will be made public to the server while their orders are kept secret.

Then, the user proceeds to specify feedback polynomials for two LFSRs, one being defined over $\mathbb{Z}_{p'}$ and the other over $\mathbb{Z}_{q'}$. Both LFSRs need to have a length λ such that $|\mathbb{F}|^\lambda > n \cdot s$. Here, for each of the two LFSRs, *two* feedback polynomials are specified: a shorter one which will be kept secret by the user

²That is, $p-1 = 2 \cdot p'$ and likewise $q-1 = 2 \cdot q'$ for two distinct primes p' and q' .

³Observe that hitting by coincidence a value outside of \mathbb{Z}_N^* allows to factor N which is considered to be a hard problem.

and a larger one that will be made public to the provider. More precisely, for the LFSR defined over $\mathbb{Z}_{p'}$ the user chooses two polynomials

$$f_a(x) := x^\lambda - \sum_{i=1}^{\lambda} \alpha_i \cdot x^{i-1}, \quad f_a^*(x) := x^{\lambda^*} - \sum_{i=1}^{\lambda^*} \alpha_i^* \cdot x^{i-1}$$

such that $f_a^*(x)$ is a multiple of $f_a(x)$ (and hence $\lambda < \lambda^*$). For security reasons, it is necessary to ensure that $\alpha_1^* \geq 2$.

The feedback polynomial $f_a(x)$ with the lower degree will be kept secret while the polynomial $f_a^*(x)$ of the higher degree and the larger coefficients will be given to the provider. $f_a(x)$ will serve as a feedback polynomial to generate for each replica $k \in \{1, \dots, r\}$ an LFSR sequence $(a_t^{(k)})$. To this end, the user chooses for each k an initial state $(a_1^{(k)}, \dots, a_\lambda^{(k)}) \in \mathbb{Z}_{p'}^\lambda$ which defines the full sequence by $a_{t+\lambda+1}^{(k)} = \sum_{i=1}^\lambda \alpha_i \cdot a_{t+i}^{(k)}$ for any $t \geq 0$. Observe that due to the fact that $f_a^*(x)$ is a multiple of $f_a(x)$, it likewise holds $a_{t+\lambda^*+1}^{(k)} = \sum_{i=1}^{\lambda^*} \alpha_i^* \cdot a_{t+i}^{(k)}$ for any $t \geq 0$. Finally, the user publishes as part of the copy parameters the values $g^{a_1^{(k)}}, \dots, g^{a_{\lambda^*}^{(k)}} \in \mathbb{Z}_N$ for each replica and the coefficients $\alpha_1^*, \dots, \alpha_{\lambda^*}^* \in \mathbb{Z}$. Afterwards, he proceeds analogously over $\mathbb{Z}_{q'}$, i.e., sample coefficients $\beta_i \in \mathbb{Z}_{q'}$, compute feedback functions $f_b(x), f_b^*(x)$, choose an initial state $(b_1^{(k)}, \dots, b_\lambda^{(k)})$ for each replica, and so on.

Summing up, and assuming that the server should construct r replicas, the user sets the file specific verification tag (which are kept secret by the user) to:

$$\tau := \left(k_{\text{prf}}, p, q, g, h, (a_1^{(k)}, \dots, a_\lambda^{(k)})_{1 \leq k \leq r}, (\alpha_1, \dots, \alpha_\lambda), (b_1^{(k)}, \dots, b_\lambda^{(k)})_{1 \leq k \leq r}, (\beta_1, \dots, \beta_\lambda) \right).$$

To enable the server to construct the r replicas, the following copy parameters are given to the server:

$$\Pi := \left((g^{a_1^{(k)}}, \dots, g^{a_{\lambda^*}^{(k)}})_{1 \leq k \leq r}, (\alpha_1^*, \dots, \alpha_{\lambda^*}^*), (h^{b_1^{(k)}}, \dots, h^{b_{\lambda^*}^{(k)}})_{1 \leq k \leq r}, (\beta_1^*, \dots, \beta_{\lambda^*}^*) \right).$$

That is, the user sends D , the values $\{\sigma_i\}_{1 \leq i \leq n}$, and Π to the service provider and keeps the verification tag τ secret. Observe that the size of τ and Π are independent of the file size.

Specification of the CheckReplica Procedure: As the replicas are completely generated by the service provider, a **CheckReplica** procedure is not required in Mirror. However, one could check the validity of the

data replicas by running the **Replicate** procedure and simply comparing the outputs.

Specification of the Replicate Procedure: Upon reception of D , the values $\{\sigma_i\}_{1 \leq i \leq n}$, and Π , the service provider \mathcal{S} stores D and starts the construction of the r additional replicas $D^{(k)}$ for $1 \leq k \leq r$, of D . Here, each sector $d_{i,j}^{(k)}$ of replica k has the following form:

$$d_{i,j}^{(k)} = d_{i,j} \cdot g_{i,j}^{(k)} \cdot h_{i,j}^{(k)}, \quad (4)$$

We call these values $g_{i,j}^{(k)}$ and $h_{i,j}^{(k)}$ *blinding factors*. Both sets of blinding factors are computed by raising g and h by elements of the LFSR sequences $a_t^{(k)}$ and $b_t^{(k)}$, respectively, but one in the forward and the other in the backward order, namely:

$$g_{i,j}^{(k)} := g^{a_{(i-1)\cdot s+j}^{(k)}}, \quad h_{i,j}^{(k)} := h^{b_{(n\cdot s+1)-(i-1)\cdot s-j}^{(k)}}. \quad (5)$$

To enable the provider to compute the blinding factors $g^{a_i^{(k)}}$, we make use of the fact that for any $t \geq 0$ it holds $a_{t+\lambda^*+1}^{(k)} = \sum_{i=1}^{\lambda^*} \alpha_i^* \cdot a_{t+i}^{(k)}$ and hence

$$g^{a_{t+\lambda^*+1}^{(k)}} = \prod_{i=1}^{\lambda^*} \left(g^{a_{t+i}^{(k)}} \right)^{\alpha_i^*}. \quad (6)$$

The computation of the blinding factors $h^{b_i^{(k)}}$ works analogously.

In summary, the server constructs replicas $D^{(k)}$ for $k = 1, \dots, r$ as follows:

$$\begin{pmatrix} d_{1,1} \cdot g^{a_1^{(k)}} \cdot h^{b_{(n-1)\cdot s+s}^{(k)}} & \dots & d_{1,s} \cdot g^{a_s^{(k)}} \cdot h^{b_{(n-1)\cdot s+1}^{(k)}} \\ d_{2,1} \cdot g^{a_{s+1}^{(k)}} \cdot h^{b_{(n-2)\cdot s+s}^{(k)}} & \dots & d_{2,s} \cdot g^{a_{2,s}^{(k)}} \cdot h^{b_{(n-2)\cdot s+1}^{(k)}} \\ \vdots & \ddots & \vdots \\ d_{n,1} \cdot g^{a_{(s-1)\cdot s+1}^{(k)}} \cdot h^{b_s^{(k)}} & \dots & d_{n,s} \cdot g^{a_{n,s}^{(k)}} \cdot h^{b_1^{(k)}} \end{pmatrix}$$

Specification of the Verify Procedure: The **Verify** protocol generates at first a random challenge C . It contains a random ℓ -element set of tuples (i, v_i) where $i \in \{1, \dots, n\}$ denotes a block index, and $v_i \stackrel{\text{R}}{\leftarrow} \mathbb{Z}_N$ is a randomly generated integer. In addition, a non-zero subset $R \subset \{1, \dots, r\}$ is sampled. The set R will indicate which replicas will be involved in the challenge. Observe that $R = \emptyset$ would mean that simply a proof of retrievability is executed without checking the replicas. The challenge is then the combination of both:

$$C = ((i_c, v_c)_{c=1}^\ell, R). \quad (7)$$

Given a challenge C , the server computes the response $\mu = (\mu_1, \dots, \mu_s) \in \mathbb{Z}_N^s$ as follows:

$$\mu_j := \prod_{c=1}^\ell d_{i_c,j}^{v_c}, \quad j = 1, \dots, s. \quad (8)$$

Observe that μ_j is the product of powers of the original data, that is $d_{i_c,j}^{v_c}$. In addition, the file tags are processed in the same manner to obtain:

$$\sigma = \prod_{c=1}^{\ell} \left(\sigma_{i_c} \cdot \prod_{j=1}^s \prod_{k \in R} d_{i_c,j}^{(k)} \right)^{v_c}. \quad (9)$$

The tuple (μ, σ) marks the response and is sent back to the user who verifies (μ, σ) similar to the private-verifiable POR of [34]. First, he computes:

$$\tilde{\sigma} := \sigma \cdot \prod_{c=1}^{\ell} \left(\prod_{j=1}^s \prod_{k \in R} g_{i_c,j}^{(k)} h_{i_c,j}^{(k)} \right)^{-v_c} \quad (10)$$

Observe that this will require the reconstruction of the blinding factors. In Appendix C, we show how to efficiently perform this verification by the user, using the knowledge of the verification tags—in particular the knowledge of the secret shorter LFSR, its initial state, and the order of g and h , respectively.

Next, the user recovers the secret parameters ε_{i_k} , $k = 1, \dots, \ell$, using the key k_{prf} as a seed for the PRF. Finally, the user verifies that the following holds:

$$\prod_{j=1}^s \mu_j^{\varepsilon_j + |R|} = \tilde{\sigma}. \quad (11)$$

We now explain why the verification step has to hold if the response has been computed correctly. First, it follows from Equation (4) that $\prod_{c=1}^{\ell} \left(\prod_{j=1}^s \prod_{r \in R} d_{i_c,j}^{(r)} \right)^{v_c}$ can be rewritten as the product of $\prod_{c=1}^{\ell} \left(\prod_{j=1}^s \prod_{r \in R} d_{i_c,j} \right)^{v_c}$ and $\prod_{c=1}^{\ell} \left(\prod_{j=1}^s \prod_{r \in R} g_{i_c,j}^{(r)} h_{i_c,j}^{(r)} \right)^{v_c}$. The second factor is exactly the part that is canceled out in Equation (10) while the first factor can be simplified to $\prod_{c=1}^{\ell} \left(\prod_{j=1}^s d_{i_c,j}^{|R|} \right)^{v_c}$.

Given a series of straightforward calculations, one can show that $\tilde{\sigma}$ can be rewritten to $\prod_{j=1}^s (\mu_j)^{\varepsilon_j + |R|}$. This proves the correctness of Equation (11)—hence the correctness with respect to extractability.

Moreover, it is easy to see that, since each sector of a replica corresponds to the multiplication of the corresponding sector of the uploaded file D with a blinding factor (that can be reconstructed from Π), the replicas are indeed copies of the original file. This means that **Replicate** is correct. Summing up, all three correctness requirements explained in Section 2 are fulfilled in **Mirror**.

4 Security Analysis

We now proceed to prove the security of our scheme according to the definitions in Section 2.4. Recall that

the user is not involved in the replica generation and that the size of the parameters involved in creating a replica is independent of the file size. This ensures the correct replication property described in Section 2.4.

It remains to prove that (i) if the service provider \mathcal{S} stores at least a fraction δ of all sectors in one replica, then the file can be reconstructed (extractability) and (ii) if the service provider stores less than a fraction of δ of any replica, this misbehavior will be detected with overwhelming probability (storage allocation).

4.1 Extractability

In principle, the computations done in the **Store** and **Verify** procedures of **Mirror** can be seen as multiplicative variants of the corresponding mechanisms of the privately-verifiable POR of [34] (see Appendix B for details on the scheme of [34]). In particular, the extractability arguments given in [34] transport directly to **Mirror**. We assume that an erasure coding is applied to the file to ensure the recovery of file contents from any fraction δ of the file. In particular, we refer to [34] for additional details on the choice of parameters (e.g., for erasure coding) such that retrievability is ensured if a fraction δ of the file is stored.

To show that **Mirror** enables the reconstruction of the file from sufficiently many correct responses, we point out that given a correct response, the user learns expressions of the form $\mu_j = \prod_{c=1}^{\ell} d_{i_c,j}^{v_c}$ for known exponents $v_c \in \mathbb{Z}$ and known indices. Let us assume some arbitrary ordering $\mu^{(1)}, \mu^{(2)}, \dots$ on these expressions. If sufficiently many responses $\mu^{(i)}$ are known, the user can choose for any (i, j) coefficients $c^{(k)} \in \mathbb{Z}$ such that $\prod_k (\mu^{(k)})^{c^{(k)}} = d_{i,j}^u =: \tilde{d}$ for a known value $u \in \mathbb{Z}$.

Recall that the order of any $d_{i,j} \in \mathbb{Z}_N^*$ is a divisor of $2p'q'$. If u is odd, u is co-prime to $p'q'$ with overwhelming probability and the user can simply compute $u^{-1} \bmod p'q'$ and determine $d_{i,j} = \tilde{d}^{u^{-1}}$. On the other hand, if u is even (i.e., $u = 2 \cdot u'$), two cases emerge. If the order of $d_{i,j}$ is a divisor of $p'q'$, the exponent is again co-prime to the order with high probability. In this case, the user computes $u^{-1} \bmod p'q'$ and checks if $\tilde{d}^{u^{-1}}$ contains the characteristic bit pattern (see description of the **Store** procedure). If this fails, this means that the order of \tilde{d} is even and the user proceeds as follows. Observe that the order of $d_{i,j}^2$ is a divisor of $p'q'$. Thus, the user first computes $(u')^{-1} \bmod p'q'$ and then $\tilde{d}^{(u')^{-1}}$. This yields $d_{i,j}^2$. As the user knows the factorization of N , he can compute all four possible roots of $d_{i,j}^2$.

(e.g., using the Chinese Remainder Theorem). Due to the characteristic pattern embedded in $d_{i,j}$ (see the specification of the `Store` procedure), the user is able to identify the correct $d_{i,j}$.⁴

4.2 Storage Allocation

Observe that `Mirror` represents in fact a proof of retrievability over the uploaded file *and* all replicas. This means that if a challenge involves sectors that are not stored, `Mirror` ensures that the service provider fails with high probability unless he is able to correctly reconstruct the missing replicas. In the following, we therefore investigate the effort of a malicious service provider in reconstructing missing sectors. That is, we consider the scenario where the service provider has stored the complete file⁵ but only parts of some replicas.

In `Mirror`, the service provider needs to compute the corresponding blinding factors in order to recompute any missing sectors. As these are products of the form $g_i^{(k)} \cdot h_j^{(k)}$ and since these sequences are independent from each other, the service provider is forced to store values of the sequences $(g_i^{(k)})_i$ and $(h_j^{(k)})_j$ separately. Moreover, since these values are different for the individual replicas, knowing (or reconstructing) a value from one sequence and one replica does not help the service provider in deriving values of other sequences and/or replicas.

A crucial aspect of `Mirror` is that a cheating service provider should require a significantly higher effort compared to an honest service provider in recomputing missing replicas. Recall that both the user and the provider determine the blinding factors by computing LFSR sequences. One difference though is that the provider has to do his computations on values $g_i^{a_i^{(k)}}, h_j^{b_j^{(k)}} \in \mathbb{Z}_N^*$ while the user can efficiently compute on the exponents in $a_i^{(k)} \in \mathbb{Z}_{p'}$ and $b_j^{(k)} \in \mathbb{Z}_{q'}$ directly. Observe that the provider is not able to transfer his computations into $\mathbb{Z}_{p'}$ and $\mathbb{Z}_{q'}$ without eventually factoring $N = p \cdot q$, which is commonly assumed to be a hard problem. A further gap is that the user deploys LFSRs with feedback functions $f_a(x) \in \mathbb{Z}_{p'}[x]$ and $f_b(x) \in \mathbb{Z}_{q'}$ where the provider only knows the feedback functions $f_a^*(x), f_b^*(x) \in \mathbb{Z}[x]$ that are multiples of $f_a(x), f_b(x)$. Given that these functions involve more inputs, and require the construc-

⁴Observe that in principle it may happen with some probability that more than one root exhibits this pattern. This is the reason why a padding length $\geq \log_2(n \cdot s)$ is proposed such that the expected number of incorrectly reconstructed sectors in the file is less than 1.

⁵Recall that this property is validated by the proof of retrievability already.

tion of larger coefficients, this would incur additional (significant) computational overhead on the provider compared to the user. For deducing the shorter feedback functions $f_a(x), f_b(x)$, the provider would have to determine $\mathbb{Z}_{p'}$ respectively $\mathbb{Z}_{q'}$ —which equally require the knowledge of the factors of N .

It remains to investigate the effort for reconstructing values of the LFSR sequences. Note that the sequences used in the replicas are defined by different independent internal states and that, for each replica, the sequences $(a^{(k)i})$ and $(b_j^{(k)})$ are independent. We can therefore without loss of generality restrict our analysis to one sequence $(g_i)_{i \geq 1}$. For the ease of representation, we omit in the sequel the index (k) and write $g_i = g^{a_i}$ for the ease of representation. We say that $\vec{v} = (v_1, \dots, v_{n \cdot s}) \in \mathbb{Z}^{n \cdot s}$ represents a *valid relation* with respect to $(g_i)_{i \geq 1}$ if:

$$\prod_{i=1}^{n \cdot s} g_i^{v_i} = 1. \quad (12)$$

It follows from known facts about LFSRs that valid relations are the only means for the service provider to compute missing values g_j from known values g_i (see Appendix D for more details).

As the provider is forced to use the feedback function defined by the coefficients $(\alpha_1^*, \dots, \alpha_{\lambda^*}^*)$ (see above), the only valid relations the provider can derive are linear combinations of:

$$\vec{b}_j := (\underbrace{0 \dots 0}_{j-1}, \alpha_1^*, \dots, \alpha_{\lambda^*}^*, \underbrace{0 \dots 0}_{n \cdot s - (j-1) - \lambda^*}), \quad (13)$$

where \vec{b}_1 corresponds to the given feedback polynomial $f_a^*(x)$ and the others are derived by simple shift of indexes.

Hence, for any valid relation $\vec{v} = (v_i)_i \in \mathbb{V}$, there exist unique coefficients $c_1, \dots, c_{n \cdot s - \lambda^* + 1} \in \mathbb{Z}$ such that $\vec{v} = \sum_i c_i \cdot \vec{b}_i$. Let i_{\min} be the smallest index with $c_{i_{\min}} \neq 0$. Then, it holds that the first $v_j = 0$ for $j < i_{\min} - 1$ and that $v_{i_{\min}} = c_{i_{\min}} \cdot \alpha_1^*$ (as the other vectors with index $i > i_{\min}$) are zero at index i_{\min} . Hence, it holds that $\max_i \{\lceil \log_2(v_i) \rceil\} \geq \lceil \log_2(\alpha_1^*) \rceil$.

This shows that the effort of *executing* a valid relation (cf. Equation (12)) involves at least one exponentiation with an exponent of size $\lceil \log_2(\alpha_1^*) \rceil$.⁶ The effort to compute one exponentiation for an exponent of bitsize k is $3/2 \cdot k \cdot T_{\text{mult}}$, where T_{mult} stands for the time it takes the resource-constrained rational attacker (see Section 2.3) to multiply two values modulo N [27].

⁶One may combine several exponentiations to reduce the overall number of exponentiations but one cannot reduce the effort to compute at least once the exponentiation with the highest exponent.

Thus, a pessimistic lower bound for reconstructing a missing value g_i is $3/2 \cdot \lceil \log_2(\alpha_1^*) \rceil \cdot T_{\text{mult}}$. Observe that we ignore here additional efforts such as finding appropriate valid relations (cf. Equation (12)), etc.

Assume now that the service provider stores less than a fraction δ of all sectors of a given replica where δ refers to the threshold chosen by the user (see also Definition 2). Thus, for any value g_i contained in the challenge, the probability that g_i has to be re-computed is at least $1 - \delta$. Due to the fact that this holds for the values h_j as well and that a challenge requests $\ell \cdot s$ sectors, the expected number of values that need to be recomputed is $2\ell \cdot s \cdot (1 - \delta)$. To achieve the binding property with respect to a rational attacker, one has to ensure that the time effort for recomputing these values incurs costs that exceed the costs for storing these values. This implies a time threshold T_{thr} which marks the minimum computational effort this should take. Given such a threshold T_{thr} , we get the following inequality:

$$\lceil \log_2(\alpha_1^*) \rceil \geq \frac{T_{\text{thr}}}{3\ell \cdot s \cdot (1 - \delta) \cdot T_{\text{mult}}}. \quad (14)$$

That is, if the parameters are chosen as displayed in (14), a dishonest provider would bear on average higher costs than an honest provider. Here, one can use the common cut-and-choose approach, by posing a number of challenges where the number is linear in the security parameter κ , to ensure that the overall probability to circumvent these computations is negligible in κ . This proves the binding property (cf. Definition 2) with respect to the class of PPT service providers that can execute a bounded number of threads in parallel only.

Notice that Mirror can easily cope with (i) different attacker strengths, and (ii) variable cost metrics, as follows:

Length of LFSR: One option would be to increase λ^* , i.e., the length of the LFSR communicated to the provider, and hence the number of values $g^{a_i^{(k)}}$ and $h^{b_j^{(k)}}$ the provider has to use for generating the replicas. In the extreme case, λ^* could be made equal to half of the total number of sectors $n \cdot s$ —which would result into a scheme whose bandwidth consumption is comparable to [18].

Bitlength of coefficients: Another alternative would be to keep λ^* short, but to increase the bitlengths of the coefficients α_i^* and β_j^* . This would preserve the small bandwidth consumption of Mirror but would increase the time effort to run Replicate. This option will

also not affect the latency borne by users in verifying the provider’s response.

Hybrid approach: Clearly, one can also aim for a hybrid scheme, by increasing both the public LFSR length λ^* and the coefficients α_i^* and β_j^* .

In Section 5, we investigate reasonable choices of α_1^* , ρ , and T_{thr} to satisfy Equation 14. Of course, the same considerations can also be applied with respect to β_1^* which we omit for space reasons.

5 Implementation & Evaluation

In this section, we evaluate an implementation of Mirror within a realistic cloud setting and we compare the performance of Mirror to the MR-PDP solution of [18].

5.1 Implementation Setup

We implemented a prototype of Mirror in Scala. For a baseline comparison, we also implemented the multi-replica PDP protocol⁷ of [18], which we denote by MR-PDP in the sequel (see Appendix A for a description of the MR-PDP of [18]). In our implementation, we relied on SHA-256, and the Scala built-in random number generator.

We deployed our implementation on a private network consisting of two 24-core Intel Xeon E5-2640 with 32GB of RAM. The storage server was running on one 24-core Xeon E5-2640 machine, whereas the clients and auditors were co-located on the second 24-core Xeon E5-2640 machine.

To emulate a realistic Wide Area Network (WAN), the communication between various machines was bridged using a 100 Mbps switch. All traffic exchanged on the networking interfaces of our machines was shaped with NetEm [31] to fit a Pareto distribution with a mean of 20 ms and a variance of 4 ms—thus emulating the packet delay variance specific to WANs [19].

In our setup, each client invokes an operation in a closed loop, i.e., a client may have at most one pending operation.

When implementing Mirror, we spawned multiple threads on the client machine, each thread corresponding to a unique worker handling a request of a client. Each data point in our plots is averaged over 10 independent measurements; where appropriate, we include the corresponding 95% confidence intervals.

⁷We acknowledge that PDP offers weaker guarantees than POR. However, to the best of our knowledge, no prior proposals for multi-replica-POR exist. MR-PDP thus offers one-of-the-few reasonable benchmarks for Mirror.

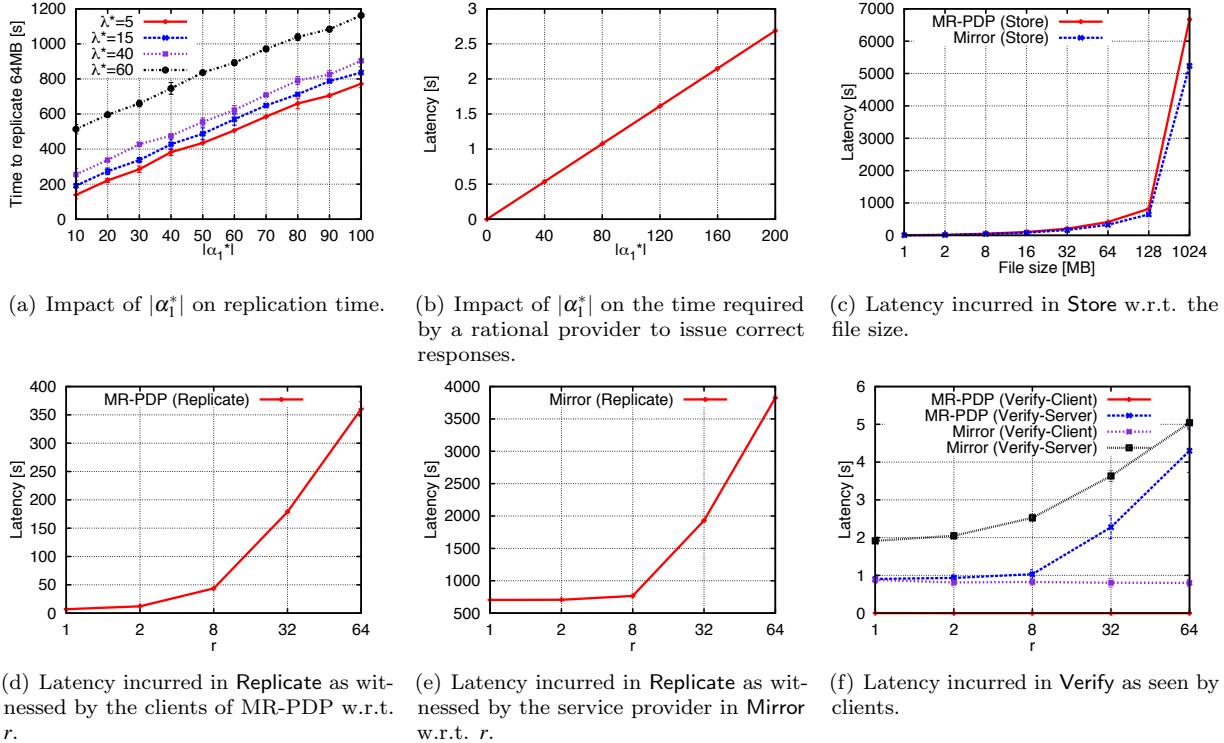

Figure 1: Performance evaluation of Mirror in comparison to the MR-PDP scheme of [18]. Each data point in our plots is averaged over 10 independent runs; where appropriate, we also show the corresponding 95% confidence intervals.

Parameter	Default Value
File size	64 MB
$ p $	1024 bits
$ q $	1024 bits
RSA modulus size	2048 bit
Number of challenges ℓ	40 challenges
Length of secret LFSR λ	2
Length of public LFSR λ^*	15
Fraction of stored sectors δ	0.9
Number of replicas r	2

Table 2: Default parameters used in the evaluation.

Table 2 summarizes the default parameters assumed in our setup.

5.2 Evaluation Results

Before evaluating the performance of Mirror, we start by analyzing the impact of the block size on the latency incurred in the verification of Mirror and in MR-PDP. Our results (Figure 4 in Appendix E) show that modest block sizes of 8 KB yield the most balanced performance, on average, across the investigated schemes. In the rest of our evaluation, we therefore set the block size to 8 KB.

Impact of the bitsize of α_1^* : In our implementation, our choice of parameters was mainly governed by the need to establish a tradeoff between the replication performance and the resource penalty incurred on a dishonest provider. To this end, we choose a small value for the public LFSR length λ^* , i.e., the LFSR length communicated to \mathcal{S} , and small coefficients α_i^* and β_j^* (these coefficients were set to 1 bit for $i, j > 1$). Recall that using smaller coefficients allows for faster exponentiations and hence a decreased replication effort.

However, as shown in Equation 14, the bitsize of α_1^* (which we shortly denote by $|\alpha_1^*|$ in the following) plays a paramount role in the security of Mirror. Note that the same analysis applies to β_1^* —which we do not further consider to keep the discussion short. Clearly, $|\alpha_1^*|$ (and λ^*) also impacts the file replication time at the service provider. In Figure 1(a), we evaluate the impact of $|\alpha_1^*|$ on the replication time, and on the time invested by a rational provider (who does not replicate) to answer every client challenge in Mirror. Our results indicate that the file replication time grows linearly with $|\alpha_1^*|$. Moreover, the higher λ^* is, the longer it takes to replicate a given file. On the other hand, as shown in Figure 1(b), $|\alpha_1^*|$ consid-

$ \alpha_1^* $	Estimated EC2 costs per challenge (USD)
40	0.000058
70	0.00011
80	0.00013
120	0.00019

Table 3: Costs borne by a rational provider who computes the responses to a challenge of size $l = 40$ on the fly. We assume two replicas of size 64 MB, and estimate costs for a compute-optimized (extra large) instance from Amazon EC2 (at 0.42 USD per hour).

erably affects the time incurred on a rational provider which did not correctly replicate (some) user files. The larger $|\alpha_1^*|$ is, the longer it takes a misbehaving provider to reply to the user challenges, and thus the bigger are the amount of computational resources that the provider needs to invest in. Here, we assume the lower bound on the effort of a misbehaving provider (i.e., which only stores a fraction δ of the sectors per replica) given by Equation 14.

Setting $|\alpha_1^*|$: Following this analysis, suitable choices for α_1^* need to be large enough such that the costs borne by a rational provider who computes the responses on the fly are higher than those borne by an honest provider who correctly stores the replicas. In Table 3, we display the corresponding costs borne by a rational provider who computes the responses on the fly to a single challenge, assuming $l = 40$, and $r = 2$ replicas of size 64 MB. Here, we estimate the computation costs as follows: we interpolate the time required by a rational provider in answering challenges from Figure 1(c). We then estimate the corresponding computation costs assuming a compute-optimized (extra large) instance from Amazon EC2 (at 0.42 USD per hour), which offers comparable computing power than that used in our implementation setup.

For comparison purposes, notice that the cost of storing two 64 MB replicas per day (based on Amazon S3 pricing [9]) is approximately 0.00011 USD. *This shows that when instantiating Mirror with parameters $|\alpha_1^*| = 70$, the provider should not gain any (rational) advantage in misbehaving, if the user issues at least one PoR² challenge of $l = 40$ randomly selected blocks per day.* Clearly, users can increase the number of challenges that they issue accordingly to ensure that the costs borne by a rational provider are even more pronounced, e.g., to account for possible fluctuations in costs.

Following this analysis, we assume that $|\alpha_1^*| = 70$ throughout the rest of the evaluation. As shown in

Figure 1(a), this parameter choice results in reasonable replication times. e.g., when $\lambda^* = 5$ or $\lambda^* = 15$. Observe that, in this case, users can *detect/suspect* misbehavior by observing the cloud’s response time. As shown in Figure 1(f), the typical response time of an honest service provider is less than 2 seconds when $r = 2$. An additional 0.9 seconds of delay (i.e., totalling 2.9 seconds) in responding to a challenge can be then detected by users.

Store performance: In Figure 1(c), we evaluate the latency incurred in Store with respect to the file size. Our findings suggest that the Store procedure of Mirror is considerably faster than that of MR-PDP. This is the case since the tag creation in Mirror requires fewer exponentiations per block (cf. Appendix A). For instance, the Store procedures is almost 20% faster than that of MR-PDP for files of 64MB in size.

Replicate performance: Figure 1(d) depicts the latency incurred on the clients of MR-PDP in the replicate procedure Replicate with respect to the number of replicas. Recall that, in MR-PDP, clients have to process and upload all replicas by themselves to the cloud. Clearly, the latency of Replicate increases with the number of replicas stored. Given our multi-threaded implementation, notice that the replication process can be performed in parallel. Here, as the number of concurrent replication requests increases, the threads in our thread pool are exhausted and the system saturates—which explains the sharp increase in the latency witnessed by clients who issue more than 8 concurrent replication requests. Notice that users of Mirror do not bear any overhead due to replication since this process is performed by the service provider.

In Figure 1(e), we show the latency incurred on the service provider in Mirror with respect to the number of replicas r . Since Mirror relies on puzzles, the replication process consumes considerable resources from the service provider. However, we point out that is a one-time effort per file, and can be performed offline (i.e., the provider can replicate files using “offline” resources in the back-end). For example, the creation of 8 additional 64 MB file replicas incurs a latency of almost 765 seconds. As mentioned earlier, Mirror trades this additional computational burden with bandwidth. Namely, users of Mirror only have to upload the file once, irrespective of the number of replicas desired. This, in turn, reduces the download bandwidth of providers and, as a consequence, the costs of offering the service.

In Figure 2, we estimate the costs of the additional computations incurred in Mirror for a 64 MB file,

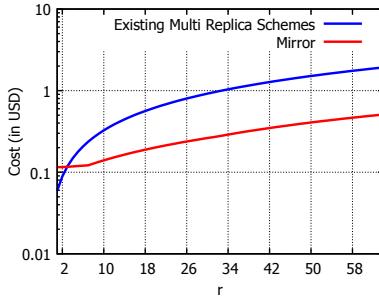

Figure 2: Replication costs for a 64 MB file (in USD) incurred **Mirror** vs. existing multi-replica schemes. We assume that the provider provisions a large general instance from Amazon EC2 at 0.441 USD per hour). We assume the replication time given by our experiments in Figure 1(e) and we estimate bandwidth costs by adapting the findings of [3] (cf. Table 3).

compared to those incurred by existing multi-replica schemes which require users to upload all the replicas. To estimate computing costs, we rely on the AWS pricing model [8]; we assume that the provider provisions a multi-core (compute-optimized) extra large instance from Amazon EC2 (at 0.441 USD per hour). We rely on our findings in Figure 1(e) to estimate the computing time for replication. We estimate bandwidth costs by adapting the findings of [3] (i.e., by assuming \$5 per Mbps per month cf. Table 3). Our estimates suggest that **Mirror** considerably reduces the costs borne on the provider by trading bandwidth costs with the relatively cheaper computing costs. We expect that the cost savings of **Mirror** will be more significant for larger files, and/or additional replicas.

Verify performance: In Figure 1(f), we evaluate the latency witnessed by the users and service provider in the Verify procedure of **Mirror** and MR-PDP, respectively. Our findings show that the verification overhead witnessed by the service provider in **Mirror** is almost twice that of MR-PDP. Moreover, users of **Mirror** require almost 1 second to verify the response issued by the provider. Notice that the majority of this overhead is spent while computing/verifying the response to the issued challenge. This discrepancy mainly originates from the fact that the challenge-response in **Mirror** involves all the 32 sectors of each block in order to ensure the extractability of all replicas⁸. We contrast this to MR-PDP where each block comprises a single sector—which only ensures data/replica possession but does not provide

⁸We point out that this is not particular to **Mirror** and applies to all schemes which ensure retrievability (e.g., [34]).

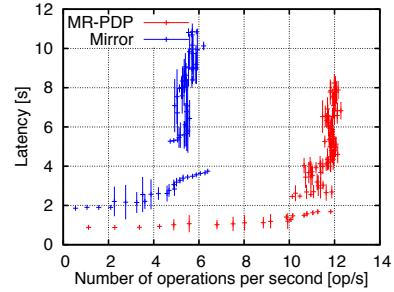

Figure 3: Latency vs. throughput comparison between MR-PDP and **Mirror**.

extractability guarantees.

In Figure 3, we evaluate the peak throughput exhibited by the service provider in the Verify procedure. Here, we require that the service provider handles verification requests back to back; we then gradually increase the number of requests in the system (until the throughput is saturated) and measure the associated latency. Our results confirm our previous analysis and show that **Mirror** attains a maximum throughput of 6 verification operations per second; on the other hand, the service provider in MR-PDP can handle almost 12 operations per second. As mentioned earlier, this discrepancy is mainly due to the fact that the MR-PDP blocks only comprise a single sector, whereas each block in **Mirror** comprises 32 sectors. However, we argue that the overhead introduced by our scheme compared to MR-PDP can be easily tolerated by clients; for instance, for 64 MB files, our proposal only incurs an additional latency overhead of 800 ms on the clients when compared to MR-PDP.

6 Related Work

Curtmola *et al.* propose in [18] a multi-replica PDP, which extends the basic PDP scheme in [12] and enables a user to verify that a file is replicated at least across t replicas by the cloud. In [16], Bowers *et al.* propose a scheme that enables a user to verify if his data is stored (redundantly) at multiple servers by measuring the time taken for a server to respond to a read request for a set of data blocks. In [13, 14], Barsoum and Hasan propose a multi-replica dynamic data possession scheme which allows users to verify multiple replicas, and to selectively update/insert their data blocks. This scheme builds upon the BLS-based SW scheme of [34]. In [22], the authors extend the dynamic PDP scheme of [21] to transparently support replication in distributed cloud storage systems. All existing schemes however share a common system model, where the user constructs and uploads the

replicas onto the cloud. On the other hand, **Mirror** conforms with the existing cloud model by allowing users need to process/upload their original files only once irrespective of the replication performed by the cloud provider.

Proofs of location (PoL) [32, 36] aim at proving the geographic position of data, e.g., if it is stored on servers within a certain country. In [36], Watson *et al.* provide a formal definition for PoL schemes by combining the use of geolocation techniques together with the SW POR schemes [34]. In [36], the authors assume a similar system model to **Mirror**, where the user uploads his files to the service provider only once. The latter then re-codes the tags of the file, and replicates content across different geo-located servers. Users can then execute individual PORs with each server to ensure that their data is stored in its entirety at the desired geographical location. We contrast this to our solution, where the user has to invoke a single **Mirror** instance to efficiently verify the integrity of all stored replicas.

Proofs of space [20] ensure that a prover can only respond correctly if he invests at least a certain amount of space or time per execution. However, this notion is not applicable to our scenario where we need to ensure that a *minimum* amount of space has been invested by the prover. Moreover, the instantiation in [20] does not support batch-verification which is essential in **Mirror** to conduct POR on several replicas in a single protocol run.

7 Conclusion

In this paper, we proposed a novel solution, **Mirror**, which enables users to efficiently verify the retrievability of their data replicas in the cloud. Unlike existing schemes, the cloud provider replicates the data by itself in **Mirror**; by doing so, **Mirror** trades expensive bandwidth resources with cheaper computing resources—a move which is likely to be welcomed by providers and customers since it promises better service while lowering costs.

Consequently, we see **Mirror** as one of the few economically-viable and workable solutions that enable the realization of verifiable replicated cloud storage.

A MR-PDP

In what follows, we briefly describe the multi-replica provable data possession scheme by Curtmola *et al.* [18]. Here, the user first splits the file D into

n blocks $d_1, \dots, d_n \in \mathbb{Z}_N$. Let $p = 2p' + 1, q = 2q' + 1$ be safe primes, and $N = pq$ an RSA modulus; moreover, let g be a generator of the quadratic residues of \mathbb{Z}_N^* , and e, d a pair of integers such that $e \cdot d = 1 \pmod{p'q'}$. The user creates authentication tags for each block $i \in [1, n]$ by computing $T_i \leftarrow (h(v||i)g^{d_i})^d \pmod{N}$, where $h: \{0, 1\}^* \rightarrow \mathbb{Z}_N$ is a hash function and $v \in \mathbb{Z}_N$.

Subsequently, each replica is created by the user as follows: $d_i^{(k)} \leftarrow d_i + \text{PRF}(k||i)$ where PRF denotes a pseudorandom function. The user sends to the service provider the tags $\{T_i\}$, the original file blocks $\{d_i\}$, and the replica blocks $d_i^{(k)}$.

At the verification stage, the user selects a replica k and creates a (pseudo-)random challenge set $I = \{(k_1, i_1), \dots, (k_\ell, i_\ell)\}$ where k_j denotes the replica number and i_j the block index. In addition, the user picks $s \in \mathbb{Z}_N^*$, and computes $g_s = g^s \pmod{N}$. The challenge query then comprises the set I and the value g_s which are both sent to the service provider who stores replica k . The service provider then computes the response (T, σ) as follows and sends it back to the verifier:

$$T \leftarrow \prod_{i \in I} T_i, \quad \sigma \leftarrow g_s^{\sum_{1 \leq j \leq \ell} d_{i_j}^{(k_j)}}$$

Finally, the user checks whether:

$$\sigma \stackrel{?}{=} \left(\frac{T^e}{\prod h(v||i)} g^{\sum_{1 \leq j \leq \ell} \text{PRF}(k_j||i_j)} \right)^s$$

B POR Schemes of Shacham and Waters

In what follows, we briefly describe the private POR scheme by Shacham and Waters [34]. This scheme leverages a pseudo-random function PRF. Here, the user first applies an erasure code to the file and then splits it into n blocks $d_1, \dots, d_n \in \mathbb{Z}_p$, where p is a large prime. The user then chooses a random $\alpha \in_R \mathbb{Z}_p$ and creates for each block an authentication value as follows:

$$\sigma_i = \text{PRF}_{key}(i) + \alpha \cdot d_i \in \mathbb{Z}_p. \quad (15)$$

The blocks $\{d_i\}$ and their authentication values $\{\sigma_i\}$ are all stored at the service provider in D^* .

At the POR verification stage, the verifier (here, the user) chooses a random challenge set $I \subset \{1, \dots, n\}$ of size ℓ , and ℓ random coefficients $v_i \in_R \mathbb{Z}_p$. The challenge query then is the set $Q := \{(i, v_i)\}_{i \in I}$ which is sent to the prover (here, service provider). The

prover computes the response (σ, μ) as follows and sends it back to the verifier:

$$\sigma \leftarrow \sum_{(i, v_i) \in Q} v_i \sigma_i, \quad \mu \leftarrow \sum_{(i, v_i) \in Q} v_i d_i.$$

Finally, the verifier checks the correctness of the response:

$$\sigma \stackrel{?}{=} \alpha \mu + \sum_{(i, v_i) \in Q} v_i \cdot \text{PRF}(i).$$

C Improving User Verification in Mirror

In what follows, we describe a number of optimizations that we adopted in our implementation in order to reduce the effort in verifying the service provider's response.

Using either g or h : Recall that the service provider's response involves powers of g and of h which have order p' and q' , respectively. One technique that allows to reduce the effort on the user's side is to rely on either g or h . That is, at the beginning of the verification step, the user randomly decides whether only g or only h shall be taken into account. For example, let us assume that the choice falls on g . Then, the user proceeds as follows:

1. The user computes:

$$\tilde{\sigma} := \sigma^{q'} \cdot \prod_{c=1}^{\ell} \left(\prod_{j=1}^s \prod_{k \in R} g_{i_c, j}^k \right)^{-(q' \cdot v_c)}. \quad (16)$$

Here, we exploit the fact that $(h^e)^{q'} = 1$ for any e .

2. The user checks if:

$$\left(\prod_{j=1}^s \mu_j^{\varepsilon_j + |R|} \right)^{q'} = \tilde{\sigma}. \quad (17)$$

This approach incurs two additional exponentiations but completely eliminates the need to compute the expressions for the values h .

Representing LFSRs by Pre-computed Matrices: According to our experiments, suitable parameter choices are to choose the length λ of the secret LFSR quite small, e.g., equal to 2, while the block size s is comparatively large. This motivates the following optimization.

Let $A_t^{(k)} := (a_t^{(k)}, \dots, a_{t+\lambda-1}^{(k)})$ for any $t \geq 1$ and any $k \in \{1, \dots, r\}$. That is, $A_1^{(k)}$ denotes the initial state of the k -th LFSR while $A_t^{(k)}$ denotes the state after $t - 1$

clocks. Recall that we consider r LFSR sequences which are all generated by the same feedback function. Namely, it holds for any $t \geq 1$ and any $k \in \{1, \dots, r\}$ that $a_{t+\lambda}^{(k)} = \sum_{i=1}^{\lambda} a_i \cdot a_{t+i-1}^{(k)}$. Due to the linearity of the feedback function, there exists a $\lambda \times \lambda$ matrix M , called the companion matrix, for which it holds that:

$$M' \cdot A_1^{(k)} = A_{t+1}^{(k)}, \quad \forall t \geq 0. \quad (18)$$

Recall that we aim to compute for each $i \in I$ the value

$$\sum_{k \in R} \left(a_{\pi(i_c, 1)}^{(k)} + a_{\pi(i_c, 1)+1}^{(k)} + \dots + a_{\pi(i_c, 1)+s-1}^{(k)} \right) \quad (19)$$

where $\pi : \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ is a mapping such that $g_{i,j}^{(k)} = g_{\pi(i,j)}^{(k)} = g^{a_j^{(k)}}$ and to raise g by the resulting value. The idea is now to combine as many computations as possible to reduce the overall effort. To this end, the goal is to sum-up for each $k \in R$ and each $i \in I$ the following internal states:

$$\begin{aligned} A_{\pi(i, 1)}^{(k)} &= (a_{\pi(i, 1)}^{(k)}, \dots, a_{\pi(i, 1)+\lambda-1}^{(k)}) \\ &\vdots \\ A_{\pi(i, 1)+\lfloor s/\lambda \rfloor \cdot \lambda}^{(k)} &= (a_{\pi(i, 1)+\lfloor s/\lambda \rfloor \cdot \lambda}^{(k)}, \dots, a_{\pi(i, 1)+\lfloor s/\lambda \rfloor \cdot \lambda-1}^{(k)}) \end{aligned}$$

This can be accomplished by computing:

$$\left(\sum_{i \in I} M^{\pi(i, 1)} \right) \cdot \left(\sum_{j=0}^{\lfloor s/\lambda \rfloor} M^{j \cdot \lambda} \right) \cdot \left(\sum_{k \in R} A_1^{(k)} \right). \quad (20)$$

Observe that $\sum_{j=0}^{\lfloor s/\lambda \rfloor} M^{j \cdot \lambda}$ is independent of the current challenge and can be precomputed. Moreover, due to the fact that we aim for a small LFSR length, e.g., $\lambda = 2$, the user may consider to precompute the value in the last bracket for any choice of R , yielding an additional storage effort of $\lambda \cdot (2^r - 1)$ sectors. In such case, the computation would boil down to the effort of computing the first bracket only. We note that if λ does not divide s , then the user has to compute in addition:

$$\left(\sum_{i \in I} M^{\pi(i, 1)} \right) \cdot M^{\lceil s/\lambda \rceil \cdot \lambda} \cdot \left(\sum_{k \in R} A_1^{(k)} \right), \quad (21)$$

and to add the sum of the first $s \bmod \lambda$ entries to the value computed above. Also here, similar precomputations can be done to accelerate this step.

D Valid Relations

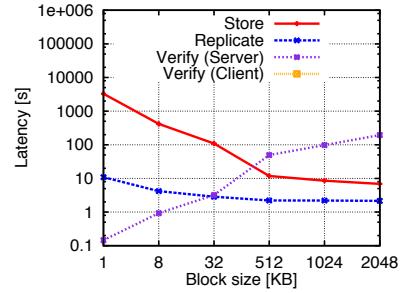

We now explain why $\vec{v} = (v_1, \dots, v_{n \cdot s}) \in \mathbb{Z}^{n \cdot s}$ such that

$$\prod_{i=1}^{n \cdot s} g_i^{v_i} = 1, \quad (22)$$

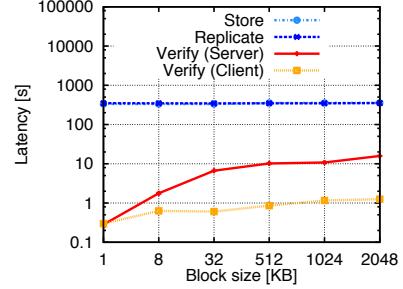

represents the only type of equations that allows the provider to compute missing values g_j from known values g_i .

To see why, recall that $g_j = g^{a_j}$ where $(a_j)_j$ represents an LFSR-sequence. More precisely, this sequence is defined by the feedback polynomial and the initial state, i.e., the first λ entries. Without knowing these entries, it is (information-theoretically) impossible to determine a_j for larger indices. Also, any element in $(a_j)_j$ is a linear combination of the initial state values. Let us denote this combination by L_1 . This can be relaxed as follows: the knowledge of any λ elements $a_{j_1}, \dots, a_{j_\lambda}$ of the sequence $(a_j)_j$ allows almost always to compute another element by an appropriate linear combination (say L_2) of $a_{j_1}, \dots, a_{j_\lambda}$. Notice that the coefficients of L_2 have to be a linear combination of the coefficients (or shifted versions) of L_1 (this is an inherent property of LFSRs). This is exactly the definition of “valid relations” given in Equation (12).

E Impact of the Block Size on the Performance of MR-PDP and Mirror

ZKBoo: Faster Zero-Knowledge for Boolean Circuits

Irene Giacomelli Jesper Madsen Claudio Orlandi
Computer Science Department, Aarhus University

Abstract

In this paper we describe ZKBoo¹, a proposal for practically efficient zero-knowledge arguments especially tailored for Boolean circuits and report on a proof-of-concept implementation. As a highlight, we can generate (resp. verify) a non-interactive proof for the SHA-1 circuit in approximately 13ms (resp. 5ms), with a proof size of 444KB.

Our techniques are based on the “MPC-in-the-head” approach to zero-knowledge of Ishai et al. (IKOS), which has been successfully used to achieve significant asymptotic improvements. Our contributions include:

- A thorough analysis of the different variants of IKOS, which highlights their pros and cons for practically relevant soundness parameters;
- A generalization and simplification of their approach, which leads to faster Σ -protocols (that can be made non-interactive using the Fiat-Shamir heuristic) for statements of the form “I know x such that $y = \phi(x)$ ” (where ϕ is a circuit and y a public value);
- A case study, where we provide explicit protocols, implementations and benchmarking of zero-knowledge protocols for the SHA-1 and SHA-256 circuits.

1 Introduction

Since their introduction in the 80s [16], zero-knowledge (ZK) arguments have been one of the main building blocks in the design of complex cryptographic protocols. However, due to the lack of practically efficient solutions for proving generic statements, their application in real-world systems is very limited. In particular, while there is a large body of work considering the efficiency of ZK protocols for algebraic languages (following the seminal work of Schnorr for discrete logarithm [26]), things are quite different when it comes to general purpose ZK.

A notable exception is the recent line of work on *succinct non-interactive arguments of knowledge* (SNARKs) (e.g. Pinocchio [23], libsnark [4], etc.). SNARKs are an extremely useful tool when the size of the proof and the verification time matters: SNARKs are less than 300 bytes and can be verified in the order of 5ms, which makes them perfect for applications such as ZeroCash [3]. However, on the negative side, SNARKs require very large parameters (which must be generated in a trusted way) and the time to generate proofs are prohibitive for many applications. As an example, the running time of the prover for generating a proof for SHA-1 is in the order of 10 seconds. There is an inherent reason for this inefficiency: current SNARKs technology requires to perform expensive operations (in pairing friendly groups) for each gate in the circuit.

Jawurek et al. [21] proposed a different approach to efficient ZK, namely using garbled circuits (GC). Using GC, it is possible to prove any statement (expressed as a Boolean circuit) using only a (low) constant number of symmetric key operations per gate in the circuit, thus decreasing the proving time by more than an order of magnitude. On the flip-side, GC-based ZK are inherently interactive, and they still require a few public-key operations (used for implementing the necessary oblivious transfers).

In this paper we describe efficient ZK protocols for circuits based on the “MPC-in-the-head” paradigm of Ishai et al. [19] (IKOS). In IKOS, a prover simulates an MPC protocol between a number of “virtual” servers (at least 3) and then commits to the views and internal state of the individual servers. Now the verifier challenges the prover by asking to open a subset of these commitments. The privacy guarantee of the underlying MPC protocol guarantees that observing the state of a (sufficiently small) subset of servers does not reveal any information. At the same time, the correctness of the MPC protocol guarantees that if the prover tries to prove a false statement, then the joint views of some of the server must nec-

¹Sounds like Peekaboo.

essarily be inconsistent, and the verifier can efficiently check that. By plugging different MPC protocols into this approach, [19] shows how to construct ZK protocols with good asymptotic properties. However, to the best of our knowledge, no one has yet investigated whether the IKOS approach can be used to construct practically efficient ZK protocols. This paper is a first step in this direction.

Structure of the paper. In Section 3 we describe the different variants of the IKOS framework. IKOS presents two strategies to achieve a negligible soundness error: either repeating a passive secure MPC protocol with few parties, or using a single instance of an active secure MPC protocol with a large number of parties. While IKOS only provides asymptotic estimates of the soundness parameters, we concretely estimate the soundness of IKOS with different kind of MPC protocols and show that, if one is interested in a (reasonable) soundness error of 2^{-80} , then the version of IKOS without repetition does not (unfortunately) lead to any practical advantage. Then (in Section 4) we present a new interpretation of the IKOS framework when instantiated with a 2-private 3-party version of the GMW [15] protocol, where each pair of parties is connected with an OT-channel. We observe that in general the OT-channels can be replaced with arbitrary 2-party functionalities. Since those ideal functionalities do not have to be implemented using cryptographic protocols (remember, they are executed between pair of virtual servers in a simulation performed by the prover), this increases the degrees of freedom of the protocol designer and allows to construct more efficient MPC protocols (or, as we prefer to call them, function decompositions) that can be used for constructing ZK protocols. (Note that this class of protocol has not been studied before, since it does not lead to any advantage in the standard MPC setting, and therefore we expect future work to improve on our approach by designing better MPC protocols for this special setting.) All resulting protocols are Σ -protocols (3-move honest-verifier zero-knowledge protocols with special soundness) which can therefore be made *non-interactive* in the random oracle model using the Fiat-Shamir heuristic.

Finally (in Section 5) we describe how our approach can be used to construct very efficient ZK protocols for proving knowledge of preimages for SHA-1 and SHA-256. The resulting proofs are incredibly efficient: the verification time is essentially the same as the verification time for SNARKs, but the prover runs approximately 1000 times faster. On the negative side the size of our proofs scales linearly with the circuit size, but we believe that in some applications this is a desirable trade-off.

Recent Related Work. Ranellucci *et al.* [25] proposed a general-purpose public-coin ZK protocol which can be based on any commitment scheme. The asymptotic performances are the same as ours (both communication and computation complexity are linear in the circuit size) but the concrete constants are higher (e.g., the proofs are approximately 3 times larger and computation more than 10 times slower). Hazay *et al.* [18] show how to extend the IKOS technique to the case of two-party MPC protocols (2PC) with application to *adaptive* ZK protocols. It is an open question whether their approach might lead to concrete efficiency improvements.

2 Preliminaries

Standard notations: For an integer n , we write $[n] = \{1, 2, \dots, n\}$ and, given $A \subseteq [n]$, $|A|$ denotes the cardinality of A . We say that a function ε is *negligible* in n , $\varepsilon(n) = negl(n)$, if for every polynomial p there exists a constant c such that $\varepsilon(n) < \frac{1}{p(n)}$ when $n > c$. Given two random variables X ad Y with support S , the statistical distance between X and Y is defined as $SD(X, Y) = \frac{1}{2} \sum_{i \in S} |\Pr[X = i] - \Pr[Y = i]|$. Two families $X = \{X_k\}$ and $Y = \{Y_k\}$, $k \in \{0, 1\}^*$ of random variables are said to be *statistically indistinguishable* if there exists a negligible function $\varepsilon(\cdot)$ such that for every $k \in \{0, 1\}^*$, $SD(X_k, Y_k) \leq \varepsilon(|k|)$. They are said to be *computationally indistinguishable* if for every efficient non-uniform distinguisher D there exists a negligible function $\varepsilon(\cdot)$ such that for every $k \in \{0, 1\}^*$, $|\Pr[D(X_k) = 1] - \Pr[D(Y_k) = 1]| \leq \varepsilon(|k|)$.

2.1 Multi-Party Computation (MPC)

Consider a public function $f : (\{0, 1\}^k)^n \rightarrow \{0, 1\}^\ell$ and let P_1, \dots, P_n be n players modelled as PPT machines. Each player P_i holds the value $x_i \in \{0, 1\}^k$ and wants to compute the value $y = f(x)$ with $x = (x_1, \dots, x_n)$ while keeping his input private. The players can communicate among them using point-to-point secure channels $CH_{i,j}$ in the synchronous model. These can be classical secure channels (*i.e.* encrypted channels) or more powerful channels (*e.g.* OT-channel [11, 24]). If necessary, we also allow the players to use a broadcast channel. To achieve their goal, the players jointly run a n -party MPC protocol Π_f . The latter is a protocol for n players that is specified via the next-message functions: there are several rounds of communication and in each round the player P_i sends into the channel $CH_{i,j}$ (or in the broadcast channel) a message that is computed as a deterministic function of the internal state of P_i (his initial input x_i and his random tape k_i) and the messages that P_i has received in the previous rounds of communications. The view of the player P_j , denoted by $View_{P_j}(x)$, is defined as the

concatenation of the private input \mathbf{x}_j , the random tape \mathbf{k}_j and all the messages received by P_j during the execution of Π_f . Each channel $\text{CH}_{i,j}$ defines a relation of *consistency* between views. For instance, in a plain channel *two views are consistent if* the messages reported in $\text{View}_{P_j}(\mathbf{x})$ as incoming from P_i are equal to the outgoing message implied by $\text{View}_{P_i}(\mathbf{x})$ ($i \neq j$). More powerful channels (such as OT channels), are defined via some function φ and we say that *two views are consistent if* the view of the sender implies an input \mathbf{x} to the channel and the view of the receiver implies an input \mathbf{y} and contains an output \mathbf{z} such that $\mathbf{z} = \varphi(\mathbf{x}, \mathbf{y})$. For instance, in OT channels $\mathbf{x} = (m_0, m_1)$, \mathbf{y} is a bit and $\mathbf{z} = m_y$.

Finally, the output \mathbf{y} can be computed from any of the view $\text{View}_{P_i}(\mathbf{x})$, *i.e.* there are n functions $\Pi_{f,1}, \dots, \Pi_{f,n}$ such that $\mathbf{y} = \Pi_{f,i}(\text{View}_{P_i}(\mathbf{x}))$ for all $i \in [n]$. In order to be private, the protocol Π_f needs to be designed in such a way that a curious player P_i can not infer information about \mathbf{x}_j with $j \neq i$ from his view $\text{View}_{P_i}(\mathbf{x})$. An additional security property, robustness, assures that a cheating player P_i (who may not follow the instructions in the protocol) can not mislead the honest players, who still compute the correct output \mathbf{y} . More precisely, we have the following definition.

Definition 2.1. • (*Correctness*) We say that the protocol Π_f realizes f with perfect (resp. statistical) correctness if for any input $\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_n)$, it holds that $\Pr[f(\mathbf{x}) \neq \Pi_{f,i}(\text{View}_{P_i}(\mathbf{x}))] = 0$ (resp. negligible) for all $i \in [n]$. The probability is over the choice of the random tapes \mathbf{k}_i .

• (*Privacy*) Let $1 \leq t < n$, the protocol Π_f has perfect t -privacy if it is correct and for all $A \subseteq [n]$ satisfying $|A| \leq t$ there exists a PPT algorithm S_A such that the joint views $(\text{View}_{P_i}(\mathbf{x}))_{i \in A}$ have the same distribution as $S_A(f, (\mathbf{x}_i)_{i \in A}, \mathbf{y})$, for all $\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_n)$.

We will speak about statistical (resp. computational) t -privacy if the two distributions $S_A(f, (\mathbf{x}_i)_{i \in A}, \mathbf{y})$ and $(\text{View}_{P_i}(\mathbf{x}))_{i \in A}$ are statistically (resp. computationally) indistinguishable.

• (*Robustness*) Let $0 \leq r < n$, the protocol Π_f has perfect (resp. statistical) r -robustness if it is correct and for all $A \subseteq [n]$ satisfying $|A| \leq r$ even assuming that all the players in A have been arbitrarily corrupted, then $\Pr[f(\mathbf{x}) \neq \Pi_{f,i}(\text{View}_{P_i}(\mathbf{x}))] = 0$ (resp. negligible) for all $i \in A^c$.

3 Zero Knowledge

In this section we recall the notion of zero-knowledge and Σ -protocols, we review the IKOS construction [19] for zero-knowledge, and we discuss different possible instantiations.

3.1 Definitions

Let $R \subseteq \{0,1\}^* \times \{0,1\}^*$ be a binary relation representing some computational problem (*e.g.* $R = \{(\mathbf{y}, \mathbf{x}) \mid \mathbf{y} = \text{SHA-256}(\mathbf{x})\}$). We will interpret R as a binary function from $\{0,1\}^* \times \{0,1\}^*$ to $\{0,1\}$ (*i.e.* $R(\mathbf{y}, \mathbf{x}) = 1 \Leftrightarrow (\mathbf{y}, \mathbf{x}) \in R$) and we will assume that:

- $\forall \mathbf{y}$ and $\forall \mathbf{x}$, $R(\mathbf{y}, \mathbf{x})$ can be computed in polynomial-time by a probabilistic Turing machine;
- there exists a polynomial p such that if $R(\mathbf{y}, \mathbf{x}) = 1$ then the length of \mathbf{x} is less or equal to $p(|\mathbf{y}|)$.

Such relation is called NP relation. With L we indicate the set of the yes-instances of the relation R , *i.e.* $L = \{\mathbf{y} \mid \exists \mathbf{x} \text{ s.t. } R(\mathbf{y}, \mathbf{x}) = 1\}$.

An *argument* for L is a cryptographic protocols between two players: the prover P and the verifier V with the following features. We assume that both P and V are probabilistic polynomial time (PPT) machines and that they know \mathbf{y} , an instance of the relation R . The situation is that P wants to convince V that $\mathbf{y} \in L$. This clearly makes sense only if the prover has some advantage over the verifier. Thus, we allow the prover to have an extra private input (for example P knows \mathbf{x} such that $R(\mathbf{y}, \mathbf{x}) = 1$). The protocol is described by instructions for the players and has different rounds of communication. At the end of the protocol, the verifier outputs accept if he is convinced or reject otherwise. If $\mathbf{y} \in L$, we require that an honest verifier convinces an honest prover with probability 1 (the protocol is complete). On the other hand, we say that the protocol has *soundness error* ϵ if for all $\mathbf{y} \notin L$ $\Pr[V(\mathbf{y}) = \text{accept}] \leq \epsilon$, no matter what the prover does. In other words, ϵ is an upper-bound of the probability that a cheating prover makes an honest verifier output accept for a false instance.

However, in many interesting cryptographic applications, the language L is trivial and therefore the soundness property gives absolutely no guarantees: for every string \mathbf{y} there exist a \mathbf{x} s.t., $\mathbf{y} = \text{SHA-256}(\mathbf{x})$. In this case we need a stronger property, namely *proof-of-knowledge* (PoK), which informally states that the verifier should output accept only if the prover *knows* the value \mathbf{x} .

Finally, ZK protocols get their name from the *zero-knowledge* property: Here, we want to express the requirement that whatever strategy a cheating verifier follows, he learns nothing except for the truth of the prover's claim. In particular, he can not obtain information about the private input of P . This is captured using the simulation-paradigm and saying that the messages received by the verifier during the protocol can be efficiently simulated only knowing the public input \mathbf{y} . More precisely, we have the following requirement: for any corrupted PPT verifier V^* , there is a PPT algorithm S (the “simulator”) with access to V^* such that the output

of $S(\mathbf{y})$ and the real conversation between P and V^* on input \mathbf{y} are indistinguishable.

In the rest of the paper we will be concerned with public-coin two-party protocols with a specific communication pattern known as Σ -protocols.

Definition 3.1 (Σ -protocol). *A protocol Π_R between two players P and V is a Sigma Protocol for the relation R if it satisfies the following conditions:*

- Π_R has the following communication pattern:
 1. (Commit) P sends a first message \mathbf{a} to V ;
 2. (Challenge) V sends a random element \mathbf{e} to P ;
 3. (Prove) P replies with a second message \mathbf{z} .
- (**Completeness**) If both players P and V are honest and $\mathbf{y} \in L$, then $\Pr[(P,V)(\mathbf{y}) = \text{accept}] = 1$;
- (**s -special soundness**) For any \mathbf{y} and any set of s accepting conversations $\{(\mathbf{a}, \mathbf{e}_i, \mathbf{z}_i)\}_{i \in [s]}$ with $\mathbf{e}_i \neq \mathbf{e}_j$ if $i \neq j$, a witness \mathbf{x} for \mathbf{y} can be efficiently computed;
- (**Special honest-verifier ZK**) There exists a PPT simulator S such that on input $\mathbf{y} \in L$ and \mathbf{e} outputs a triple $(\mathbf{a}', \mathbf{e}', \mathbf{z}')$ with same probability distribution of real conversations $(\mathbf{a}, \mathbf{e}, \mathbf{z})$ of the protocol.

Figure 1: The communication pattern of a Σ -protocol.

Σ -protocols have several properties (e.g. parallel composition, witness indistinguishability) that make them a useful building block for many other cryptographic primitives (identification schemes, signatures, etc). See [7] or [17, Chapter 6] for more details on this. Here we are mainly interested in the following facts: First, Σ -protocols are public-coin protocols and thus they can be made non-interactive in the random oracle model using the Fiat-Shamir heuristic [12]. Second, there exist efficient transformations from Σ -protocols to fully-fledged ZK and PoK: indeed, it is possible to efficiently transform a Σ -protocol into a zero-knowledge argument (resp. zero-knowledge proof of knowledge) with the addition of one additional round (resp. two additional rounds). Note

finally that if the challenge \mathbf{e} is chosen uniformly at random form a set of cardinality c , then s -special soundness implies a bound of $(s-1)/c$ on the soundness error of the protocol: if $\mathbf{y} \notin L$, then there exist no \mathbf{x} s.t. $R(\mathbf{x}, \mathbf{y}) = 1$, and therefore fixed any \mathbf{a} there are at most $s-1$ challenges such that an accepting conversation for them exists.

3.2 IKOS Construction

In 2007 Ishai *et al.* show how to use any MPC protocol and the commitment-hybrid (Com) model² to obtain a ZK proof for an arbitrary NP relation R with asymptotically small soundness error. Here we briefly recall their construction and moreover we explicitly analyse its soundness error.

Let Π_f be an MPC protocol that realizes any n -party function f with perfect correctness (Definition 2.1). Depending on the features of Π_f (privacy, robustness, communication channels used), [19] presents slightly different ZK protocols. However, the general structure is always the same and is the structure of a Σ -protocol, see Figure 1. The high-level idea is the following: assume that $\mathbf{y} \in L$ is the public input of the ZK protocol, while \mathbf{x} is the private input of the prover (*i.e.* $R(\mathbf{y}, \mathbf{x}) = 1$). The prover first takes n random values $\mathbf{x}_1, \dots, \mathbf{x}_n$ such that $\mathbf{x} = \mathbf{x}_1 \oplus \dots \oplus \mathbf{x}_n$, then he considers the n -input function f_y defined as

$$f_y(\mathbf{x}_1, \dots, \mathbf{x}_n) := R(\mathbf{y}, \mathbf{x}_1 \oplus \dots \oplus \mathbf{x}_n)$$

and emulates “in his head” the protocol Π_{f_y} on inputs $\mathbf{x}_1, \dots, \mathbf{x}_n$. After the emulation, he computes the commitments to each of the n produced views (*i.e.* $\text{Com}(\text{View}_{P_i}(\mathbf{x}))$ for $i = 1, \dots, n$). After all the commitments have been stored, the verifier challenges the prover to open some of them (*i.e.* the challenge is a random subset of $[n]$ of a given size). Finally, the prover opens the requested commitments and the verifier outputs accept if and only if all the opened views are consistent with each other and with output 1.

Here we focus on the ZK protocols presented in [19] that assume a perfectly correct (and eventually perfectly robust) MPC protocol and we collect them in two versions. Version 1 considers the case of an MPC protocol with t -privacy and perfect r -robustness with $t > 1$.³ Version 2 shows that 2-privacy is not necessary condition and indeed considers the case of an MPC protocol with 1-privacy only.

²In the *commitment-hybrid model* the two parties have access to an idealized implementation of commitments, which can be imagined as a trusted third party which stores the messages of the sender and only reveals them if told so by the sender.

³This is a generalization of [19] as they only consider the case $t = r$.

IKOS Protocol (Version 1)

The verifier and the prover have input $\mathbf{y} \in L$. The prover knows \mathbf{x} such that $R(\mathbf{y}, \mathbf{x}) = 1$. A perfectly correct and t -private n -party MPC protocol Π_{f_y} is given ($2 \leq t < n$).

Commit: The prover does the following:

1. Sample random vectors $\mathbf{x}_1, \dots, \mathbf{x}_n$ s.t. $\mathbf{x}_1 \oplus \dots \oplus \mathbf{x}_n = \mathbf{x}$;
2. Run $\Pi_{f_y}(\mathbf{x}_1, \dots, \mathbf{x}_n)$ and obtain the views $\mathbf{w}_i = \text{View}_{P_i}(\mathbf{x})$ for all $i \in [n]$;
3. Commit to $\mathbf{w}_1, \dots, \mathbf{w}_n$.

Prove: The verifier chooses a subset $E \subseteq [n]$ such that $|E| = t$ and sends it to the prover. The prover reveals the value \mathbf{w}_e for all $e \in E$.

Verify: The verifier runs the following checks:

1. If $\exists e \in E$ s.t. $\Pi_{f,e}(\text{View}_{P_e}(\mathbf{x})) \neq 1$, output reject;
2. If $\exists \{i, j\} \subset E$ s.t. $\text{View}_{P_i}(\mathbf{x})$ is not consistent with $\text{View}_{P_j}(\mathbf{x})$, output reject;
3. Output accept;

Figure 2: The IKOS zero-knowledge protocol for the relation R in the commitment-hybrid model.

Version 1: Let t and r be two integers, $2 \leq t < n$ and $0 \leq r \leq t$. We assume that the protocol Π_{f_y} is perfectly correct and satisfies two more properties: perfect, statistical or computational t -privacy and perfect r -robustness. In this version of the IKOS protocol (Figure 2) the verifier is allowed to ask for the openings of t of the commitments $\text{Com}(\text{View}_{P_i}(\mathbf{x}))$. In this way, the zero-knowledge property follows easily by the t -privacy of the protocol Π_{f_y} .

For the analysis of the soundness error of this protocol we use the so-called *inconsistency graph* G . Given an execution of Π_{f_y} , the graph G has n nodes and there is an edge (i, j) if and only if the views of the players P_i and P_j are inconsistent. Assume that $\mathbf{y} \notin L$ and that the execution of Π_{f_y} is not a correct one (otherwise $\Pr[V(\mathbf{y}) = \text{accept}] = 0$ because of the checks in step 1 of the procedure **Verify**). Then we have two cases:

1. There is in G a vertex cover set⁴ B of size at most

⁴ B is a vertex cover set for the graph G if each edge in G is incident to at least 1 node in B .

⁵ $\binom{r}{t}$ is 0 if $r < t$.
⁶A matching is a set of edges without common nodes.

r . Intuitively, this means that in the current execution of Π_{f_y} only the players in B have been actively corrupted. Indeed, if we remove the nodes in B , we obtain a graph without edges. That is, all the players not in B have views consistent among them and we can consider these players honest. Since the size of B is less or equal to the parameter r , the robustness property assures that for all the players not in B (honest players) the view implies a 0 output (the correct output of the protocol Π_{f_y}). The probability that the verifier will not see one of these views choosing t of them uniformly at random is less or equal to⁵

$$p_1(n, t, r) = \binom{r}{t} \binom{n}{t}^{-1}$$

2. If the size of the minimum vertex cover is $> r$, then the graph G has a matching⁶ of size $> r/2$. The probability that the verifier accepts the wrong proof is equal to the probability that between the t nodes that he chooses there are no edges of G and this is less or equal to the probability that there are no edges from the matching. Clearly, this probability reaches the maximum when the matching is the smallest possible, that is it has size $k = \lfloor r/2 \rfloor + 1$. In this situation the aforementioned probability is

$$p_2(n, t, r) = \begin{cases} 0 & \text{otherwise} \\ \left(\sum_{j=0}^k 2^j \binom{k}{j} \binom{n-2k}{t-j} \right) \binom{n}{t}^{-1} & \text{if } n - 2k > 0 \end{cases}$$

In general, the soundness error is equal to the value $p(n, t, r) = \max\{p_1(n, t, r), p_2(n, t, r)\}$.

Version 2: A second version of the protocol was proposed in [20] to show that 2-privacy is not a necessary condition for the IKOS construction. In other words, we can construct ZK proofs in from 1-private MPC protocols. Notice that in this case the MPC protocol is allowed to use only standard point-to-point secure channels. The idea of the construction is very similar to the previous one, but now the prover commits to all the $\binom{n}{2}$ channels in addition to committing to the n views. The verifier picks a random $i \in [n]$ and challenges the prover to open the view of the player P_i and all the $n - 1$ channels CH_{ij} incident to him. Finally, the verifier accepts if the opened view is consistent with the channels and with the output 1. Again, the ZK property follows from the privacy property of the MPC protocol: the information revealed to the verifier is implied by the view of a single player. To compute the soundness error in this case, observe that for any

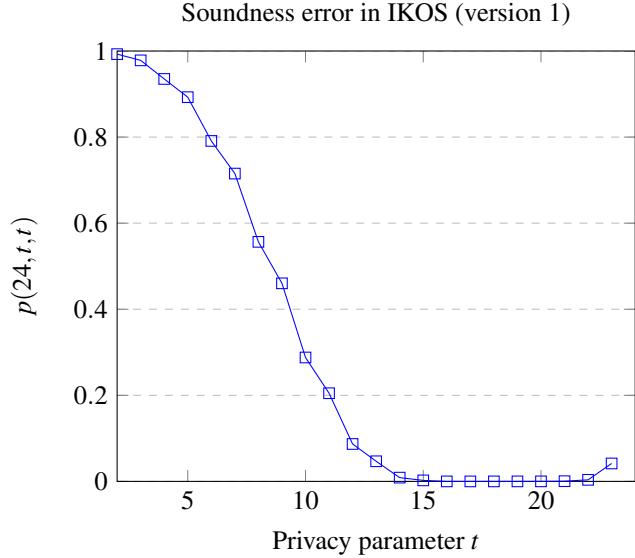

Figure 3: The graph represents the soundness error $p(n, t, r)$ in function of t when $t = r$ and $n = 24$. The table shows the values of σ such that $p(24, t, t) = 2^{-\sigma}$ for $t \in \{15, \dots, 20\}$.

incorrect execution of Π_{f_y} there is at least one player P_i such that $\text{View}_{P_i}(\mathbf{x})$ is inconsistent with a channel CH_{ij} . The probability $\Pr[V(\mathbf{y}) = \text{accept}]$ is less or equal to the probability that V does not choose this index i . Therefore, the soundness error of this version is $1 - 1/n$.

3.3 Our choice of version and parameters

In this section we discuss and motivate some of our design choices.

Which MPC protocol? As discussed, IKOS can be instantiated with a large number of MPC protocols. In particular, using MPC protocols with good asymptotic properties (such as [8, 9], etc.), one can obtain ZK protocols with equally good asymptotic properties. However in this paper we are concerned with concrete, constant size circuits, and we do not want to put any restriction on the shape or width of the circuits. Thus, the best two choices are BGW [2] style protocols with $t = r = \lfloor \frac{n-1}{3} \rfloor$ which use simple point-to-point channels and GMW [15] style protocols with $t = n-1, r = 0$ which use OT channels between each pair of parties. Then we have the following two cases:

1. (GMW [15]:) In this case the soundness error is $\frac{2}{n}$

and we open $n-1$ views. Note that in these protocols each party must communicate with every other party, thus the size of the proof for soundness $2^{-\sigma}$ is given by

$$c \cdot \frac{(n-1)^2}{\log_2(n)-1} \cdot \sigma$$

where c is a constant which depends on the exact protocol. It is easy to see that the function grows with n and therefore smallest proofs are achieved with $n = 3$. Looking ahead, our protocol in Section 4 has $c = 1/2$ and $\sigma = 80$ and therefore the size of the proof is 274 bits per multiplication gate.

2. (BGW [2]:) In this case the soundness error is given by $p_2(n, \lfloor \frac{n-1}{3} \rfloor, \lfloor \frac{n-1}{3} \rfloor)$. To get soundness error $\leq 2^{-80}$, we get that $n \geq 1122$ and therefore the number of opened views is $\lfloor \frac{n-1}{3} \rfloor = 373$. Thus, even if each party only had to store a single bit for each multiplication gate, the size of the proof would already be larger than in the previous case.
3. (Future Work:) Our analysis shows that using an MPC protocol with $t = r = \lceil \frac{2}{3}n \rceil$ it would be enough to use $(n, t, r) = (92, 64, 64)$ to achieve soundness 2^{-80} . The existence of such a protocol, where in addition each party only needs to store ≤ 4 bits per multiplication gate, would give rise to ZK proofs of size smaller than the one we construct. We are not aware of any such protocols, however we cannot rule out their existence. In particular, we note that such protocols have *not* been considered in the literature, since they give rise to poor MPC protocols in practice (note that such a protocol necessarily uses advanced channels, which in the standard MPC protocol need to be implemented using expensive cryptographic operations), and we believe that the quest for “MPC protocols” optimized for the ZK applications has just begun. Figure 3 shows how, for a fixed number of parties n , the soundness error decreases as a function of $t = r$. Note that the soundness error for $\frac{2}{3}n$ is much smaller than $\frac{1}{3}n$.

Why only perfect correctness and robustness? [19] presented also two extensions of the basic construction that allow to use MPC protocol with statistical correctness or with statistical robustness, but we are not considering those cases here for two reasons: first, the resulting ZK protocols have higher round complexity (and are therefore not Σ -protocols); second, perfectly secure MPC protocols are *more efficient*: practically efficient MPC protocols which only achieve statistical security (even when allowing arbitrary two-party channels, such as in [5, 22]) require parties to store *tags* or *MACs* together with their shares, and to make sure that the sta-

tistical error is negligibly small these tags need to be at least as long as the security parameter⁷, whereas in perfectly secure MPC protocols the share size can be made constant.

Why not Version 2? Note that the soundness error of Version 1 with $(n, t, r) = (3, 2, 0)$ is the same as the soundness error of Version 2 with $(n, t, r) = (3, 1, 0)$, thus the number of required rounds is exactly the same. However (i) Version 2 requires to compute and open more commitments and (ii) Version 2 only works with plain channels, while Version 1 allows to use arbitrary channels which helps in constructing more efficient protocols.

4 Generalizing IKOS

This section contains a generalized and optimized version of the IKOS protocol that works for any relation defined by a function, $\phi : X \rightarrow Y$ which can be decomposed in the “right way”. In particular, in Section 4.2 we will describe a ZK Σ -protocol for the relation R_ϕ defined by $R_\phi(\mathbf{y}, \mathbf{x}) = 1 \Leftrightarrow \phi(\mathbf{x}) = \mathbf{y}$, while the decomposition used to construct it is formalized in the following section.

Protocol Π_ϕ^*

Let $\phi : X \rightarrow Y$ be a function and \mathcal{D} a related $(2, 3)$ -decomposition as defined in Definition 4.1.

Input: $\mathbf{x} \in X$

1. Sample random tapes $\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3$;
2. Compute $(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3) \leftarrow \text{Share}(\mathbf{x}; \mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3)$;
3. Let $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3$ be vectors with $N + 1$ entries;
 - Initialize $\mathbf{w}_i[0] = \mathbf{x}_i$ for all $i \in \{1, 2, 3\}$;
 - For $j = 1, \dots, N$, compute:
 - For $i = 1, 2, 3$, compute
$$\mathbf{w}_i[j] = \phi_i^{(j)}((\mathbf{w}_m[0..j-1], \mathbf{k}_m)_{m \in \{i, i+1\}})$$
4. Compute $\mathbf{y}_i = \text{Output}_i(\mathbf{w}_i, \mathbf{k}_i)$ for $i \in \{1, 2, 3\}$;
5. Compute $\mathbf{y} = \text{Rec}(\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3)$;

Output: $\mathbf{y} \in Y$

Figure 4: Given a correct decomposition \mathcal{D} , the protocol Π_ϕ^* can be used to evaluate the function ϕ .

⁷This can be avoided for SIMD computations [10].

4.1 $(2, 3)$ -Function Decomposition

Given an arbitrary function $\phi : X \rightarrow Y$ and an input value $\mathbf{x} \in X$ we want to compute the value $\phi(\mathbf{x})$ splitting the computation in 3 branches such that the values computed in 2 branches reveals no information about the input \mathbf{x} . In order to achieve this, we start by “splitting” the value \mathbf{x} in three values $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3$ (called *input shares*) using a surjective function that we indicate with *Share*. These input shares as well as all the intermediate values are stored in 3 string $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3$ called the *views*. More precisely, \mathbf{w}_i contains the values computed in the computation branch i . In order to achieve the goal and compute the value $\mathbf{y} = \phi(\mathbf{x})$, we use a finite family of efficiently computable functions that we indicate with $\mathcal{F} = \bigcup_{j=1}^N \{\phi_1^{(j)}, \phi_2^{(j)}, \phi_3^{(j)}\}$. The function $\phi_m^{(j)}$ takes as inputs specific values from the views $\mathbf{w}_m, \mathbf{w}_{m+1}$ with $m = \{1, 2, 3\}$ and where $3 + 1 = 1$. The functions are used in the following way: we use functions $\phi_1^{(j)}, \phi_2^{(j)}, \phi_3^{(j)}$ to compute the next value to be stored in each view \mathbf{w}_m : The function $\phi_m^{(1)}$ takes as input $\mathbf{w}_m, \mathbf{w}_{m+1}$ (which at this point contain only the shares $\mathbf{x}_m, \mathbf{x}_{m+1}$) and outputs one value which is saved in position 1 of the views \mathbf{w}_m . We continue like this for all N functions, with the difference that in step $j > 1$, the function $\phi_m^{(j)}$ can receive as input (any subset of) the current views $\mathbf{w}_m, \mathbf{w}_{m+1}$. The initial function *Share* and all subfunctions $\phi_m^{(j)}$ are allowed to be randomized, and they get their coins from $\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3$, three random tapes which correspond to the three branches. Finally, after the N steps described, the 3 functions $\text{Output}_1, \text{Output}_2, \text{Output}_3$ are used to compute the values $\mathbf{y}_i = \text{Output}_i(\mathbf{w}_i)$ that we call *output shares*. From these three values we compute the final output $\mathbf{y} = \phi(\mathbf{x})$ using the function *Rec*. The entire procedure is described in detail in Figure 4 (Protocol Π_ϕ^*).

Definition 4.1. A $(2, 3)$ -decomposition for the function ϕ is the set of functions

$$\mathcal{D} = \{\text{Share}, \text{Output}_1, \text{Output}_2, \text{Output}_3, \text{Rec}\} \cup \mathcal{F}$$

such that *Share* is a surjective function and $\phi_m^{(j)}$, Output_i and *Rec* are functions as described before. Let Π_ϕ^* be the algorithm described in Figure 4, we have the following definitions.

- (**Correctness**) We say that \mathcal{D} is correct if $\Pr[\phi(\mathbf{x}) = \Pi_\phi^*(\mathbf{x})] = 1$ for all $\mathbf{x} \in X$. The probability is over the choice of the random tapes \mathbf{k}_i .
- (**Privacy**) We say that \mathcal{D} has 2-privacy if it is correct and for all $e \in [3]$ there exists a PPT simulator S_e such that

$$(\{\mathbf{k}_i, \mathbf{w}_i\}_{i \in \{e, e+1\}}, \mathbf{y}_{e+2}) \text{ and } S_e(\phi, \mathbf{y})$$

have the same probability distribution for all $\mathbf{x} \in X$.

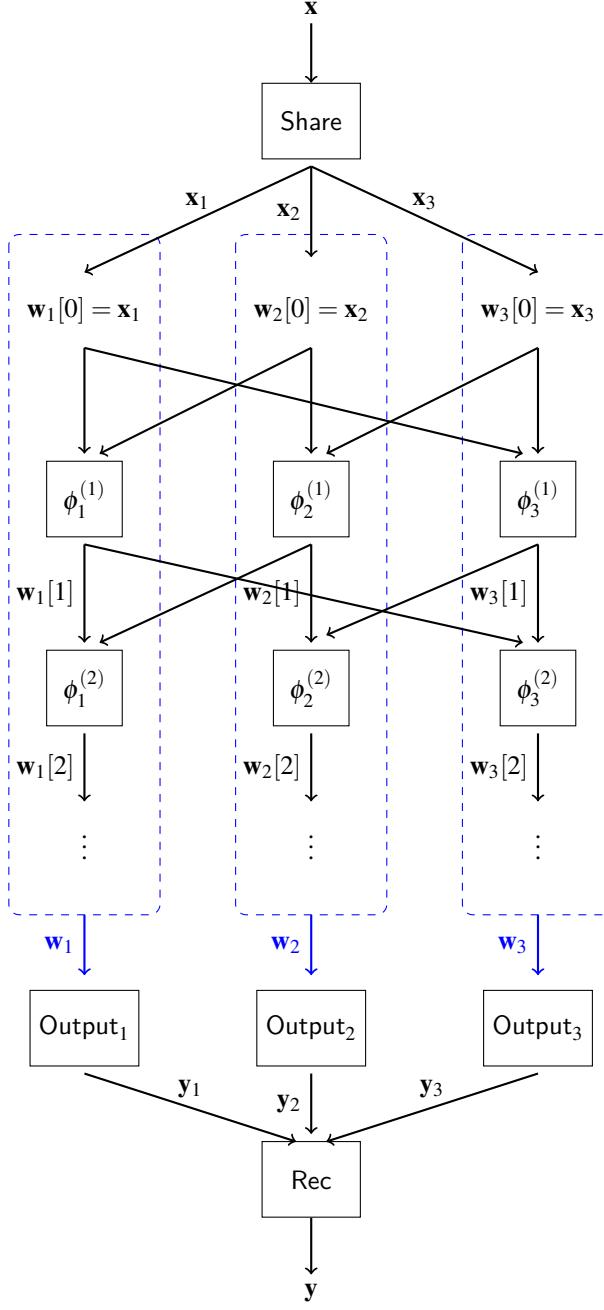

Figure 5: Pictorial representation of a (2,3)-decomposition of the computation $\mathbf{y} = \phi(\mathbf{x})$ showing the three branches.

4.1.1 The Linear Decomposition

We present here an explicit example of a convenient (2,3)-decomposition. Let \mathbb{Z} be an arbitrary finite ring such that $\phi : \mathbb{Z}^k \rightarrow \mathbb{Z}^\ell$ can be expressed by an arithmetic circuit over the ring using addition by constant, multiplication by constant, binary addition and binary multipli-

cation gates⁸. The total number of gates in the circuit is N , the gates are labelled with indices in $[N]$. The *linear* (2,3)-decomposition of ϕ is defined as follows:

- Share $^{\mathbb{Z}}(\mathbf{x}; \mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3)$ samples random $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3$ such that $\mathbf{x} = \mathbf{x}_1 + \mathbf{x}_2 + \mathbf{x}_3$;
- The family $\mathcal{F}^{\mathbb{Z}} = \bigcup_{c=1}^N \{\phi_1^{(c)}, \phi_2^{(c)}, \phi_3^{(c)}\}$ is defined in the following way. Assume that the c -th gate has input wires coming from the gate number a and the gate number b (or only gate number a in the case of a unary gate), then the function $\phi_i^{(c)}$ is defined as follows: If the c -th gate is a ($\forall \alpha \in \mathbb{Z}$)
 - unary “add α ” gate, then $\forall i \in [3]$:
$$\mathbf{w}_i[c] = \phi_i^{(c)}(\mathbf{w}_i[a]) = \begin{cases} \mathbf{w}_i[a] + \alpha & \text{if } i = 1 \\ \mathbf{w}_i[a] & \text{else} \end{cases}$$
- unary “mult. α ” gate, then $\forall i \in [3]$:
$$\mathbf{w}_i[c] = \phi_i^{(c)}(\mathbf{w}_i[a]) = \alpha \cdot \mathbf{w}_i[a]$$
- binary addition gate, then $\forall i \in [3]$:
$$\mathbf{w}_i[c] = \phi_i^{(c)}(\mathbf{w}_i[a], \mathbf{w}_i[b]) = (\mathbf{w}_i[a] + \mathbf{w}_i[b])$$
- binary multiplication gate, then $\forall i \in [3]$:
$$\begin{aligned} \mathbf{w}_i[c] &= \phi_i^{(c)}(\mathbf{w}_i[a, b], \mathbf{w}_{i+1}[a, b]) \\ &= \mathbf{w}_i[a] \cdot \mathbf{w}_i[b] + \mathbf{w}_{i+1}[a] \cdot \mathbf{w}_i[b] \\ &\quad + \mathbf{w}_i[a] \cdot \mathbf{w}_{i+1}[b] + R_i(c) - R_{i+1}(c) \end{aligned}$$

where $R_i(c)$ is a uniformly random function sampled using \mathbf{k}_i .

- For all $i \in [3]$, Output $^{\mathbb{Z}}_i(\mathbf{w}_i, \mathbf{k}_i)$ simply selects all the shares of the output wires of the circuit;
- Finally, Rec $^{\mathbb{Z}}(\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3)$ outputs $\mathbf{y} = \mathbf{y}_1 + \mathbf{y}_2 + \mathbf{y}_3$

Proposition 4.1. *The decomposition $\mathcal{D}^{\mathbb{Z}} = \{\text{Share}^{\mathbb{Z}}, \text{Rec}^{\mathbb{Z}}, \text{Output}_1^{\mathbb{Z}}, \text{Output}_2^{\mathbb{Z}}, \text{Output}_3^{\mathbb{Z}}\} \cup \mathcal{F}^{\mathbb{Z}}$ defined above is a (2,3)-decomposition. Moreover, the length of each view in $\mathcal{D}^{\mathbb{Z}}$ is $(k+N+\ell) \log |\mathbb{Z}| + \kappa$ bits.*

Correctness of the decomposition follows from inspection. Privacy can be shown by constructing an appropriate simulator as shown in Appendix A

In the linear decomposition just presented, the parameter N is equal to the total number of gates (unary and binary) in the circuit computing ϕ . It is easy to slightly modify the definition of the functions $\phi_i^{(c)}$ in $\mathcal{D}^{\mathbb{Z}}$ in such

⁸Note that Boolean circuits are a special case of this, with the XOR, AND and NOT gate.

a way that N results equal to the number of multiplication gates only. In particular, note that the evaluation of *addition gates* (both unary and binary) only requires computation on values from the same branch, thus they can be embedded in a generalized multiplication gates which take as input arbitrary subsets of wires A, B , contains constants α, β, γ and computes the value:

$$\mathbf{w}[c] = \left(\sum_{a \in A} \alpha[a] \mathbf{w}[a] \right) \cdot \left(\sum_{b \in B} \beta[b] \mathbf{w}[b] \right) + \gamma$$

4.2 ZKBoo Protocol

Following the idea of [19], we turn a $(2,3)$ -decomposition of a function ϕ into a zero-knowledge protocol for statements of the form “I know \mathbf{x} such that $\phi(\mathbf{x}) = \mathbf{y}$ ”. We indicate with L_ϕ the language $\{\mathbf{y} \mid \exists \mathbf{x} \text{ s.t. } \phi(\mathbf{x}) = \mathbf{y}\}$.

Assume that a $(2,3)$ -decomposition of the function ϕ is known (see Section 4.1). The structure of the resulting protocol (Figure 6) is very similar to the structure of the IKOS protocol. If $\mathbf{y} \in L_\phi$ is the public input of the proof, then the prover P uses his private input \mathbf{x} (with $\phi(\mathbf{x}) = \mathbf{y}$) to run “in his head” the protocol Π_ϕ^* . After the emulation of the protocol, P commits to each of the 3 produced views $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3$. Now the verifier challenges the prover to open 2 of the commitments. Finally, the verifier accepts if the opened views are consistent with the decomposition used and with output \mathbf{y} .

Proposition 4.2. *The ZKBoo protocol (Figure 6) is a Σ -protocol for the relation R_ϕ with 3-special soundness.*

Proof. Clearly, the ZKBoo protocol has the right communication pattern and it is complete given that the decomposition \mathcal{D} is correct. Moreover, the protocol satisfies the 3-special soundness property: consider 3 accepting conversations $(\mathbf{a}, i, \mathbf{z}_i)$, $i \in [3]$: first note that thanks to the binding property of the commitment, the view \mathbf{w}_1 contained in \mathbf{z}_1 and the one contained in \mathbf{z}_3 are identical, and the same holds for the other views $\mathbf{w}_2, \mathbf{w}_3$ and random tapes $\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3$. Then, we can traverse the decomposition of ϕ backwards from the output to the input shares: since the three conversations are accepting, we have that $\text{Rec}(\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3) = \mathbf{y}$, that $\mathbf{y}_i = \text{Output}_i(\mathbf{w}_i) \forall i$, and finally that every entry in all of \mathbf{w}_i was computed correctly. Therefore, since the Share function is surjective, we can compute $\mathbf{x}' = \text{Share}^{-1}(\mathbf{w}_1[0], \mathbf{w}_2[0], \mathbf{w}_3[0])$. Thanks to the correctness of the decomposition we thus have that $\phi(\mathbf{x}') = \mathbf{y}$, which is what we wanted to prove. Note that the protocol does not satisfy 2-special soundness, even if two accepting conversation actually contain all three views: in this case, since one of the branches of

ZKBoo Protocol

The verifier and the prover have input $\mathbf{y} \in L_\phi$. The prover knows \mathbf{x} such that $\mathbf{y} = \phi(\mathbf{x})$. A $(2,3)$ -decomposition of ϕ is given. Let Π_ϕ^* be the protocol related to this decomposition.

Commit: The prover does the following:

1. Sample random tapes $\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3$;
2. Run $\Pi_\phi^*(\mathbf{x})$ and obtain the views $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3$ and the output shares $\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3$;
3. Commit to $\mathbf{c}_i = \text{Com}(\mathbf{k}_i, \mathbf{w}_i)$ for all $i \in [3]$;
4. Send $\mathbf{a} = (\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3, \mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3)$.

Prove: The verifier choose an index $e \in [3]$ and sends it to the prover. The prover answers to the verifier’s challenge sending opening $\mathbf{c}_e, \mathbf{c}_{e+1}$ thus revealing $\mathbf{z} = (\mathbf{k}_e, \mathbf{w}_e, \mathbf{k}_{e+1}, \mathbf{w}_{e+1})$.

Verify: The verifier runs the following checks:

1. If $\text{Rec}(\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3) \neq \mathbf{y}$, output reject;
2. If $\exists i \in \{e, e+1\}$ s.t. $\mathbf{y}_i \neq \text{Output}_i(\mathbf{w}_i)$, output reject;
3. If $\exists j$ such that

$$\mathbf{w}_e[j] \neq \phi_e^{(j)}(\mathbf{w}_e, \mathbf{w}_{e+1}, \mathbf{k}_e, \mathbf{k}_{e+1})$$

output reject;
4. Output accept;

Figure 6: ZKBoo protocol for the language L_ϕ in the commitment-hybrid model.

the computation has not been checked, $\exists i$ s.t. \mathbf{w}_i might not be equal to $\phi_i^{(j)}(\mathbf{w}_i, \mathbf{w}_{i+1}, \mathbf{k}_i, \mathbf{k}_{i+1})$.

To prove the special honest-verifier ZK property, we consider the simulator S defined by the following steps. The input are $\mathbf{y} \in L_\phi$ and $e \in [3]$: run the 2-privacy simulator (which is guaranteed to exist thanks to the 2-privacy property of the decomposition \mathcal{D} as in Definition 4.1), which returns $(\{\mathbf{k}_i, \mathbf{w}_i\}_{i \in \{e, e+1\}}, \mathbf{y}_{e+2})$, sets $\mathbf{w}_{e+2} = 0^{|\mathbf{w}|}, \mathbf{k}_{e+2} = 0^{|\mathbf{k}|}$ and then constructs \mathbf{a} by committing to the three views and tapes. \square

Efficiency. Let $\phi : \mathbb{Z}^k \rightarrow \mathbb{Z}^\ell$ be a function that can be expressed by a circuit over the finite ring \mathbb{Z} with N mul-

tiplication gates. If we repeat $\sigma(\log_2 3 - 1)^{-1}$ copies of the ZKBoo protocol instantiated with the linear decomposition described in Section 4.1.1, and where we generate the random tapes pseudo-randomly with security parameter κ , we get a Σ -protocol with soundness $2^{-\sigma}$ and bit-size

$$\sigma(\log_2 3 - 1)^{-1} \cdot 2 \cdot [\log_2(|\mathbb{Z}|)(k + N + \ell) + \kappa]$$

5 Zero-Knowledge for SHA-1/SHA-256

In this section we describe our case study, in which we implemented the protocol described in Section 4 for proving knowledge of preimages of SHA-1 and SHA-256. We start describing the choices we made in our implementation, describe the result of our empirical validation and finally compare with state-of-the-art protocols for the same task. Our implementation is available at <https://github.com/Sobuno/ZKBoo>.

5.1 Circuits For SHA-1/SHA-256

The linear-decomposition protocol described in Section 4 can be used with arithmetic circuits over arbitrary rings. Our first choice is picking a ring in which to express the computation of SHA-1/SHA-256. The two functions are quite similar, and they both use vectors of 32 bits for internal representation of values. Three kind of operations are performed over these bit-vectors: bitwise XORs, bitwise ANDs, and additions modulo 2^{32} . Implementing the two algorithms (after some simple optimization to reduce the number of bitwise ANDs) requires the following number of operations⁹:

	AND	XOR	ADD
SHA-1	40	372	325
SHA-256	192	704	600

Hence, the two natural choices for the ring are \mathbb{Z}_2 (where XOR gates are for free but AND/ADD require 32 multiplication gates) and $\mathbb{Z}_{2^{32}}$ (where ADD is free but bitwise operations require a linear number of multiplication gates). Since the number of XORs dominates in both algorithms, we opted for an implementation over the ring \mathbb{Z}_2 .

5.2 Implementation of Building Blocks

We wrote our software in C, using the OpenSSL¹⁰ library. We instantiated the building blocks in our protocol in the following way:

⁹Note that the AND complexity of our circuits is approximately 1/3 of the “standard MPC circuit” from <https://www.cs.bris.ac.uk/~Research/CryptographySecurity/MPC/>.

¹⁰<https://www.openssl.org>

RNG: We generate the random tapes pseudorandomly using AES in counter mode, where the keys are generated via the OpenSSL secure random number generator. In the linear decomposition of multiplication gates, we use a random function $R : [N] \rightarrow \mathbb{Z}_2$. We implement this function by picking a bit from the stream generated using AES. In particular, we compute

$$R(i) = \text{AES}(K, [i/128])[i \bmod 128]$$

which means that 3 calls to AES are sufficient to evaluate 128 individual AND gates. Note that since N (the number of AND gates) is known in advance, we can precompute all calls to AES at the beginning of the protocol. These two optimizations, together with the native support for AES in modern processors, proved very effective towards decreasing running times.

Commitments: In the first step of the protocol the prover commits to the three views $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3$. Those commitments have been implemented using SHA-256 as the commitment function i.e., $\text{Com}(x, r) = \text{SHA-256}(x, r)$. Under the (mild) assumptions that SHA-256 is collision resistant and that $\text{SHA-256}(\cdot, r)$ is a PRF (with key r) the commitments are binding and hiding.

The Fiat-Shamir Oracle. To make the proofs non-interactive, we need a random oracle $H : \{0, 1\}^* \rightarrow \{1, 2, 3\}^r$ where r is the number of repetitions of our basic protocol. We instantiate this using SHA-256 as a random oracle and by performing rejection sampling. In particular, we compute the first output coordinate of $H(x)$ by looking at the first two output bits of $\text{SHA-256}(0, x)$ and mapping $(a, b) \rightarrow 2a + b + 1$. In case that $(a, b) = (1, 1)$ we look at the third-fourth bit instead and repeat. If there are no more bits left in the output of the hash function, we evaluate $\text{SHA-256}(1, x)$ and so on. In our experiments the maximum number of repetition is $r \in \{69, 137\}$, thus we call the hash function once or twice (on expectation).

5.3 Experimental Setup

We report on the results of the implementation of SHA-1 and SHA-256 for 69 and 137 repetitions each. Those correspond to soundness errors 2^{-40} and 2^{-80} . While the security level 2^{-40} is not sufficient for the case of non-interactive zero-knowledge, it offers reasonable security guarantees in the interactive case – note however that in this case our timings are only indicative of the local computation as they do not account for the necessary network communication.

Our experiments were run on a machine with an AMD FX-8350 CPU, running 8 cores at 4.00 GHz. The programs were run under Windows 10 Pro version 1511 (OS Build 10586.14) on a Seagate Barracuda 7200 RPM SATA 3.0 Gb/s hard drive with 16MB cache. Note that

computing and verifying our proofs is an embarrassingly parallel task, thus it was possible to effortlessly take advantage of our multi-core architecture using OpenMP¹¹, an API useful for making a C program multi-threaded. We note that we have only done this for the main loop of the program, which iterates over the individual repetitions of the proofs (which are clearly independent from each other), thus it is likely that there is room for further parallelisation. Timings were done using C native `clock()` function and are measured in milliseconds.

5.4 Experimental Results

Breakdown. In Table 1 we report on the timings we obtained for both SHA-1 and SHA-256, with 69 and 137 rounds, both enabling and disabling parallelisation. In this table we also present a breakdown of the running time. In particular we measure the following phases for the prover:

- *Commit*: This is the time to run the **Commit** procedure (Figure 6) to produce **a**. It is further divided into the following sub-timings: (*Rand. gen.*) Generation of all needed randomness using OpenSSL RNG as well as preprocessing of the PRF; (*Algorithm exec.*) Time taken to run the algorithm Π_ϕ^* . This is the total time for all 69/137 rounds; (*Commitment*) Generating commitments of the views;
- *Gen. challenge*: Using the random oracle to generate the challenge vector as $\mathbf{e} = H(\mathbf{y}, \mathbf{a})$;
- *Prove*: Building the vector **z**;
- *Output to disk*: Writing $(\mathbf{a}, \mathbf{e}, \mathbf{z})$ to disk;¹²

For the verifier:

- *Input from disk*: Reading the proof from file;
- *Gen. challenge*: Regenerate the challenge vector using the random oracle;
- *Verify*: The time to run all the rounds of the **Verify** procedure;

Finally, with *proof size* we indicate the size of the string $\pi = (\mathbf{y}, \mathbf{a}, \mathbf{z})$ on disk in KB.

Parallelisation. Figure 7 and 8 show how the running time of the prover (resp. verifier) changes when we change the number of rounds (from 1 to 137) and the number of threads (from 1 to 8). We include the graphs for SHA-256 only. It is easy to see that the running time

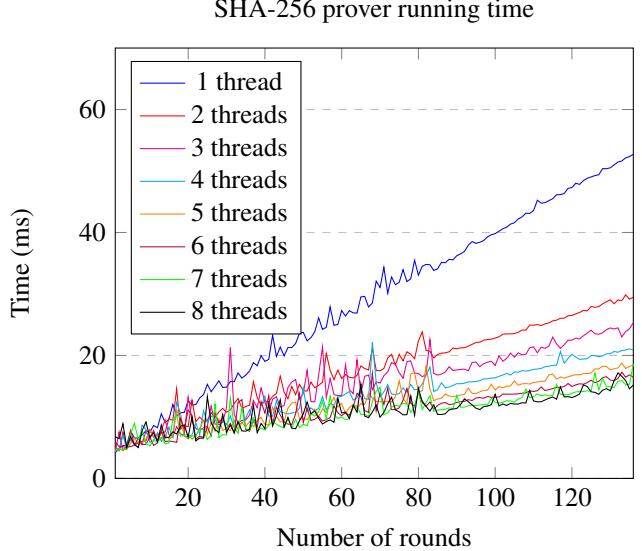

Figure 7: Relation between the total running time and the number of rounds for the SHA-256 prover, average over 100 runs.

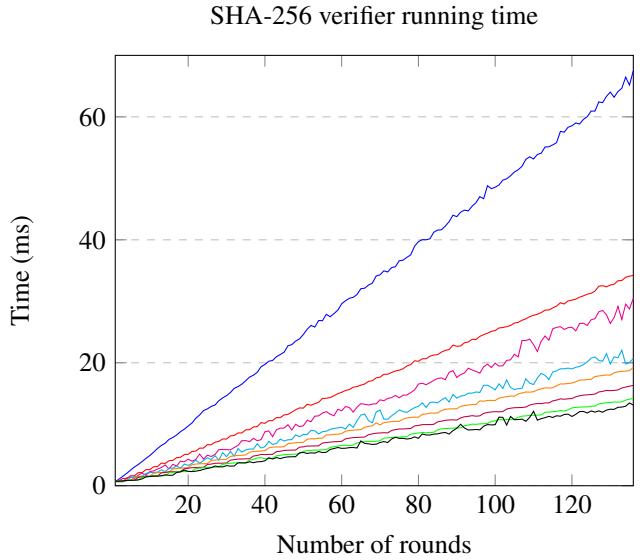

Figure 8: Relation between the total running time and the number of rounds for the SHA-256 verifier, average over 100 runs.

increases linearly with the number of rounds, and that the improvement due to multithreading is significant. The graph indicates that there is some fluctuation in the algorithm's run time for all number of threads when using up to about 85 rounds, which is mostly due to the

¹¹<http://openmp.org>

¹²We observed that the timings of writing to disk are very noisy, and not always monotone in the size of the written file.

noise introduced by disk operations¹³. We note that the runtime of the verifier benefits more from parallelisation. This is consistent with Amdahl’s law since, as shown in Table 1, the prover spends significantly more time performing tasks which do not benefit from parallelisation (e.g., writing to disk).

5.5 Comparison

Here we compare the performances of ZKBoo with some of the state-of-the-art protocol for the same task. In particular, we compare the performances of proving/verifying knowledge of SHA-1 preimages across ZKBoo, Pinocchio [23] and ZKGC [21].

Pinocchio [23] is an implementation of SNARKs for verifiable outsourcing of computation. While not its main purpose, it can generate zero-knowledge proofs at a negligible extra cost over sound-only proofs. The choice of benchmarking SHA-1 only (and not SHA-256) is due to the fact that the Pinocchio library only contains SHA-1. The runtime reported for Pinocchio are obtained on the same machine as our implementation. The results shows that ZKBoo is faster at both proving and verifying, with an incredible 10^3 factor for the prover. Note

¹³See the full version [14] for graphs showing the running times without disk operations.

here that if the underlying circuit had been larger, the proof size and the verification time of Pinocchio would not change, while its preprocessing and proving time would grow accordingly. We note also that Pinocchio has a large preprocessing time where some prover/verifier key are generated. Those keys are circuit dependent, and for SHA-1 the prover key is 6.5 MB and the verifier key is 1.1 MB. To Pinocchio’s defence, it must be noted that 1) Pinocchio is a general purpose system that can generate proofs for any circuit (provided as an input file) while our implementation contains the SHA circuit hard-coded; 2) according to [23], Pinocchio has not been parallelised; and 3) Pinocchio uses a SHA-1 circuit which is approximately 3 times larger than ours. While it is conceivable that Pinocchio could be made faster using some of the optimizations introduced here, we do not believe that Pinocchio could ever reach proving times similar to ZKBoo, due to the use of heavy public-key technology (exponentiations in a pairing-friendly group) for each gate in the circuit.

ZKGC [21]. For the case of ZKGC, we could not directly compare implementations, since the source code for [21] is not publicly available. In addition, since the publication of [21], several significant improvements have been proposed but have not been implemented yet. Therefore, in Table 2, we give an accurate estimate of

the size of the proofs generated using ZKGC but only a lower-bound for its runtime. The estimates are computed using the following tools: (*GC*) we estimate the proof size using the communication complexity of the most efficient (in terms of communication complexity) garbled circuits, namely *privacy-free garbled circuits* [13, 27] that can be instantiated with as little as one ciphertext (128 bits using AES) per AND gate in the circuit; (*OT*) we plug the size and runtime given by the most efficient OT available [6]. Since the input size of SHA-1 is quite large (512 bits), it might be that using OT extension would prove useful. Therefore, to make the comparison even more favourable towards ZKGC, we only count the runtime of 190 base OTs necessary for active secure OT extensions [1] and we do not account at all for the runtime of the OT extension protocol nor the generation/verification of the GC. The resulting estimates show that even when *counting the base OTs alone*, the runtime of ZKGC is already larger than the runtime of ZK-Boo for the SHA-1 circuit. As for proof size, we note that ZKGC produces shorter proofs. However, the approach of ZKGC cannot be made non-interactive which is a qualitative drawback and it is likely to introduce significant slow-downs due to network latency.

6 Conclusions

In this paper we described ZKBoo, the first attempt to make general purpose zero-knowledge practical using the “MPC-in-the-head” approach of Ishai et al. [19]. We discussed how to generalize their protocol using the idea of $(2, 3)$ -function decompositions, we showed simple linear decompositions for arithmetic circuits over any ring and we leave it as a future work to find compact decompositions for other interesting functions.

Our experimental results show that for practically relevant circuits (such as SHA-1), our protocol is the fastest in terms of proving time, and where the verification time is comparable even with SNARKs technology.

A Appendix

Proof of Proposition 4.1

Proof. In order to prove that the decomposition $\mathcal{D}^{\mathbb{Z}}$ is correct is enough to prove that for any $c \in [N]$ the following holds.

(1) if the c -th gate is an “add α ” gate, then:

$$\sum_{i=1}^3 \mathbf{w}_i[c] = \left(\sum_{i=1}^3 \mathbf{w}_i[a] \right) + \alpha$$

(2) if the c -th gate is an “mult. α ” gate, then:

$$\sum_{i=1}^3 \mathbf{w}_i[c] = \left(\sum_{i=1}^3 \mathbf{w}_i[a] \right) \cdot \alpha$$

(3) if the c -th gate is an addition gate, then:

$$\sum_{i=1}^3 \mathbf{w}_i[c] = \left(\sum_{i=1}^3 \mathbf{w}_i[a] \right) + \left(\sum_{i=1}^3 \mathbf{w}_i[b] \right)$$

(4) if the c -th gate is a multiplication gate, then:

$$\sum_{i=1}^3 \mathbf{w}_i[c] = \left(\sum_{i=1}^3 \mathbf{w}_i[a] \right) \cdot \left(\sum_{i=1}^3 \mathbf{w}_i[b] \right)$$

Indeed, using (1), (2), (3) and (4) iteratively for all the gates in the circuit we can prove that $\sum_{i=1}^3 \mathbf{w}_i[N] = \phi(\sum_{i=1}^3 \mathbf{x}_i)$ and from this it follows that

$$\begin{aligned} \Pi_{\phi}^*(\mathbf{x}) = \text{Rec}^{\mathbb{Z}}(\mathbf{y}_1, \dots, \mathbf{y}_n) &= \sum_{i=1}^3 \mathbf{y}_i \\ &= \sum_{i=1}^3 \mathbf{w}_i[N] = \phi \left(\sum_{i=1}^3 \mathbf{x}_i \right) = \phi(\mathbf{x}) \end{aligned}$$

The first three follow trivially by the definition of the function $\phi_{A_i}^{(c)}$ when the c -th gate is a an “add α ”, “mult. α ” and addition gate, respectively. Now assume that the c -th gate is a multiplication gate. Then, using the definition for the function $\phi_{A_i}^{(c)}$ for this case and recalling that the index values are computed modulo 3, we have that

$$\begin{aligned} \sum_{i=1}^3 \mathbf{w}_i[c] &= \sum_{i=1}^3 \left(\mathbf{w}_i[a] \cdot \mathbf{w}_i[b] + \mathbf{w}_{i+1}[a] \cdot \mathbf{w}_i[b] + \mathbf{w}_i[a] \cdot \mathbf{w}_{i+1}[b] \right. \\ &\quad \left. + R_i(c) - R_{i+1}(c) \right) \\ &= \sum_{i=1}^3 \mathbf{w}_i[a] \cdot (\mathbf{w}_i[b] + \mathbf{w}_{i+1}[b]) + \sum_{i=1}^3 \mathbf{w}_i[a] \cdot \mathbf{w}_{i+2}[b] + \\ &\quad + \sum_{i=1}^3 R_i(c) - \sum_{i=1}^3 R_{i+1}(c) \\ &= \left(\sum_{i=1}^3 \mathbf{w}_i[a] \right) \cdot \left(\sum_{i=1}^3 \mathbf{w}_i[b] \right) \end{aligned}$$

We now pass to prove the 2-privacy property. Given $e \in [3]$, we define the simulator S_e on input \mathbf{y} with the following instructions:

1. Sample random tapes $\mathbf{k}'_e, \mathbf{k}'_{e+1}$;
2. Sample uniformly at random the values $\mathbf{w}'_e[0]$ and $\mathbf{w}'_{e+1}[0]$. Then, for all $c \in [N]$: If the c -th gate is an “add α ”, “mult. α ” or addition gate then define $\mathbf{w}'_e[c]$ and $\mathbf{w}'_{e+1}[c]$ using the functions $\phi_e^{(c)}$ and $\phi_{e+1}^{(c)}$, respectively. If the c -th gate is a multiplication gate then sample uniformly at random the value $\mathbf{w}'_{e+1}[c]$ and compute the value $\mathbf{w}'_e[c]$ using $\phi_e^{(c)}$; In this way define the entire views \mathbf{w}'_e and \mathbf{w}'_{e+1} ;
3. Compute $\mathbf{y}'_e = \text{Output}_e(\mathbf{w}'_e)$ and $\mathbf{y}'_{e+1} = \text{Output}_{e+1}(\mathbf{w}'_{e+1})$;
4. Compute $\mathbf{y}'_{e+2} = \mathbf{y} - (\mathbf{y}'_e + \mathbf{y}'_{e+1})$;
5. Output $(\{\mathbf{k}'_i, \mathbf{w}'_i\}_{i \in \{e, e+1\}}, \mathbf{y}'_{e+2})$

It is easy to verify that the output of the simulator S_e has the same distribution of the string $(\{\mathbf{k}_i, \mathbf{w}_i\}_{i \in \{e, e+1\}}, \mathbf{y}_{e+2})$ produced by the protocol Π_ϕ^* . Indeed, all the elements in the output of S_e are computed using the same commands used in Π_ϕ^* , except for the element $\mathbf{w}'_{e+1}[c]$ when the c -th gate is a multiplication gate. In this case $\mathbf{w}'_{e+1}[c]$ is sample uniformly at random, while $\mathbf{w}_{e+1}[c]$ in the protocol is computed using the function $\phi_{e+1}^{(c)}$. In particular, $\mathbf{w}_{e+1}[c]$ is computed by subtracting to determined value the element $R_{i+2}(c)$. Since R_{i+2} is an uniformly random function sampled using an independent tape \mathbf{k}_{e+2} , the distribution of $\mathbf{w}_{e+1}[c]$ in the protocol is the uniform one, that is it has the same distribution of $\mathbf{w}'_{e+1}[c]$ in the output of S_e . Therefore, we can conclude that S_e is a correct simulator for the decomposition $\mathcal{D}^\mathbb{Z}$.

Finally, by inspection we have that $|\mathbf{w}_i| = (k + N + \ell) \log |\mathbb{Z}| + \kappa$ for all $i \in [3]$. \square

The Cut-and-Choose Game and its Application to Cryptographic Protocols

Abstract

The *cut-and-choose* technique plays a fundamental role in cryptographic-protocol design, especially for secure two-party computation in the malicious model. The basic idea is that one party constructs n versions of a message in a protocol (e.g., garbled circuits); the other party randomly *checks* some of them and *uses* the rest of them in the protocol. Most existing uses of cut-and-choose fix *in advance* the number of objects to be checked and in optimizing this parameter they fail to recognize the fact that checking and evaluating may have dramatically different costs.

In this paper, we consider a refined cost model and formalize the cut-and-choose parameter selection problem as a constrained optimization problem. We analyze “cut-and-choose games” and show equilibrium strategies for the parties in these games. We then show how our methodology can be applied to improve the efficiency of three representative categories of secure-computation protocols based on cut-and-choose. We show improvements of up to an-order-of-magnitude in terms of bandwidth, and 12–106% in terms of total time. Source code of our game solvers is available to download at <https://github.com/cut-n-choose>.

1 Introduction

Most efficient implementations for secure two-party computation in the semi-honest setting rely on *garbled circuits*. One party, acting as circuit generator, prepares a garbled circuit for the function of interest and sends it to the other party along with garbled values corresponding to its input. The second party, who will serve as the circuit evaluator, obtains garbled values for its own inputs using oblivious transfer, and then evaluates the garbled circuit to obtain the result.

The primary challenge in handling *malicious* adversaries is to ensure that the garbled circuit sent by the

first party is constructed correctly. The *cut-and-choose paradigm* is a popular and efficient mechanism for doing so. The basic idea is that the circuit generator produces and sends *several* garbled circuits; the circuit evaluator *checks* a random subset of these, and *evaluates* the rest to determine the final result. Since its formal treatment by Lindell and Pinkas [16], numerous works have improved various aspects of the cut-and-choose methodology and used it to design secure protocols [28, 18, 24, 25, 26, 17, 14, 6, 15, 10, 27, 4, 2, 19, 11, 1, 20]. These prior works fall roughly into three categories:

1. **MajorityCut.** Here the circuit evaluator determines its output by taking the majority value among the evaluated garbled circuits. Thus, security holds as long as a majority of the evaluated circuits are correct. This is the classic approach adopted by many papers [16, 28, 18, 17] and implementations [25, 26, 14].
2. **SingleCut.** Here the circuit evaluator is able to obtain the correct output as long as *at least one* of the evaluated circuits are correctly generated. Schemes adopting this approach include [15, 10, 4, 2].
3. **BatchedCut.** This considers a slightly different setting in which the parties repeatedly evaluate some function, and the goal is to obtain good amortized efficiency by batching the cut-and-choose procedure either across multiple instances of secure computation [19, 11], or at the gate level [24, 6].

Although SingleCut is asymptotically better than MajorityCut, some SingleCut protocols [15] require using MajorityCut on a smaller circuit as a sub-routine, and therefore optimizations to MajorityCut can result in efficiency improvements to SingleCut. In addition, MajorityCut works better for applications with long outputs as its cost does not grow with output length.

When setting parameters for cut-and-choose protocols, in order to optimize efficiency for some target level of security, state-of-the-art approaches treat circuit checking roughly as expensive as circuit evaluation, and hence strive to optimize the total number of garbled cir-

cuits involved. Although some researchers [15, 7, 2] observed the asymmetry in the cost of checking and evaluation, they did not explore the cost asymmetry further, and did not investigate the possibility of optimizing cut-and-choose parameters based on this asymmetry.

As evidenced by many recent prototypes [21, 29, 20, 5, 9, 26, 25, 14, 13], network communication has become the most prominent bottleneck of garbled-circuit protocols, especially when exploiting dedicated hardware [3, 8] or parallelism [5, 23, 13] for faster garbling/evaluation. However, the bandwidth costs are markedly different for checking and evaluating circuits: garbled circuits that are evaluated must be transmitted in their entirety, but checking garbled circuits can be done by generating the circuit from a short seed and committing to the circuit using a succinct commitment [7, 14, 2]. Table 1 presents, in the context of a few example applications, the bandwidth costs for sending an entire circuit (i.e. the costs for an evaluated circuit) versus the cost for committing to the circuit (which, for simplicity, requires only one SHA256 hash), and thus a sample ratio r that we use in this paper as a variable.

Based on these observations, we propose a new approach to optimizing parameters in cut-and-choose protocols. Our approach casts the interaction between the circuit generator and circuit evaluator as a game, computes the optimal strategies in this game (which, interestingly, turn out to be mixed strategies), and then sets parameters while explicitly taking into account the relative costs of circuit checking and circuit evaluation. Our optimizations result in cut-and-choose approaches that can be easily integrated into prior protocols, and can reduce the bandwidth in these protocols by an order-of-magnitude in some settings.

1.1 Prior Work

The protocol of Lindell and Pinkas [16] checks exactly half the circuits, an idea followed in many subsequent works [25, 17]. They showed that by generating n circuits and checking a random subset of size $n/2$, a cheating generator succeeds in convincing the evaluator to accept an incorrect output with probability at most $2^{-0.311n}$. Thus, to achieve (statistical) security level 2^{-40} , their protocol requires 128 garbled circuits. Shen and Shelat [26] slightly improved the bound to $2^{-0.32s}$ by opening roughly 60% (instead of one half) of the circuits; this reduces the number of garbled circuits needed to 125 for 2^{-40} security. These protocols belong to the MajorityCut category in our terminology.

The idea of using SingleCut protocols was subsequently introduced [15, 4, 2]. Here, the evaluator chooses whether to check each circuit with independent probability $1/2$; now n circuits suffice to achieve security level 2^{-n} .

Most recently, several works [19, 11, 20] have proposed to amortize the cost of cut-and-choose across multiple evaluations of the same function. Along with the LEGO family of protocols [6, 24] that amortize checks at the gate level (rather than the circuit level), they all fall in the class of BatchedCut protocols. These works show that cut-and-choose can be very efficient in an amortized sense, requiring fewer than 8 circuits per execution to achieve 2^{-40} security when amortizing over 1000 executions. A brief explanation of the BatchedCut idea is given at the beginning of Section 3.3.

1.2 Contributions

We introduce a game-theoretic approach to study cut-and-choose in the context of secure-protocol design. The simplest version of cut-and-choose can be treated as a *zero-sum* game (where the utilities are 0/1 for the loser/winner) between the evaluator and the generator in which the generator wins if it can produce enough incorrect circuits to skew the protocol without being detected. Finding an optimal strategy for the evaluator can be cast as solving a linear-program and results in a randomized strategy for choosing the number of circuits to check. This linear program can be further refined to take into consideration the different cost of checking vs evaluating (i.e., the ratio r). Analyzing the equilibrium of this game leads to a constrained optimization problem that can be used to derive more efficient protocols meeting a targeted security bound (e.g. $\epsilon = 2^{-40}$ as per many published implementations).

Our techniques enable optimization based on the precise relative costs of checking and evaluating, which in turn may depend on the function being computed as well

as characteristics of specific deployment settings, such as software, hardware configuration and network condition, etc. This provides the ability to “tune” protocols to specific applications in a much more fine-grained way than before. We demonstrate that doing so can lead to bandwidth savings of 1.2–10×.

We concretely apply our methodology to three representative types of cut-and-choose-based secure-computation protocols, and show a significant overall improvement in the bandwidth usage. For example, we are able to reduce the network traffic by up to an order-of-magnitude in comparison with the state-of-the-art SingleCut (see Figure 5) and MajorityCut (see Figure 2) protocols, and savings of 20% ~ 80% for state-of-the-art (already highly optimized) BatchedCut protocols (see Figure 8). Our improvements do not require any additional cryptographic assumptions and come with little development overhead.

2 Overview

Notation. Throughout this paper, we implicitly fix the semantic meaning for a few frequently-used variables (unless explicitly noted otherwise) as in Table 2.

Table 2: Frequently-used variables

ϵ	Failure probability of the cut-and-choose game
r	Cost ratio between circuit evaluation and checking
n	Total number of circuit copies ($n = k + e$)
k	Number of circuit copies used for checking
e	Number of circuit copies used for evaluation
b	Number of bad circuit copies generated
T	Total number of circuits used in BatchedCut.
B	Bucket size in BatchedCut.
τ	Evaluator’s detection rate checking a bad gate/circuit

2.1 Problem Abstraction

Let e and k be the numbers of evaluate-circuits and check-circuits, respectively. Let r be the ratio between the costs of evaluating and checking a circuit. In the case when the parameters e, k are set deterministically and public, the cut-and-choose parameter optimization problem can be expressed as the following non-linear programming problem:

$$\arg \min_{e,k} r \cdot e + k$$

subject to

$$\max_b \Pr_a(e, k, b) \leq \epsilon,$$

where ϵ, r are known input constants; $\Pr_a(e, k, b)$ is the probability of a successful attack; and b is the total number of bad circuits generated by the malicious generator.

In the case when at least one of the two parameters (e and k) is randomly picked by the circuit evaluator from some public distributions (but sampled values remain secret to the circuit generator at the time of circuit generation), the optimization problem takes a more general form

$$\arg \min_{S_E} \mathbb{E}[cost(r, S_E)]$$

subject to

$$\mathbb{E}[\Pr_a(S_E, S_G)] \leq \epsilon, \quad \forall S_G$$

where S_E and S_G are the circuit evaluator’s and the circuit generator’s strategies, respectively; $cost$ is the cut-and-choose cost function, and $\mathbb{E}[\cdot]$ denotes the expectation function. Note that the cost function does not need to account for pre-maturely terminated protocol executions (due to detected cheating activity). Our goal is to identify the best S_E for the evaluator. We leave the notion of S_E and S_G abstract for now but will give more concrete representations when analyzing specific protocols in Section 3.

We stress that, in contrast to the common belief used in the state-of-the-art cost analysis of cut-and-choose protocols, the cost of cut-and-choose is usually not best represented by n —the total number of circuits generated, but rather by a cost ratio r between checking and evaluation which depends on many factors such as (1) the kind of cost (e.g., bandwidth or computation); (2) the deployment environment (e.g., network condition, distribution of computation power on the players, buffering, etc.) (3) the specific cryptographic primitives and optimization techniques (e.g., the garbling scheme) used in a protocol. Therefore, the best practice would be always micro-benchmarking the ratio between the per circuit cost of evaluation and checking before running the protocol, and then select the best cut-and-choose strategies accordingly.

2.2 Summary of Our Results

The main thesis of this work is,

Cut-and-choose protocols should be appropriately configured based on the security requirement (ϵ) and the cost ratio (r) benchmarked at run-time. Such practice can bring significant cost savings to many cut-and-choose based cryptographic protocols.

To support our thesis, we have formalized the cut-and-choose-based protocol configuration problem into a constrained optimization problem over a refined cost model.

Our solutions to the constrained optimization problem imply randomized strategies are optimal. We show how to support randomized strategies in the state-of-the-art cut-and-choose-based cryptographic protocols with only small changes. We applied this methodology to analyze three major types of cut-and-choose schemes and the experimental results corroborate our thesis. We have implemented a search tool for each category of schemes to output the optimal parameters. The tool is available at <https://github.com/cut-n-choose>.

3 Case Studies

In this section, we show how our general idea can be applied to three main types of two-party secure computation protocols that are based on the cut-and-choose method to substantially improve their performance. We assume that n is fixed and public, while e will be selected from some distribution and remain hidden to the generator until all circuits are generated and committed.

3.1 MajorityCut Protocols

MajorityCut strategy stems from an intuitive folklore idea: the circuit evaluator randomly selects k (out of a total n circuits) to check for correctness, evaluates the remaining $e = n - k$ circuits, and outputs the *majority* of the e evaluation results. All previous work assumed the use of fixed and public n, e, k parameter values, which grants a malicious generator unnecessary advantages. For example, knowing e , a malicious generator can choose to generate $\lceil e/2 \rceil$ bad circuits to maximize the chance that an honest evaluator outputs a wrong result. Thanks to its simplicity, it is the scheme the most widely adopted by implementations thus far.

In the following, we show how to apply our observations to MajorityCut protocols, which involves delaying the revelation of cut-and-choose parameters and employing a mixed strategy (instead of a pure one) to minimize the total cost of cut-and-choose.

Analysis. We represent the evaluator’s strategy by a vector $\mathbf{x} = (x_0, x_1, \dots, x_n)$ where x_i is the probability that the evaluator evaluates i uniform-randomly chosen circuits and checks the remaining $n - i$. The expected cost of MajorityCut is

$$\sum_{i=0}^n [x_i \cdot (i \cdot r + (n - i))] = n + (r - 1) \sum_{i=0}^n x_i \cdot i$$

If the generator produces b incorrect circuits and the evaluator evaluates i circuits, the probability that the evaluator’s check passes is $\binom{n-b}{n-i} / \binom{n}{n-i}$. After a successful check, the evaluator loses the security game if and only if $2b \geq i$, i.e., there is no majority of correct

evaluation circuits. Hence, when the evaluator uses strategy \mathbf{x} , the expected failure probability of the MajorityCut scheme is

$$\sum_{i \leq 2b} x_i \cdot \binom{n-b}{n-i} / \binom{n}{n-i}$$

Since $i \leq n$ and $\binom{n-b}{n-i} = 0$ for all $i < b$, this sum can be further reduced to $\sum_{i=b}^{\min(n, 2b)} x_i \cdot \binom{n-b}{n-i} / \binom{n}{n-i}$. The security requirement stipulates that for every choice of b by the malicious generator, the resulting cut-and-choose failure probability should be less than ε . In other words, the goal of picking optimal cut-and-choose parameters can be achieved by solving the following linear program:

$$\min_{\mathbf{x}} n + (r - 1) \sum_{i=0}^n x_i \cdot i$$

subject to

$$\begin{aligned} x_i &\geq 0 \\ \sum_{i=0}^n x_i &= 1, \\ \sum_{i=b}^{\min(n, 2b)} x_i \cdot \binom{n-b}{i-b} / \binom{n}{i} &< \varepsilon, \quad \forall b \in \{1, \dots, n\}. \end{aligned}$$

Solving this linear program provides us an equilibrium strategy for every fixed n, ε, r . Using standard LP solvers, such programs can be solved exactly for n that ranges into the thousands (i.e., all practical settings).

With this capability, we can identify, for a given target ε and ratio r , the optimal n (that leads to the least overall cost) by solving the linear programs for all feasible n values. While this leads to the search algorithm described in Figure 1, we note several important observations that speedup the search:

1. We begin our search at $n_0 = \lfloor \varepsilon \rfloor$ and consider $n = n_0, n_0 + 1, \dots$. After solving each LP, we identify a current best cost c^* . Observe that $c^* - (r - 1)$ is an upper-bound of the best n (noted n^*), since any feasible strategy with $n > c^* - (r - 1)$ will cost at least c^* (the evaluator need to evaluate at least one circuit except with at most ε probability). Thus, as our search continues, we update c^* , and terminate the search as soon as all values of n between n_0 and $c^* - (r - 1)$ are examined.
2. When the value of r is beyond moderate (i.e., $r > t_r$ for some constant t_r like 128 with our laptop), searching for the optimal cost becomes time-consuming as it involves solving the above linear programming problem for many relatively large n values (e.g., $n > 500$). In these settings, however, we opt to live with a sub-optimal *pure* strategy, based on the observation that the standard deviation of e is already so small (less

than 0.6 and only keeps decreasing as r grows) that the cost of a sub-optimal pure strategy (i.e. a combination of n and e) approximates the theoretical optimal pretty well (Figure 3b).

3. We note that when $r > t_r$ (step 2), it suffices to search all e less than e_0 (recall (e_0, n_0, c_0) is the starting point of our search, simply derived from the traditional setup with MajorityCut) instead of the infinite range because any strategy with $e = e_0 + 1$ that is more efficient than one with $e = e_0$ has to use at least $r - 1$ fewer check circuits. Since $t_r = 128$, such strategy would have used at least 127 fewer check-circuits, which will contradict with $n_0 = 128$ (assuming $\epsilon = 2^{-40}$).

Results. We have implemented the search algorithm of Figure 1 and run it with a wide range of practically possible r values (see Figure 2). For r values ranging from 5000 to 10^9 , which are typical regarding the cost in network traffic, we can achieve 6 to 16 times savings compared to traditional MajorityCut protocols. Even when r is small, such as $8 \sim 128$ which are representative when considering only the timing cost, our approach brings about 1.45 to 3 times savings. When circuit-level parallelism is exploited like in the work of [14, 13, 5], where r typically ranges from 50 to 500 (see Table 5), we are able to speedup the best existing works by $2.3 \sim 3.9$ times.

Table 3 gives two example optimal strategies for achieving $\epsilon = 2^{-40}$ security when $r = 10$ and $r = 100$, respectively. We observe that the solution mixes fewer pure strategies (which is consistent to the decrease of variance) as r grows. Also note that all pure strategies with even e s are dominated by ones with odd e s. In contrast to current implementations, these strategies suggest that the generator produce a few hundred circuits, but only send roughly 13–21 of them. (Such a scheme is for example quite feasible when using the GPU to produce and commit to garbled circuits.) In comparison, the best protocols that use BatchedCut need to amortize 1000s of protocol executions to achieve security when sending roughly 10 circuits.

In Figure 2, the cross-marked solid curve delineates the optimal cost of mixed strategies (among all strategies with public fixed n), while the dot-marked dashed curve delineates pure-strategy approximation of the optimal mixed strategies (efficiently computed as a result of step 2 of Figure 1 search algorithm). We observe that the pure-strategy approximation actually improves as r get bigger. But when r is relatively small ($100 \geq r \geq 1$), our optimization-based approach can indeed bring about $1\% \sim 11\%$ extra improvement (Figure 2). Last, the curves for two different ϵ values have similar shape but the improvement as a result of our approach is significantly larger for smaller ϵ values.

We also observe from Figure 2 that the performance

Table 3: Example optimal strategies for MajorityCut protocols. ($\epsilon = 2^{-40}$, only non-zero x_i s are listed.)

$r = 10$			$r = 100$		
n	i	x_i as %	n	i	x_i as %

boost seems to be upper-bounded by some value related to ϵ , no matter how big r becomes. This makes some intuitive sense because the cost of our optimized protocols will be upper-bounded by a linear function of r (as the solution comes out of solving the linear programming problem where r constitutes the coefficients of the unknowns). We leave the formal proof of this intuition as an interesting future work.

To examine the characteristic of our solution more closely for $1 \leq r \leq 128$, we have plotted the comparison of overall cost of the optimal strategy with respect to best prior works (Figure 3a), the standard deviation of the overall cost (Figure 3b, recall the optimal strategy is a randomized strategy), and the best n used in every optimal strategy (Figure 3c). Note that the standard deviation of the overall cost is also exactly the standard deviation of e because the randomness in cost all comes from the randomness in selecting e . The fact that the standard deviation quickly drops to less than 0.3 (when $r \geq 100$) and strictly decreases justifies the accuracy of pure strategy approximation for large r .

Changes to Existing Protocols. Our approach to MajorityCut applies to many published cut-and-choose based two-party computation protocols; in particular, it applies directly to those protocols in which the generator first commits to n garbled circuits, and later, after a coin-tossing protocol between generator and evaluator, opens each check circuit by sending either (a) both the 0 and 1 labels for all of its input wires, or (b) the random coins used to construct the circuit. Goyal, Smith and Mohassel [7] were the first to use this technique and the second

Input: ϵ, r .
Output: c^*, n^*, \mathbf{x}^* .

1. If $r \leq t_r$,
 - (a) Initialize $n_0 := \lfloor \log \epsilon \rfloor$ and $c^* := +\infty$.
 - (b) For $n := n_0$ to $c^* - (r-1)(1-\epsilon)$,
 - i. Solve the MajorityCut linear programming problem for (n, ϵ, r) to obtain (c, \mathbf{x}) where c is the minimal cost of $\text{LP}(n, \epsilon, r)$ and \mathbf{x} represents the corresponding strategy to achieve c .
 - ii. If (c, \mathbf{x}) is a feasible solution and $c^* > c$, then $(c^*, \mathbf{x}^*, n^*) := (c, \mathbf{x}, n)$.
 - (c) Output (c, n^*, \mathbf{x}^*) .
2. If $r > t_r$,
 - (a) Initialize $n_0 := 3 \lfloor \log \epsilon \rfloor, e_0 = n_0/2, c_0 := 3 \lfloor \log \epsilon \rfloor + (r-1)e_0$ and $c^* = c_0, n^* = n_0$.
 - (b) For $i := 1$ to $+\infty$ until $e_{i-1} = 1$,
 - i. Set $e_i = e_{i-1} - 1$ and compute the smallest (c_i, n_i) that satisfies the security constraints.
 - ii. If $c^* > c_i$, then $(c^*, n^*, e^*) := (c_i, n_i, e_i)$.
 - (c) Output $(c, n^*, \{x_0, \dots, x_n\})$ where $x_i = 1$ if $i = e^*$, and $x_i = 0$ otherwise.

Figure 1: Search the most efficient strategy (n, \mathbf{x}) for MajorityCut protocols. $\log(\cdot)$ is base-2. c is the minimal cost, n is the fixed total number of circuits and $\mathbf{x} = (x_0, \dots, x_n)$ stands for the evaluator’s best strategy to sample e . While the value of t_r depends on hardware and users’ tolerance of performance. $t_r = 128$ works well on a MacBook Air for $\epsilon = 2^{-40}$.

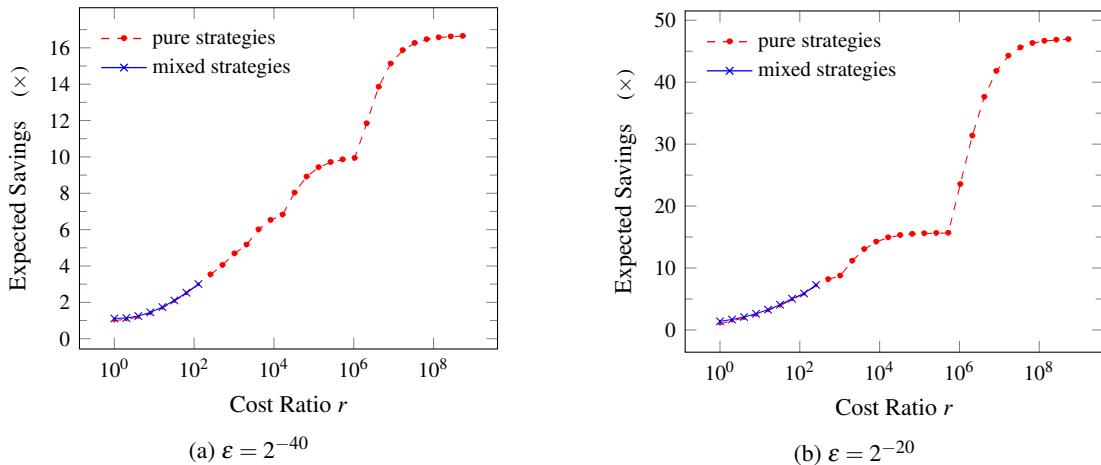

Figure 2: Our savings for MajorityCut protocols

(“ $I + 2C$ ”) protocol from Kreuter, Shelat, Shen [14] also operates in this way. In these cases, no modifications to the security analysis are needed. For every specific ϵ and r , our solver outputs a particular n and a distribution \mathbf{x} for picking e . Roughly speaking, the only changes needed in the protocol are straightforward: the evaluator announces this n beforehand and the result of the coin-tossing protocol ρ is used to sample e according to \mathbf{x} using standard methods (instead of the $1/2$ or $3/5$ fractions as before). The simulation of a malicious evaluator proceeds as in the original security proof with the exception that the simulator first samples e according to \mathbf{x} using random tape ρ and then (as before), uses a simulated coin-tossing to ensure the outcome of the toss induces ρ . (The coin-tossing method is a simple and effective method to prove security; other proofs may also exist.)

Similarly, the first protocol of Lindell and Pinkas [16]

can be modified to adopt this idea: step (3) should send commitments to garbled circuits, modify step (4) to use the random tape from coin-tossing to sample e , modify step (8) so that the garbler sends the entire garbled circuits for the evaluation specimens as well as openings to the commitments so that the evaluator can check consistency.

The idea seems applicable to many protocols which have the property that the set of checked circuits becomes publicly verifiable. For example, Mohassel and Riva [22] use a different idea in their protocol to allow the same output labels to be used across all n copies of the garbled circuit. In their original protocol, the evaluator and generator then use coin-tossing to select the open circuits, but then proceed to evaluate the remaining circuits first, perform some checks, and then the evaluator commits to the output labels. Finally, the generator opens the check

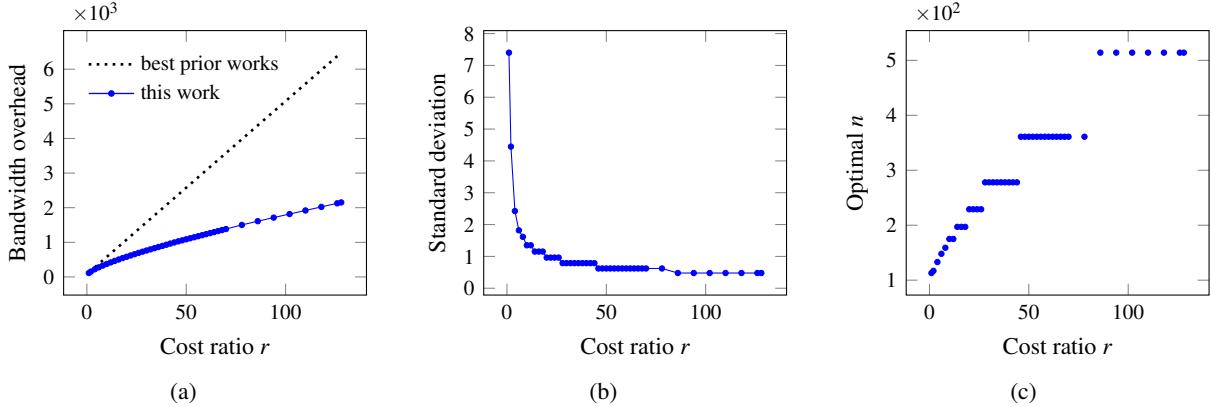

Figure 3: Characteristics of optimal mixed-strategy solutions for MajorityCut protocols ($\varepsilon = 2^{-40}$). The bandwidth overhead is measured in *units*. A unit cost is that of evaluating a evaluation-circuit. The standard deviation chart applies to both the overall cost and e .)

circuits for the evaluator to check, and if all succeed, the evaluator opens a commitment to the output. Although a different order, the modifications noted above seem to apply without the need to modify the security proof.

The protocols of Lindell and Pinkas [17] and shelat and Shen [27], however, seem to require more subtle modifications and new security arguments to use our technique. In both cases, the protocols use a special oblivious transfer (instead of coin-tossing) to allow the evaluator to independently choose the set of check circuits. In the case of [17], the fact that the size of the set of checked circuits is *fixed*, and therefore verifiable by the garbler, is needed in the security proof. This restriction can be lifted with a variant of cut-and-choose oblivious transfer proposed and used in Lindell’s Single-Cut protocol [15]. For a different reason, a new security argument will also be needed for shelat and Shen [27].

3.2 SingleCut Protocols

With SingleCut protocols, extra cryptographic mechanisms (e.g., a second-stage fully secure computation as in [15] or an additive homomorphic commitment as in [2]) are employed in order to *weaken* the requirement for the soundness property. In particular, in such protocols, it suffices to ensure that *at least one evaluation circuit selected by the evaluator is not corrupted*. If one evaluation circuit is properly formed, then the evaluator will either receive the same output from all of the evaluated circuits (in which case it can accept the output since one circuit is good), or it receives two different outputs. In the latter case, the evaluator uses the two different authenticated output labels to recover the garbler’s input, and then evaluate the function itself.

The state-of-the-art SingleCut protocols implicitly assume $r = 1$, in which case an honest evaluator’s best

strategy is to *evaluate each garbled circuit with probability 1/2*, as there is only a single way for the malicious generator to win the cut-and-choose game. In reality, however, r is not necessarily equal to 1. In order to achieve ε statistical security, this strategy will lead to an expected $\lfloor \log \varepsilon \rfloor \cdot (r+1)/2$ units of cost.

Analysis. As before, let i be the number of evaluation circuits and x_i is the probability that the evaluator chooses to evaluate i circuits. An evaluator’s strategy is denoted by $\mathbf{x} = \{x_0, \dots, x_n\}$. Then the cost of the cut-and-choose scheme is $n + (r-1) \sum_{i=0}^n x_i \cdot i$.

Fix b , the number of incorrect circuits chosen by the generator. The first observation is that when the evaluator picks $e \neq b$, then the generator certainly loses the game. When $e = b$, recall that there are $\binom{n}{b}$ different ways to select b evaluation circuits (out of n circuits in total). Assuming the evaluator uniform-randomly picks one of the $\binom{n}{b}$ ways, then the generator looses the cut-and-choose game with probability $1/\binom{n}{b}$ because it happens only if the generator guesses all n of the evaluator’s check-or-evaluate decisions correctly. Since the event that the evaluator picks $e = b$ is independent of the event that the generator guessed all decisions correctly, the overall failure probability is $x_b / \binom{n}{b}$. As a result, the security requirement can be dramatically simplified in comparison to MajorityCut. In particular, we need that every pure strategy for the generator, i.e., every choice of b , wins with probability at most ε : $x_b / \binom{n}{b} < \varepsilon$.

Therefore, fixing n , r and ε , the original cut-and-choose game configuration problem can be translated into the following linear programming problem:

$$\min_{\mathbf{x}} n + (r-1) \sum_{i=0}^n x_i \cdot i$$

Input: ε, r .
Output: c^*, n^*, \mathbf{x}^*

1. Initialize $n_0 := \lfloor \log \varepsilon \rfloor$ and $c^* := n_0 \cdot (r + 1)/2$.
2. For $n := n_0$ to $c^* - (r - 1)(1 - \varepsilon)$,
 - (a) Solve the SingleCut linear programming problem for (n, ε, r) to obtain (c, \mathbf{x}) where c is the minimal cost of LP(n, ε, r) and \mathbf{x} represents the corresponding strategy to achieve c .
 - (b) If $(c, \mathbf{x}) \neq \perp$ and $c^* > c$, then $(c^*, \mathbf{x}^*, n^*) := (c, \mathbf{x}, n)$.
3. Output (c, n^*, \mathbf{x}^*) .

Figure 4: Search the optimal strategy (n, \mathbf{x}) for SingleCut protocols. $\log(\cdot)$ is base-2. c is the minimal cost, n is the fixed total number of circuits and $\mathbf{x} = (x_0, \dots, x_n)$ stands for the evaluator’s best strategy to sample e .

subject to

$$\begin{aligned} x_i &\geq 0, \quad \forall i \in \{0, \dots, n\} \\ \sum_{i=0}^n x_i &= 1, \\ x_b / \binom{n}{b} &< \varepsilon, \quad \forall b \in \{0, \dots, n\}. \end{aligned}$$

Next, we show that the linear programming problem above can actually be solved highly efficiently thanks to its special form. The key observation is that this linear programming problem is in essence a special *continuous knapsack program* (where the weight $w_i = i$). In order to minimize $\sum_{i=0}^n x_i \cdot i$, we aim to maximize x_i (which is upper-bounded by $\varepsilon \cdot \binom{n}{i}$ and collectively constrained by $\sum_{i=0}^n x_i = 1$) for all small i ’s. This leads to the following simple greedy algorithm that solves the problem in linear time (of n).

1. For $i = 0$ to n ,
 - (a) Set $x_i := \varepsilon \cdot \binom{n}{i}$.
 - (b) If $\sum_{j=0}^i x_j \geq 1$ then set $x_i := 1 - \sum_{j=0}^{i-1} x_j$, $x_j := 0$ for all $j > i$, and return $\{x_i | 0 \leq i \leq n\}$.
2. If $\sum_{j=0}^i x_j < 1$, return \perp (i.e., the problem has no feasible solution); otherwise, return $\{x_i | 0 \leq i \leq n\}$.

As with the MajorityCut setting, we scan all possible values of n to identify the best n leading to the smallest overall cost (Figure 4). Fortunately, thanks to this highly efficient special solver, we are always able to identify the best n within seconds for r as large as 10^{10} .

Results. Using the search algorithm described above, we are able to compute the fixed- n , variating e optimal randomized strategies for every ε and r . We summarize the performance gains in Figure 5a. The savings due to our approach rise steadily for $r < 10^4$ and can get to about 10X for reasonably large r (e.g., $r = 7 \times 10^7$, which roughly corresponds to the bandwidth-based cost-ratio for privately computing the edit distance between

two 1000-character strings). Generally, it appears that the improvement-curves (Figure 5) for different ε share some similarity in their shape but smaller ε results in bigger improvements.

Table 4 shows two example optimal strategies of SingleCut protocols for $r = 10$ and $r = 100$, respectively. We observe that the optimal strategy exhibit some pattern: the number of evaluation circuits with positive support falls within $[0, g]$ where $g < n$ and g shrinks as r grows. An interesting note is that $e = 0$ (i.e., checking all n circuits) has positive support, albeit with probability less than 2^{-40} (note the “%” sign), hence preserving security. Instead of artificially preventing $e = 0$ as Lindell did [15], our solution indicates that a rational evaluator should set $e = 0$ with some negligible probability to maximize its chance to win (while keeping the expected cost low).

Table 4: Example optimal strategies for SingleCut protocols. ($\varepsilon = 2^{-40}$, only non-zero x_i ’s are listed)

$r = 10$			$r = 100$		
n	i	x_i as %	n	i	x_i as %
65	0	$9 \cdot 10^{-11}$	180	0	$9 \cdot 10^{-11}$
	1	$5.91 \cdot 10^{-9}$		1	$1.64 \cdot 10^{-8}$
	2	$1.89 \cdot 10^{-7}$		2	$1.47 \cdot 10^{-6}$
	3	$3.97 \cdot 10^{-6}$		3	$8.69 \cdot 10^{-5}$
	4	$6.16 \cdot 10^{-5}$		4	$3.85 \cdot 10^{-3}$
	5	$7.51 \cdot 10^{-4}$		5	0.14
	6	$7.51 \cdot 10^{-3}$		6	3.95
	7	$6.33 \cdot 10^{-2}$		7	95.91
	8	0.46			
	9	2.91			
	10	16.28			
	11	80.28			
			Saves 26.4% b/w		
			Saves 57.0% b/w		

Figure 6 presents a closer look at various characteristics of the optimal strategies, including expected costs (Figure 6a), the standard deviation of the costs (which also applies to e , Figure 6b), and the best ns associated with those optimal strategies (Figure 6c). We note in Figure 6b that the standard deviation for SingleCut optimal strategies are generally smaller (about half) than that for MajorityCut strategies (Figure 3b). In addition, the ns for the optimal strategies also exhibit a staircase effect like in MajorityCut. This is because for any fixed ε , it does not make sense to trade in a larger n for a smaller e ,

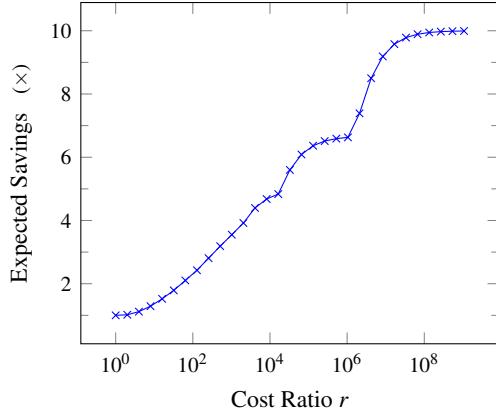

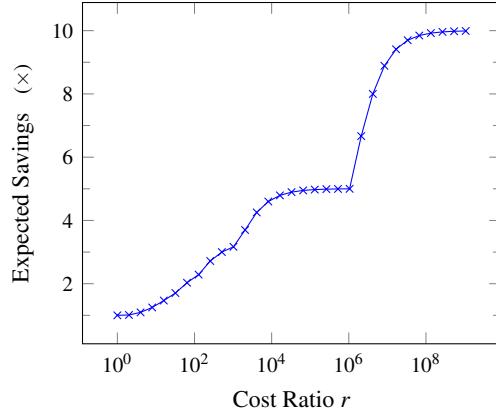

(a) $\epsilon = 2^{-40}$ (b) $\epsilon = 2^{-20}$

Figure 5: Bandwidth savings for SingleCut protocols

unless r exceeds certain discrete threshold values.

Changes to Existing Protocols. The changes needed in protocol 3.2 of Lindell (CRYPTO, 2013) to support our technique are standard:

- Add a step 0 to [15, Protocol 2], where an n is fixed in advance based on ϵ and r .
- Change step 2(b) of [15, Protocol 2] to: P_2 picks the check-set J at random so that $|J| = k$, where k is randomly sampled from the distribution computable (from n, r, ϵ) by the 2-step algorithm given above.

Afshar et al. [2] present a conceptually simple and elegant non-interactive secure computation protocol; it uses a cut-and-choose technique and achieves security 2^{-40} by sending 40 garbled circuits. Surprisingly, this can be done in just one round. Like Lindell, they create a trapdoor which allows an evaluator to recover the garbler’s inputs with high probability if inconsistent but valid output wire-labels are obtained. However, since their protocol is only 1 round, the cut-and-choose is implemented through oblivious transfer; specifically, the evaluator recovers a seed for all of the check circuits through OT, and the garbler sends all circuits in its one message. In order to apply our technique, we need to add extra rounds (in order to save substantial communication costs). Instead of sending the full circuits in the first message, we change the protocol to send succinct commitments of the circuits (thereby committing the sender) which keeps the first message short. In the next message, the evaluator asks the garbler to send the evaluation circuits only; and the evaluator uses its previous messages to continue running the original protocol. We believe these modifications are consistent with the security proof implicitly given in [2]. As a result, we can run this protocol with significantly less communication when $r > 1$.

3.3 BatchedCut Protocols

The basic idea of BatchedCut is to amortize the cost of cut-and-choose across either many protocol executions (of the same circuit) [11, 19] or many basic gates [12, 6, 24] of a big circuit. Without loss of generality, we focus on the setting of batched execution of a single functionality. Roughly speaking, the evaluator randomly selects and checks k out of T circuits in total and randomly groups the remaining circuits in buckets of size B . The state-of-the-art can ensure correctness as long as at least one good circuit is included in every bucket. This can effectively reduce the number of circuit copies to less than 8 (c.f. the optimal 40 without amortization [2, 15]) per execution to ensure 2^{-40} security. However, optimality of this result holds only if $r = 1$. In this section, we present our approach to optimize BatchedCut protocols for general r values.

We note one technical complication in this setting: in the checking stage, a bad circuit (or gate) might only be detected by the evaluator with probability τ . Although $\tau = 1$ for most protocols, it can be less than 1 for some other protocols, e.g., $\tau = 1/2$ for [12] and $\tau = 1/4$ for MiniLEGO [6]. Our analysis below is generalized to account for any $0 \leq \tau \leq 1$. State-of-the-art BatchedCut protocols [19, 11, 12] only require one object in each bucket to evaluate being correct, hence the focus of our analysis.

Analysis. Let N be the number of times a particular functionality will be executed, T be the total number of circuits generated to realize the N executions, and let B denote the bucket size.

With any positive r , we want to identify parameters (T, B) such that $cost(T, B)$ is minimized over all (T, B) configurations that satisfy the security constraint. That is, Pr_{fail} , the overall failure probability of cut-and-choose, should be no more than ϵ . Therefore, the problem reduces to the following constrained optimization

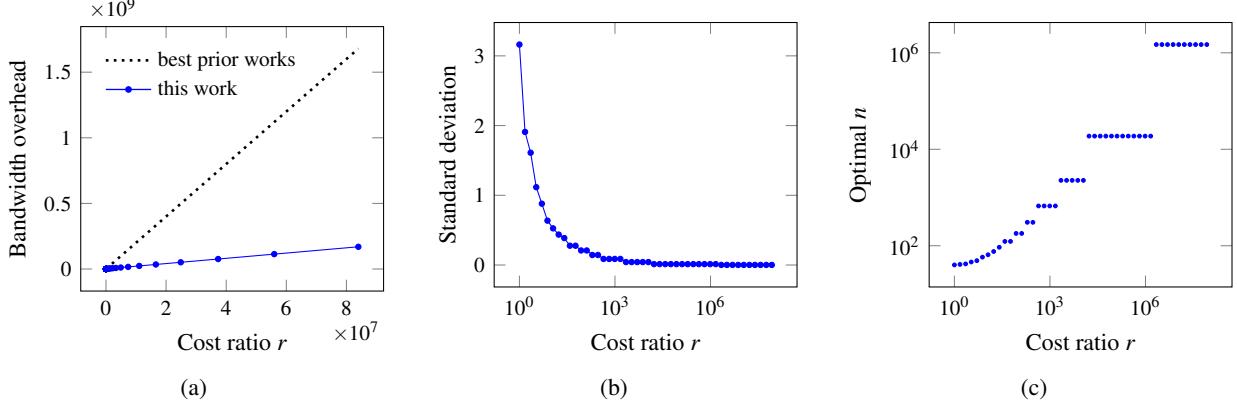

Figure 6: Characteristics of optimal mixed-strategy solutions for SingleCut protocols ($\varepsilon = 2^{-40}$). The bandwidth overhead is measured in *units*. A unit cost is that of evaluating a evaluation-circuit. The standard deviation chart applies to both the overall cost and e .)

problem:

$$\min T + (r - 1)BN$$

subject to

$$\Pr_{fail}(N, T, B, \tau, b) < \varepsilon, \quad \forall b \in \{0, \dots, T\}$$

where b is the number of bad circuits a malicious generator chooses to inject.

Note that \Pr_{fail} describes the failure across all N executions as follows: In the first move of the game, the evaluator picks $T - BN$ circuits to open and verifies all are correct. In the second move, the evaluator randomly partitions the BN unopened circuits into buckets of B circuits. A failure occurs if (i) the adversary is able to corrupt b circuits such that the first check passes, and (ii) there is some bucket containing only corrupted circuits. We let $\Pr_c(N, B, T, \tau, b, i)$ denote the probability of (i) and $\Pr_e(N, B, b)$ denote that of (ii).

First, as before, when i circuits are opened in the first phase, the garbler succeeds with probability

$$\Pr_c(N, B, T, \tau, b, i) = (1 - \tau)^i \binom{b}{i} \binom{T - b}{T - BN - i} / \binom{T}{T - BN}.$$

Here the extra $(1 - \tau)$ term reflects the case when checking a circuit can succeed with some chance even if it is corrupt. There are T total circuits, and $T - BN - i$ of them can be checked. The next term, \Pr_e reflects the probability that conditioned on the first phase passing, the evaluator randomly assigns the remaining circuits to buckets, and one bucket of size B contains all corrupted circuits.

$$\Pr_e(N, B, b) = 0, \quad \forall 0 \leq b \leq B \tag{1}$$

$$\Pr_e(N, B, b) = \binom{b}{B} / \binom{BN}{B} + \sum_{i=0}^{b-1} \Pr_e(N-1, B, b-i) \cdot \frac{\binom{b}{B-i} \binom{BN-b}{i}}{\binom{BN}{B}} \tag{2}$$

The first equation holds because a garbler who corrupts fewer than B circuits never succeeds. Finally, since phase

1 and phase 2 are independent, we conclude that

$$\Pr_{fail}(N, B, T, \tau, b) = \sum_{i=0}^b \Pr_c(N, B, T, \tau, b, i) \Pr_e(N, B, b-i)$$

The summation over i occurs because every check only succeeds with probability τ , and thus even after i checks on corrupted circuits, $b - i$ corrupted circuits may remain in the second phase.

Having explained the constraint, Figure 7 describes our search algorithm to solve the BatchedCut parameter optimization problem. The basic idea is simple—for every $B = 2, 3, \dots$, find the least T such that the security constraint is satisfied for every $b \in \{0, \dots, T\}$. Our main contribution here is to make the search efficient enough for realistic r, N , and ε , which is achieved based on a new efficient and accurate way to calculate \Pr_{fail} and the following observations to ensure efficiency and completeness of the search:

- For every B , the cost $cost(T, B)$ strictly increases with T while the failure rate \Pr_{fail} strictly decreases with T . So the best T for a given B can be identified efficiently using a combination of *exponential backoff* and *binary search*.
- The constraint that $\Pr_{fail} < \varepsilon$ regardless of the attacker’s strategy can be verified by computing \Pr_{fail} for every $b \in \{1, \dots, T\}$ (where b is the number of corrupted circuits generated by the attacker), which, if naively implemented, would require computing \Pr_{fail} $T \cdot T$ times for every B . We can leverage the idea of generating functions to reduce it to $T + T$ inexpensive operations (we will detail this in a bit).
- Assuming $c = (T - BN)/T > c_0$ (where c_0 is a small positive constant determined solely by the evaluator), it does not make sense for a malicious generator to insert more than $b^u = -(s+1)/\log(c_0/2 + 2/(1-c_0) - i_0/N)$ bad circuits. We shall prove this obser-

- vation as Claim 2. This observation further reduces $T + T$ down to $b^u + b^u$ inexpensive operations.
4. Assuming $(T - BN)/T > c_0$, a smaller feasible T identified during the search stipulates an upper-bound on the Bs that needs to be examined.

Compute Pr_{fail} Efficiently. For every N, B, T, τ, b , the probability of a malicious generator's successful attack can be described by equations described above. However, for most N, T values (e.g., $N > 2^{15}$), it is infeasible to compute Pr_c (which involves calculating large binomial coefficients) and Pr_e (which involves exponential number of slow recursions) accurately based on (3.3) and (2).

Hence, we propose an efficient way to compute Pr_e and Pr_c with provable accuracy.

1. **Compute $\text{Pr}_e(N, B, b)$.** The idea is to use *generating functions* to efficiently calculate Pr_e as the ratio between the number of ways to group garbled circuits into buckets that will result a failure (i.e., at least one bucket is filled with all B bad circuits) and the total number of ways to group the garbled circuits. First, we use function $g(x, y) = (1+x)^B + (y-1)x^B$ to model the circuit assignment process for a single bucket, where 'x' denotes a "bad" gate and '1' denotes a "good" gate, thus the coefficient of x^i in $g(x, y)$ equals to the number of ways to assign i bad gates to a bucket. Note that the symbol 'y' we intentionally introduce as the coefficient of x^B term of $g(x, y)$ denotes the event that "all B gates in a bucket are bad". Next, we use the generating function $G(x, y) = g(x, y)^N$ to model the circuit assignment process over all of the N buckets: the coefficient of x^i (which is a polynomial in y , hence written as $f_i(y)$) in $G(x, y)$ denotes the number of assignments involving i bad gates. Let $f_i(y) = \sum_{j=0}^{\infty} c_j y^j$ (where c_j are constants efficiently computable from $G(x, y)$), then $f_b(1) = \sum_{j=0}^{\infty} c_j$ is the total number of assignments with b bad gates used in the evaluation stage; and $f_b(1) - f_b(0) = \sum_{j=1}^{\infty} c_j$ is the number of assignments (among all with b bad circuits) that result in at least one broken bucket. Hence, we compute $\text{Pr}_e(N, B, b) = (f_b(1) - f_b(0))/f_b(1)$. Further, we can dramatically reduce the cost of computing the coefficients of $G(x, y)$ by not distinguishing any terms y^{j_1} and y^{j_2} for any $j_1, j_2 \geq 1$. That is, multiplying $(u+vy)$ and $(w+ty)$ yields $uw + (ut + vw + vt)y$, hence, however big N and B are, $f_i(y)$'s are linear formulas in y .
2. **Compute $\text{Pr}_c(N, B, T, \tau, b, i)$.** Recall that typically T, N are large while b, i are far smaller than N . So the dominating cost in computing Pr_c is to calculate $\left(\frac{T-b}{T-BN-i}\right) / \left(\frac{T}{T-BN}\right)$. To this end, we approximate $\text{Pr}_c(N, B, T, \tau, b, i)$ using $\left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i}\right)^{b-i}$, whose high accuracy is formally proved in Claim 1.

To illustrate the precision of the above calculation, e.g., when $s = 40$, if $N = 50,000$, the overall error in our calculation of $\log \text{Pr}_{fail}(N, B, T, \tau, b)$ is less than 1. Note the error only decreases as N grows (following Claim 1 and Claim 2).

Claim 1 *Let T, B, N, b, i be defined as above. Then*

$$\lim_{N \rightarrow \infty} \frac{\left(\frac{T-b}{T-BN-i}\right)}{\left(\frac{T}{T-BN}\right)} = \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i}\right)^{b-i}.$$

Claim 2 *Let $\text{Pr}_{fail}(N, B, T, \tau, b)$ be the probability that the cut-and-choose game fails in a BatchedCut scheme (with b bad circuits up-front). For every ϵ , $c_0 = (T - BN)/T, \tau > 0$, if $N > i_0 / \left(\frac{B}{1-c_0} - \frac{B}{1-(1-\tau)c_0}\right)$ and $b > -(\lceil \log \epsilon \rceil + 1) / \log \left((1-\tau)c_0 + \frac{B}{B/(1-c_0)-i_0/N}\right)$, then $\text{Pr}_{fail}(N, B, T, \tau, b) < \epsilon$.*

Last, we also considered employing mixed strategies for BatchedCut protocols (i.e., fixing T to some public value up-front while randomizing the selection of B) to further reduce the cost. However, our analysis show that the extra improvement brought by randomized strategies is very small in this setting. This is consistent with our intuition: (1) It only makes sense to alternate B between two consecutive integers, which can be derived as a corollary of [12, Lemma 9]; (2) The strategy with smaller B is almost dominated by the one with larger B such that mixing them brings little extra benefit. Therefore, we opt to avoid using randomized strategies for BatchedCut protocols.

Results. Figure 8 depicts the improvements induced by the refined cost model for cut-and-choose. In this scenario, our search algorithm is able to identify the optimal pure strategies for r up to 10^5 , assuming the check rate c is always larger than 0.02. We note that the optimal strategy (characterized by (T, B) pairs) does not change much for $10^5 < r \ll \infty$. Experimental results show that roughly 20 ~ 80% performance gain can be achieved (while the exact improvement depends on r, ϵ and N). Note the effects of the bad circuits detection rate τ on the benefits of our approach (through comparing Figure 8a and 8b).

Changes to Existing Protocols. In this case, because we do not use randomized strategies, our proposal applied to the BatchedCut scenario requires *no protocol changes* other than setup the public parameters to the suggested value output by our search algorithm.

4 Benefits in Time

Recall that circuit checking will result in negligible network traffic because only a short circuit seed and a circuit

Input: ϵ, N, c_0 .

Output: T^*, B^*

1. Choose b^u and B^u .
 - (a) Let $s = \lceil \log \epsilon \rceil$. Compute $i_0 := s + 2$ and $b^u := -(s+1) / \log(\frac{c_0}{2} + \frac{2}{2/(1-c_0)-i_0/N})$
 - (b) Set $T^* := \infty$ and $B^u := \infty$.
2. For B ranging from 2 to B^u ,
 - (a) Precompute $\text{Pr}_e(N, B, b) = 1 - f_b(0)/f_b(1)$ for every $b \in [B, b^u]$.
 - (b) Find the smallest T , call it T_B , such that $T < T^*$ and $\text{Pr}_{fail}(N, B, T_B, \tau, b) < \epsilon$ for all $b \leq b^u$, using exponential backoff and binary search. (Note that $\text{Pr}_{fail}(N, B, T, \tau, b)$ monotonically decreases with T while the cost $T + NB(r-1)$ monotonically increases with T .)
 - (c) If $T^* + NB^*(r-1) > T_B + NB(r-1)$, then update $T^* := T_B$, $B^* := B$, and $B^u := \lceil (1 - c_0)T_B/N \rceil$.
3. Output T^*, B^* .

Figure 7: Find cost-efficient (T, B) for BatchedCut protocols.

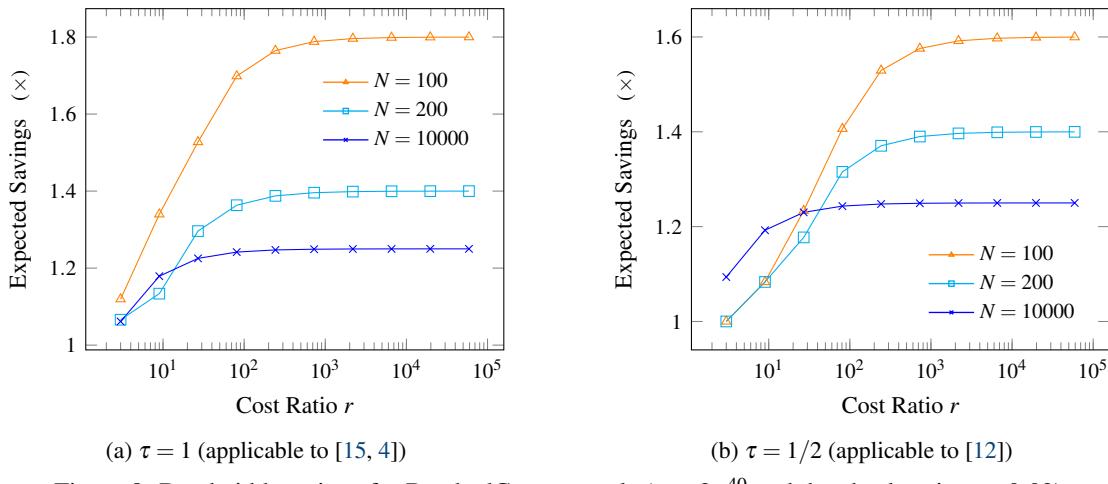

Figure 8: Bandwidth savings for BatchedCut protocols ($\epsilon = 2^{-40}$ and the check ratio $c \geq 0.02$)

hash needs to be transferred. This gap in bandwidth overhead also leads to a substantial gap in execution speeds, due to the significant difference in the throughputs of garbling/checking (about 50 ns/gate on a single-core processor) and that of network transmission (typically a wide range of 50~3000 ns/gate).

To evaluate the benefit of our technique in terms of time, we modified OblivC [29] to measure the ratios of speed for circuit evaluation and circuit checking tasks in various network settings. Our test implementation utilizes Intel AES-NI instructions and the half-gate garbling technique [30] to minimize bandwidth usage, and SHA256 implementation provided by Libgcrypt for circuit hashing. In circuit checking tasks, the circuit generator garbles a number of circuits but sends only a $(\text{Seed}, \text{Hash})$ pair for each garbled circuit, while the circuit verifier re-computes the hash from the seed for each circuit. We record the per circuit time cost for this task as T_c . For circuit evaluation tasks, the circuit generator garbles a number of circuits and sends the garbled gates to the evaluator, who not only evaluates, but also computes the hash of the received circuit. We record the per circuit time cost for this task as T_e . (In both tasks, the two

ends work in a pipelined fashion.) Thus, the time cost ratios between evaluation and checking can be calculated as $(T_c + T_e)/(2T_c)$ (recall that every circuits will be generated twice, once for committing their hashes and once for check/evaluate to avoid storing the typically gigantic circuits).

We used a benchmark circuit (provided by OblivC) with 31×10^6 non-free gates. Our experiments were run on two Amazon EC2 boxes (instance type: c4.large, \$0.105/hour, Intel Xeon E5-2666, 2.9GHz, 3.75GB memory) with Ubuntu 14.04 Server edition in the VA region.

We detail our experimental results in Table 5. The r values (in terms of wall-clock time) range from a little over 1 (with high speed connection) to 30 (with ordinary home-to-home connections). Such time gaps can be well-explained by the difference in the throughputs of computation and communication. The observed speedups of the proposed cut-and-choose technique can range from 12% up to 106%. Note that our approach yields no noticeable time savings for the settings of running SingleCut or BatchedCut protocols in a 1 Gbps LAN with single-core processors (compared to the their

state-of-the-art counterparts), because the cost ratio r is already very close to 1.

We note that due to the use of SHA256 in computing circuit hashes, we observe only 2.23×10^6 gates/second for circuit verification while 1.30×10^6 gates/second for circuit evaluation. It would be interesting to replace SHA256 with some hashing algorithm that leverages AES-NI instructions to match up with the speed of AES-NI based garbling (more than 10^9 gates/second, as was reported in [3]). That will imply a time ratio up to 100× larger than we observe in our experiments.

Table 5: Timing gaps between circuit evaluation and verification and our speedup benefits (measurements taken from 10 runs with 0.1% relative standard deviation) for a 31m gate circuit.

	LAN 1 Gbps	WAN 100 Mbps	WAN 10 Mbps
T_e (seconds)	24.1	103.5	818
T_c (seconds)	13.9	13.9	13.9
r	1.37	4.22	29.9
Speedup	MajorityCut	12%	26%
	SingleCut	0%	13%
	BatchedCut	0%	14%
			106%
			76%
			41%

5 Conclusion

The state-of-the-art design of cut-and-choose protocols considers an overly simplified cost model, and does not exploit the opportunity of dynamically variating e to thwart cheating adversaries. We have shown, through experiments, the dramatic gap in the bandwidth costs between circuit evaluation and circuit verification. We revisit the cut-and-choose protocol design problem in a refined cost model and give three highly efficient solvers, one for each class of cut-and-choose protocols, that output the best strategy for a particular cost ratio in our model. Simulation results show that our approach bring significant savings in bandwidth cost, as well as substantial speedups (especially when running secure computation protocols outside idealized laboratory environments). Most importantly, the benefits require very small changes to existing protocols and come completely from formal proofs that do not depend on any unprovable assumptions.

A Proofs

Claim 1 Let T, B, N, b, i be defined as above. Then

$$\lim_{N \rightarrow \infty} \frac{\binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} = \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i}\right)^{b-i}.$$

Proof There exists N_0 such that if $N > N_0$,

$$\begin{aligned} \frac{\binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} &= \frac{(T-b)!(T-BN)!(BN)!}{T!(T-BN-i)!(BN-b+i)!} \\ &= \frac{((T-BN-i+1)\cdots(T-BN))((BN-b+i+1)\cdots BN)}{(T-b+1)\cdots T} \\ &= \frac{(T-BN-i+1)\cdots(T-BN)}{(T-i+1)\cdots T} \cdot \frac{(BN-b+i+1)\cdots BN}{(T-b+1)\cdots(T-i)} \\ &\leq \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i}\right)^{b-i} \triangleq U. \end{aligned}$$

Similarly, we have, there exists N_1 such that if $N > N_1$,

$$\frac{\binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \geq \left(\frac{T-BN-i+1}{T-i+1}\right)^i \left(\frac{BN-b+i+1}{T-b+1}\right)^{b-i} \triangleq L.$$

So, we know that, for sufficiently large N ,

$$\begin{aligned} U / \frac{\binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} &\leq \frac{U}{L} = \left(\frac{T-BN}{T-BN-i+1} \cdot \frac{T-i+1}{T}\right)^i \left(\frac{BN}{BN-b+i+1} \cdot \frac{T-b+1}{T-i}\right)^{b-i} \\ &= \left[\frac{(T-BN)T - (i-1)T + (i-1)BN}{(T-BN)T - (i-1)T} \right]^i \cdot \left[\frac{(BN-b+i+1)(T-i) + (b-i-1)(T-BN-i)}{(BN-b+i+1)(T-i)} \right]^{b-i} \\ &= \left[1 + \frac{(i-1)BN}{(T-BN)T - (i-1)T} \right]^i \left[1 + \frac{(b-i-1)(T-BN-i)}{(BN-b+i+1)(T-i)} \right]^{b-i} \\ &\leq \left(1 + \frac{i-1}{T-BN-i+1} \right)^i \left(1 + \frac{b-i-1}{BN-b+i+1} \right)^{b-i} \tag{3} \\ &\leq \left(1 + \frac{i-1}{T-BN-i+1} \right)^i \left(1 + \frac{b-1}{BN-b+1} \right)^b \tag{4} \end{aligned}$$

Note that the inequality (3) holds because $T > BN$. Thanks to the upper-bound of b (Claim 2) and hence on i (recall $i \leq b$), $\lim_{N \rightarrow \infty} \left(1 + \frac{i-1}{T-BN-i+1}\right)^i \left(1 + \frac{b-1}{BN-b+1}\right)^b = 1$. \blacksquare

Claim 2 Let $\Pr_{\text{fail}}(N, B, T, \tau, b)$ be the probability that the cut-and-choose game fails in a BatchedCut scheme (with b bad circuits up-front). For every ε , $c_0 = (T-BN)/T$, $\tau > 0$, if $N > i_0 / \left(\frac{B}{1-c_0} - \frac{B}{1-(1-\tau)c_0}\right)$ and $b > -(\lceil \log \varepsilon \rceil + 1) / \log \left((1-\tau)c_0 + \frac{B}{B/(1-c_0)-i_0/N}\right)$, then $\Pr_{\text{fail}}(N, B, T, \tau, b) < \varepsilon$.

Proof Let $0 < \tau \leq 1$ be the probability that P_2 detects the abnormality in checking garbled gate g conditioned on g is indeed bad. We have

$$\Pr_{\text{fail}}(N, b) = \sum_{i=0}^b (1-\tau)^i \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i)$$

where $(1 - \tau)^i \binom{b}{i} \binom{T-b}{T-BN-i} / \binom{T}{T-BN}$ is the probability that P_1 who generates b bad gates survives the gate verification stage with i bad gates selected for verification (but P_2 fails to detect any of them). Because there exists i_0 such that $(1 - \tau)^{i_0} < \varepsilon/2$,

$$\begin{aligned}
\Pr_{fail}(N, b) &= \sum_{i=0}^b (1 - \tau)^i \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i) \\
&= \sum_{i=0}^{i_0} (1 - \tau)^i \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i) + \sum_{i=i_0+1}^b (1 - \tau)^i \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i) \\
&\leq \sum_{i=0}^{i_0} (1 - \tau)^i \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i) + (1 - \tau)^{i_0} \sum_{i=i_0+1}^b \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i) \\
&\leq \sum_{i=0}^{i_0} (1 - \tau)^i \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i) + \frac{\varepsilon}{2} \sum_{i=i_0+1}^b \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \\
&\leq \sum_{i=0}^{i_0} (1 - \tau)^i \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i) + \frac{\varepsilon}{2} \sum_{i=1}^b \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \\
&\leq \sum_{i=0}^{i_0} (1 - \tau)^i \frac{\binom{b}{i} \binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \Pr_e(N, b-i) + \frac{\varepsilon}{2} \cdot 1 \\
&\leq \sum_{i=0}^{i_0} (1 - \tau)^i \binom{b}{i} \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i}\right)^{b-i} \Pr_e(N, b-i) + \frac{\varepsilon}{2} \quad [\text{Claim 3}] \\
&\leq \sum_{i=0}^{i_0} (1 - \tau)^i \binom{b}{i} \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i}\right)^{b-i} \Pr_e(N, b) + \frac{\varepsilon}{2} \\
&\leq \sum_{i=0}^{i_0} (1 - \tau)^i \binom{b}{i} \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i_0}\right)^{b-i} \Pr_e(N, b) + \frac{\varepsilon}{2} \\
&\leq \sum_{i=0}^b (1 - \tau)^i \binom{b}{i} \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i_0}\right)^{b-i} \Pr_e(N, b) + \frac{\varepsilon}{2} \\
&= \left((1 - \tau) \frac{T-BN}{T} + \frac{BN}{T-i_0}\right)^b \Pr_e(N, b) + \frac{\varepsilon}{2} \\
&\leq \left((1 - \tau) \frac{T-BN}{T} + \frac{BN}{T-i_0}\right)^b + \frac{\varepsilon}{2}.
\end{aligned}$$

Thus, $N > i_0 / \left(\frac{B}{1-c_0} - \frac{B}{1-(1-\tau)c_0} \right)$ ensures $(1 - \tau) \frac{T-BN}{T} + \frac{BN}{T-i_0} < 1$, while $b > -(s + 1) / \log \left((1 - \tau)c_0 + \frac{B}{B/(1-c_0)-i_0/N} \right)$ ensures $\left((1 - \tau) \frac{T-BN}{T} + \frac{BN}{T-i_0} \right)^b + \frac{\varepsilon}{2} \leq 2^{-s}$. Hence, we conclude that $\Pr_{fail}(N, B, T, \tau, b) < \varepsilon$. \blacksquare

Claim 3 If T, N, b, i are non-negative integers such that $T > BN$, $T \geq b$, and $i \leq b$, then

$$\frac{\binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} \leq \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i}\right)^{b-i}.$$

Proof

$$\begin{aligned}
\frac{\binom{T-b}{T-BN-i}}{\binom{T}{T-BN}} &= \frac{(T-b)!(T-BN)!(BN)!}{T!(T-BN-i)!(BN-b+i)!} = \frac{[(T-BN-i+1) \cdots (T-BN)][(BN-b+i+1) \cdots BN]}{(T-b+1)(T-b+2) \cdots T} \\
&= \frac{(T-BN-i+1) \cdots (T-BN)}{(T-i+1) \cdots T} \cdot \frac{(BN-b+i+1) \cdots BN}{(T-b+1) \cdots (T-i)} \leq \left(\frac{T-BN}{T}\right)^i \left(\frac{BN}{T-i}\right)^{b-i}
\end{aligned}$$

On Demystifying the Android Application Framework: Re-Visiting Android Permission Specification Analysis

Abstract

In contrast to the Android application layer, Android’s application framework’s internals and their influence on the platform security and user privacy are still largely a black box for us. In this paper, we establish a static runtime model of the application framework in order to study its internals and provide the first high-level classification of the framework’s protected resources. We thereby uncover design patterns that differ highly from the runtime model at the application layer. We demonstrate the benefits of our insights for security-focused analysis of the framework by re-visiting the important use-case of mapping Android permissions to framework/SDK API methods. We, in particular, present a novel mapping based on our findings that significantly improves on prior results in this area that were established based on insufficient knowledge about the framework’s internals. Moreover, we introduce the concept of permission locality to show that although framework services follow the principle of separation of duty, the accompanying permission checks to guard sensitive operations violate it.

1 Introduction

Android’s application framework—i.e., the middleware code that implements the bulk of the Android SDK on top of which Android apps are developed—is responsible for the enforcement of Android’s permission-based privilege model and as such is also a popular subject of recent research on security extensions to the Android OS. These extensions provide various security enhancements to Android’s security, ranging from improving protection of the user’s privacy [26, 46], to establishing domain isolation [29, 12], to enabling extensible access control [21, 8].

Android’s permission model and its security exten-

sions are currently designed and implemented as best-effort approaches. As such they have raised questions about the efficacy, consistency, or completeness [3] of the policy enforcement. Past research has shown that even the best-efforts of experienced researchers and developers working in this environment introduce potentially exploitable errors [15, 44, 35, 33]. In light of the framework size (i.e., millions of lines of code) and based on past experience [15, 44, 16, 33, 36], static analysis promises to be a suitable and effective approach to (help to) answer those questions and hence to demystify the application framework from a security perspective. Unfortunately, on Android, the technical peculiarities of the framework impinging on the analysis of the same have not been investigated enough. As a consequence, past attempts on analyzing the framework had to resort to simple static analysis techniques [7]—which we will show in this paper as being insufficient for precise results—or resort to heuristics [33].

In order to improve on this situation and to raise efficiency of static analysis of the Android application framework, one is confronted with open questions on *how to enable more precise static analysis of the framework’s codebase*: where to start the analysis (i.e., what is the publicly exposed functionality)? Where to end the analysis (i.e., what are the data and control flow sinks)? Are there particular design patterns of the framework runtime model that impede or prevent a static analysis? For the Android application layer, those questions have been addressed in a large body of literature. Thanks to those works, the community has a solid understanding of the sinks and sources of security- and privacy-critical flows within apps (e.g., well-known Android SDK methods) and a dedicated line of work further addressed various challenges that the Android *application* runtime model poses for precise analysis (e.g., inter-component communication [28, 40, 24, 27] or modelling the Android

app life-cycle[25, 6]). Together those results form a strong foundation on which effective security- and privacy-oriented analysis is built upon. In contrast to the app layer, for the application framework we have an intuitive understanding of what constitutes its entry points, but no in-depth technical knowledge has been established on the runtime model, and almost no insights exist on what forms the security and privacy relevant targets of those flows (i.e., what technically forms the sinks or “protected resources”).

Our Contributions. This paper contributes to the demystification of the application framework from a security perspective by addressing technical questions of the underlying problem on *how* to statically analyze the framework’s code base. Similar to the development of application layer analyses, we envision that our results contribute some of the first results to a growing knowledge base that helps future analyses to gain a deeper understanding of the application framework and its security challenges.

How to statically analyze the application framework. We present a systematic top-down approach, starting at the framework’s entry points, that establishes knowledge and solutions about analyzing the control and data flows within the framework and that makes a first technical classification of the security and privacy relevant targets (or resources) of those flows. The task of establishing a precise static runtime model of the framework was impeded by the absence of any prior knowledge about framework internals beyond black-box observations at the framework’s documented API and manual analysis of code fragments. Hence we generate this model from scratch by leveraging existing results on statically analyzing Android’s application layer at the framework layer. The major conceptual problem was that the design patterns of the framework strongly differ from the patterns that had been previously encountered and studied at the application layer. Consequently we devised a static analysis approach that systematically encompasses all framework peculiarities while maintaining a reasonable runtime. As result of this overall process, we have established a dedicated knowledge base that subsequent analyses involving the application framework can be soundly based upon.

AXPLORER tool and evaluation. Unifying the lessons learned above, we have built an Android application framework analysis tool, called AXPLORER. We evaluate AXPLORER on four different Android versions—v4.1.1 (API level 16), v4.2.2 (17), v4.4.4 (19), and v5.1 (22)—validate our new insights and demonstrate how specialized framework analyses, such as message-

based IPC analysis and framework component interconnection analysis, can be used to speed up subsequent analysis runs (e.g. security analyses) by 75% without having to sacrifice precision. As additional benefit the resulting output can be used by independent work *as is* to create a precise static runtime model of the framework without the need to re-implement the complex IPC analysis.

Android permission analysis. Finally, to demonstrate the benefits of our insights for security analysis of the framework, we conduct an Android permission analysis. In particular, we re-visit the challenge of creating a permission map for the framework/SDK API. In the past, this problem has been tackled [32, 7] without our new insights in the peculiarities of the framework runtime model, and our re-evaluation of the framework permission map reveals discrepancies that call the validity of prior results into question. Using AXPLORER, we create a new permission map that improves upon related work in terms of precision. Moreover, we introduce a new aspect of permission analysis, permission locality, by investigating which framework components enforce a particular permission. We found permissions that are checked in up to 10 distinct and not necessarily closely related components. This indicates a violation of the separation of duty principle and can impede a comprehensive understanding of the permission enforcement.

2 Background

We first provide necessary technical background information on the Android software stack and the abstract control and data flows in the system. Android OS is an open source software stack on top of the Linux OS. Between the apps at the top of the stack and the Linux kernel at the bottom is the Android middleware. This middleware consists of the application runtime environment, default native libraries (like SSL), and the Java-based application framework (see Figure 1).

2.1 Android Application Framework

The application framework consists of the various services that implement the Android app API (e.g., retrieving location data or telephony functionality). Every framework service is responsible for providing access to one specific system resource, such as geolocation, radio interface, etc.

Bound services. These services are implemented as bound services [4] as part of the SystemServer.

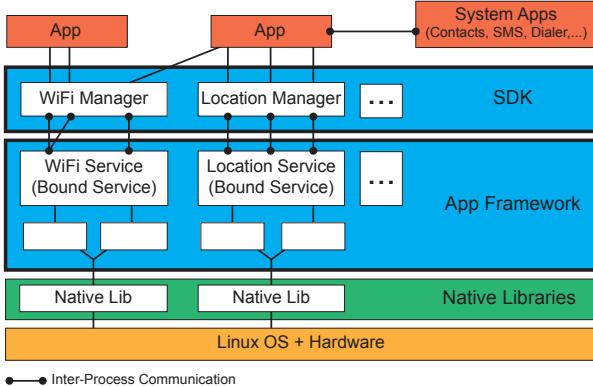

Figure 1: Android Software Stack with abstract control and data flows.

Bound service is the fundamental pattern to realize Android services that are remotely callable via a well-defined interface. Such interfaces are described in the *Android Interface Definition Language* (AIDL) and an AIDL compiler allows automated generation of **Stub** and **Proxy** classes that implement the interface-specific Binder-based RPC protocol to call the service. Here, **Stubs** are an abstract class that implements the **Binder** interface and needs to be extended by the actual service implementation. **Proxies** are used by clients to call the service. On top of **Stubs** and **Proxies**, the Android SDK provides **Managers** as abstraction from the low-level RPC protocol. **Manager** classes encapsulate pre-compiled **Proxies** and allow developers to work with **Manager** objects that translate local method calls into remote-procedure calls to their associated service and hence enable app developers to easily engage into RPC with the framework’s services. However, **Proxies** and **Managers** are just abstractions for the sake of app developer’s convenience and nothing prevents an app developer from bypassing the **Managers** or re-implementing the default RPC protocol to directly communicate with the services.

A small number of framework services does not use AIDL to auto-generate their **Stub/Proxy**, but instead provides a custom class that implements the **Binder** interface. The most prominent exception is the **ActivityManagerService** (AMS), which provides essential services such as application life-cycle management or Intent distribution. Since its interface is also called from native code, for which the AIDL compiler does not auto-generate native **Proxies/Stubs** and hence requires manual implementation of those, the RPC protocol for the AMS is hardcoded to avoid misalignment between manually written and auto-generated code.

The services are an essential part of the middleware front-end to the application layer and calling their interfaces triggers control and data flows within the application framework. Naturally, the flows of some services lead to interaction with the underlying platform through the native libs. For instance, the **WifiService** is interacting with the WiFi daemon. Other services, such as Clipboard, do not rely on any hardware features. However, the exact control and data flows have not yet been studied or charted (see blank boxes in Figure 1) and facilitating this mapping by enabling analysis of the framework is part of the contributions of this work.

System apps. System apps, such as Contacts, Dialer, or SMS complement the application framework with commonly requested functionality. However, in contrast to the application framework services that are fixed parts of any Android deployment, system apps are exchangeable or omittable (as can be observed in the various vendor customized firmwares) and, more importantly, are simply apps that are programmed against the same application framework API as third-party applications.

2.2 Permissions

One cornerstone of the Android security design are *permissions*, which an app must hold to successfully access the security and privacy critical methods of the application framework. Every application on Android executes under a distinct Linux UID and permissions are simply Strings¹ that are associated with the application’s UID. There is no centralized policy for checking permissions on calls to the framework API. Instead, framework services that provide security or privacy critical methods to applications (must) enforce the corresponding, hard-coded permission that is associated with the system resources that the services expose. To enforce permissions, the services programmatically query the system whether their currently calling app—identified by its UID—holds the required permission, and if not take appropriate actions (such as throwing an exception). For instance, the **LocationManagerService** would query the system whether a calling UID is associated with the String `android.permission.ACCESS_FINE_LOCATION`, which represents the permission to retrieve the GPS location data from the **LocationManagerService**.

In this model, system apps differ from third-party apps in that they can successfully request security

¹Permissions that map to Linux GIDs do not involve the framework and are not further considered here.

and privacy critical system permissions from the framework, which are not available to non-system apps. Moreover, like framework services (and any non-system application), they are responsible for enforcing permissions for resources they manage and expose on their RPC interfaces (e.g., contacts information or initiating phone calls). The difference to non-system applications is, that they usually enforce well-known permissions defined in the Android SDK, although the Android design does—in contrast to the framework services—not hardcode where those permissions are enforced, thus allowing system apps to be exchanged.

3 Related work

Static (app) analysis. Different related works have analyzed Android apps for vulnerabilities and privacy violations. Enabling precise static app analysis required solving essential questions like what are the entry points of the app, what are the security relevant sinks and how can we achieve a static runtime model that takes the application peculiarities into account? Among the static analysis approaches, *CHEX* [25] was the first tool to accommodate for Android’s event-driven app lifecycle with an arbitrary number of entry points. *FlowDroid* [6] further improved the runtime model by automatically generating per-component lifecycle models that take into account the partial entry point ordering. While *FlowDroid* still analyzed components in isolation, a number of related works specifically addressed the problem of inter-component communication (ICC). The initial work *Epicc* [28] devised a new analysis technique to create specifications for each ICC sink and source. *Amandroid* [40] combined a lifecycle-aware program dependence graph with ICC analysis to generate an inter-component model of the application to improve precision for various security applications. Similarly, *IccTA* [24] extended *FlowDroid* with a precise inter-component model. Finally, *IC3* [27] uses composite constant propagation to improve retargeting of ICC-related parameters enabling a more precise ICC resolution. Moving from best effort approaches, *SuSi* [5] took a machine-learning approach for classifying and categorizing sources and sinks in the framework code that are relevant for application analysis. All of those solutions contribute to analyzing Android apps more efficiently. The focus of this work is on establishing similar knowledge on Android’s application framework and on making a first essential but non-trivial step towards enabling a holistic analysis of Android that includes the framework code with its security architecture.

Application Framework Abstractions. The application framework is generally regarded as too complex to be considered in an app analysis (cf., *CHEX* [25]) and very recent works dealt specifically with this problem of abstracting the application framework [13, 18] or making it amenable for app analysis [11]. *EdgeMiner* [13] links callback methods to their registration methods and generates API summaries that describe implicit control flow transitions through the framework. *DroidSafe* [18] distills a compact, data-dependency-aware model of the Android app API and runtime from the original framework code. *Droidele* [11] differs in its approach by explicating the reflective bridge between the application framework and applications, while trying to model the framework as less as possible. It generates app-specific versions of the application framework and replaces reflective calls with app-specific stubs. All of these approaches try to pre-compute data-dependencies through the framework API that can be used by app analyses in favor of using the complex and huge framework code base. In contrast, our work makes a first step towards enabling in-depth analyses of the application framework beyond just data dependencies in order to enable future reasoning about framework security architectures or extensions (such as guiding and verifying hook placement or separation of duties).

Permission Mapping and Inconsistencies. Both *Stowaway* [32] and *PScout* [7] built permission maps for the framework API. Stowaway used unit testing and feedback directed API fuzzing of the framework API to observe the required permission(s) for each API call. PScout, in contrast, used static reachability analysis between permission checks and API calls to create a permission mapping of different Android framework versions that improves on the results of Stowaway. Permission maps have since been a valuable input to different Android security research, such as permission analysis [20] and compartmentalization [31, 34] of third-party code, studying app developer behavior [32, 38], detecting component hijacking [25], IRM [23, 10] and app virtualization [9], or risk assessment [30, 19, 45, 42]. In this work, we re-visit the challenge of creating a permission map for Android. In contrast to the prior work, we build on top of our new insights on how to statically analyze the application framework (see Sections 4 and 5), which allow us to achieve a map that is more precise for the application framework API and that calls the validity of some prior results [7] into question. We discuss how recent work [33] that focused on inconsistent security enforcement within the framework

could benefit from a deeper understanding of the framework’s peculiarities separately in Section 8.

Android Security Frameworks. Various security extensions have been proposed, such as [26, 46, 29, 12, 21, 8] to name a few, which integrate authorization hooks into Android’s application framework to enforce a broad range of security policies. At the moment, those extensions are designed and implemented as best-effort approaches that raise questions about the completeness and consistency of the enforcement and indeed past research has shown that even the best-efforts of highly experienced researchers and developers working in this environment introduce potentially exploitable errors [15, 44, 35, 33]. This unsatisfying situation has strong parallels to earlier work on integrating authorization hooks into the Linux and BSD kernels [41, 39], where a dedicated line of work [15, 44, 16] has established tools and techniques to reason about the security properties of proposed extensions or to automate the hook placement. Prerequisite for those solutions was a clear understanding of what constitutes a resource that is (or should be) protected by an authorization hook. To allow development of similar tools for the Android application framework, we hence have to also answer the question about Android’s protected resources first. In this work we want to make a first essential step in this direction by enabling a deeper analysis of the framework and by providing a first high-level taxonomy of protected resources in the application framework.

4 Enabling In-Depth Application Framework Analysis

In contrast to the various related works on static analysis at the application level, there is no existing prior work on in-depth analysis of the application framework. Moreover, as the architecture of the framework fundamentally differs from the architecture of applications, open questions have to be answered first to be able to conduct in-depth static analysis of the framework. For instance, “*what are the entry points to the application framework?*” or “*how to establish a static runtime model of the framework’s control flows?*” In the following we identify challenges that arise for static analyses at framework level and present a systematic, top-down approach to cope with these problems (an implementation of our approach is presented in Section 5). Solving the discussed challenges lays the foundation on which a wide range of security analyses of the application frame-

work can be constructed, from which we (re-)visit the use-case of permission analysis in Section 7.

4.1 Defining Framework Entry Points

The first question to be answered is how to identify and select the starting points for the framework analysis? At application level this has already been studied in depth [25, 6, 14, 17, 43]. From a high-level view, most approaches parse the declared components from the application manifest and determine the components as well as dynamically registered callbacks as entry points; or they build component/application life-cycle models with a single main entry method.

Challenge: *The framework model is conceptually different from the application layer and existing approaches for application layer analysis do not apply in a framework analysis. Instead one has to identify the framework API methods that are exposed to app developers as analysis entry points.*

To identify the entry point methods, we have to locate the relevant framework entry point classes. Starting with the official API of the Android SDK (e.g., `Managers` in Figure 1) is not reliable as there are no means to prevent an app developer from bypassing the SDK by immediately communicating with the framework services or by using reflection to access hidden API methods of the SDK. Consequently, we do not consider the API calls within the SDK as entry points but instead the framework classes that are entry points for accessing framework functionality (i.e., framework classes that are being called by the SDK, see Figure 1). We exclude entry points that are not accessible by app developers, such as Zygote, service manager, or the property service, which are under special protection (e.g., SELinux [37]) and will not accept commands by third-party apps that have tangible side-effects on the system or other apps. This restriction is in accordance with the design of existing Android security extensions, which exclusively focus on the exported functionality of the app framework (e.g., framework’s bound services).

Inter-component communication in Android is by design based on `Binder` IPC and, thus, framework classes have to expose functionality via `Binder` interfaces to the application layer. To this end, interfaces must be derived from `IInterface`, the base class for `Binder` interfaces. `Binder` interfaces might be automatically generated by AIDL, in this case the entry point classes extend the auto-generated `Stub` class, or in case of `Binder` interfaces that are not generated by AIDL, a custom `Binder` implementation

like `ActivityManagerNative`² has to be provided, which in turn is extended by the entry point classes. These class relationships can be resolved via a class hierarchy analysis (CHA) to determine the set of all entry classes. Besides bound services this also includes callback and event listener classes that expose an implementable interface to app developers. Hence, we define entry points (EP) as the public methods of framework classes that are exposed via a `Binder` interface. In addition, permission-protected entry points (PPEP) are defined as entry points from which a permission check is control-flow reachable.

4.2 Building a Static Runtime Model

Challenge: *Generating a static model that approximates the runtime behaviour of the application framework again strongly differs from the problems that arise at application level where the component life-cycles are mimicked to approximate runtime behavior. The bound services—as entry points to the framework—might be queried simultaneously from multiple clients (apps) via IPC and hence have to handle multi-threading to ensure responsiveness of the framework. In contrast to the application space at which utility classes like `AsyncTask` are used for threading, we discovered that the framework services make intensive use of more generic but also more complex threading mechanisms like `Handler`, `AsyncChannel`, and `StateMachines`. Disregarding these concurrency patterns results in imprecise data models that cause a high number of false positives during framework analysis.*

In the following, we provide technical background for those asynchronicity patterns and explain how they can modeled correctly for static analyses.

Handler. The class `android.os.Handler` provides a mechanism for reacting to messages or submitting Java `Runnable` objects for execution on a (potentially remote) thread. `Handlers` either schedule the processing of a message or the execution of a `Runnable` at some point in the future or process a message/`Runnable` on a separate thread.

To illustrate the `Handler` mechanism, consider the example shown in Listing 1. It includes the relevant sections of the framework class `com.android.server.BluetoothManagerService`. When the service is constructed, it instantiates a `HandlerThread` object (line 6), a traditional `Thread` object associated with a `Looper`. The

```

1| class BluetoothManagerService {
2|     private HandlerThread mThread;
3|     private BluetoothHandler mHandler;
4|
5|     public BluetoothManagerService() {
6|         mThread = new
7|             HandlerThread("BluetoothManager");
8|         mThread.start();
9|         mHandler = new
10|             BluetoothHandler(mThread.getLooper());
11|     }
12|     public void enable() {
13|         Message msg =
14|             mHandler.obtainMessage(MESSAGE_ENABLE);
15|         mHandler.sendMessage(msg);
16|     }
17|     public void disable() {
18|         Message msg =
19|             mHandler.obtainMessage(MESSAGE_DISABLE);
20|         mHandler.sendMessage(msg);
21|     }
22|
23|     class BluetoothHandler extends Handler {
24|         public void handleMessage(Message msg) {
25|             switch (msg.what) {
26|                 case MESSAGE_ENABLE:
27|                     // process enable message
28|                     break;
29|                 case MESSAGE_DISABLE:
30|                     // process disable message
31|                     break;
32|                 // Other cases.
33|             }
34|         }
35|     }
36| }
```

Listing 1: Bluetooth Handler in the Bluetooth manager service. Code was simplified for readability.

purpose of the `Looper` class is to sequentially process the messages in a message queue. At line 8, the class-specific `BluetoothHandler` object is created and associated with the newly created `Looper` from the `HandlerThread`. This allows messages sent to the `BluetoothHandler` to be pushed to the message queue for this `Looper`. Methods `enable` and `disable` can be called by applications via RPC on `IBluetoothManager` to turn the bluetooth functionality on or off. Method `enable` sends a message with code `MESSAGE_ENABLE` to the `BluetoothHandler` (line 12). When the associated `Looper` instance processes the message, it calls method `handleMessage` in the `BluetoothHandler` (line 20), which then processes the request.

Statically resolving message-based IPC, requires to overcome several challenges. First, the target `Handler` type has to be inferred, to determine the concrete `handleMessage` method of the receiving class that processes the message. Second, to add precision to the analysis, it is best to make it locally path-sensitive by inferring the possible message codes of the arguments to `sendMessage` methods. For the example presented in Listing 1, this enables the analysis to be limited to the feasible paths for a given message in the switch at line 21. While it is possible to per-

²By convention non-generated class names end with `Native`.

form the analysis without this information, doing so results in a significant loss of precision and, thus, an increase in the number of false positives, which may distort the results of security analyses built on top. In light of the prevalence of the `Handler` pattern, this loss of precision is not an acceptable solution. Finally, since messages can also be associated with runnable tasks instead of message codes, the concrete `Runnable` types associated with each message have to be inferred to determine the runnable code executed when such a message is processed.

AsyncChannel. Closely related to `Handlers`, `com.android.internal.util.AsyncChannel` implements a bi-directional channel between two `Handler` objects. It provides its own `sendMessage` and `replyToMessage` methods, both of which delegate to the `sendMessage` methods in its associated `Handler`. In order to precisely model `AsyncChannel` objects, it is necessary to infer the types of the sender/receiver `Handler` objects. Similarly to `Handlers`, path-sensitivity should be added to the analysis by inferring the message codes that are sent through the channel.

StateMachine. Building on the `Handler` concept, the `com.android.internal.util.StateMachine` class models complex subsystems such as the DHCP client or the WiFi connectivity manager. This class allows processing of messages depending on the current state of the modeled system. It effectively constitutes a hierarchical state machine in which messages cause state transitions. States are organized in a hierarchical manner, such that parent states may process messages that are not handled by child states. In order to precisely model state machines, several challenges must be addressed. First, the subtype of the state machine itself must be inferred, with all the states and possible transitions. Second, the hierarchy of the states must be inferred, in order to know which `enter` and `exit` state methods are called upon state transitions. Moreover, this is necessary to know which state may handle a given message. Third, for eliminating further false positives one needs to infer the possible states for any given program location at which interaction with the state machine occurs.

4.3 Identifying Protected Resources

While the previous sections show how static analysis of the android application framework code base can be enabled, we now classify the resources inside the application framework that actually have

to be protected. Unfortunately, there is a lack of consensus in the community on what constitutes a security-sensitive resource/operation [5, 16] and no one-size-fits-all definition exists as the concrete definition depends on various aspects like operating system, programming language, or even the domain. To avoid ambiguities on what we denote as protected resource in the remainder of this paper, we note that protected resources for us are security sensitive operations that have a tangible side effect on the system state or use of privacy.

Challenge: *Defining the security-relevant resources is, in contrast to entry points, more challenging. For privacy leak analysis at application-level, there is a well-defined list of API methods that can be classified as sinks. Since the analysis now shifts into the API methods of the framework, it is unclear what kind of resources are protected by Android’s permissions and can, thus, be used as sinks for security analysis within the framework.*

To create a first high-level taxonomy of protected resources that can help to automatically discover such resources, we first have to create a ground truth about what technically forms a protected resource. To this end, we manually investigated control flows of a number of identified PPEP in the framework’s source code. Here, we make the assumption that every existing permission check within the application framework indeed controls access to at least one security- or privacy-critical system resource. Checks are usually located at the very beginning of PPEP, so that any subsequent operation is indeed authorized. Using expert knowledge in combination with descriptions of expected side effects from the Android documentation we identify and annotate relevant statements that modify the service and/or system state. To avoid a potential bias in the types of protected resources, we chose entry points from eight different entry classes. To cover a variety of disjunct cases, we based our selection on the available information such as return value, number/type of EP input arguments, or number/type of permission checks collected during the entry point discovery. After manually investigating flows from 35 entry points, distinct repetitive patterns for protected resources appeared across the different control flows, which we summarized in a taxonomy of the high-level protected resource types.

Taxonomy of protected resources. Figure 2 presents our high-level taxonomy of the protected resource types. In contrast to work at application-level that disregards field instructions [5], we found that `field update` instructions are highly relevant in the

context of the framework and in fact are the most prevalent type of protected resources that we discovered. Relevant *method invocations* can be further sub-classified into native method calls (e.g. for file system access or modification of device audio settings) and broadcast sender. We consider native method calls generally as protected resources, since distinguishing non-/security-relevant native calls would require a dedicated analysis for the native code, which is currently a general, open problem for the community and out of scope for this work. Broadcast senders are protected resources as they can potentially cause side-effects on the system or apps. However, this is statically unresolvable, as the concrete side-effects strongly depend on the current system configuration, e.g. on the installed apps and the set of active broadcast listener. We consider non-void *return values* of security-sensitive entry methods as protected resource. Returned objects of such methods constitute sensitive data, e.g., a list of WiFi connections. Return values of primitive types `int` or `boolean` may constitute sensitive values like for the method `isMultiCastEnabled` of the `WifiService` or some status/error code in method `enableNetwork` of the same service. We also found cases in which a *throw RuntimeException* (RTE) has to be considered as a protected resource. For instance, in the `crash` method of the `PowerManagerService`, which requires from the caller the permission to reboot the device, an RTE causes the runtime to crash and the device to reboot in consequence.

Coverage of the taxonomy. An inherent limitation of our taxonomy based on small-scaling manual analysis is, that there are no guarantees that corner cases are included in the current classification. To cover all corner cases in our taxonomy, a comprehensive manual analysis of the framework would be required, which would defeat the purpose of enabling a static analysis in the first place. This constitutes a high-level taxonomy of protected resource (types) in the framework. Distilling a more refined set for security analyses is discussed separately in Section 8.

5 Implementation

We combined all aforementioned steps from Section 4 for analysis of an arbitrary framework version into a tool called `AXPLORER`. We leverage the static analysis framework `WALA` [2], although our approach is equally applicable to other analysis frameworks such as `Soot` [1]. Additional code for realizing our approach comprises ≈ 15 kLOC of Java.

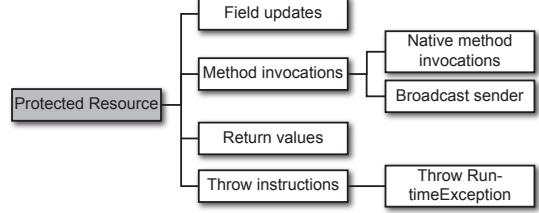

Figure 2: High-level taxonomy of protected resource operation types.

Call-graph generation. For each identified entry class, we generate an inter-procedural call-graph (CG). As opposed to related approaches [7] that use class hierarchy analysis to generate low-precision call-graphs due to the overall framework complexity—Android version 4.2.2 already includes over 35,000 classes—we generate high-precision call-graphs with object-sensitive pointer resolution. For each virtual or interface invocation we infer the runtime type(s) and hence precisely connect the invocation to its target(s). Although the costs for the points-to computation are computational very expensive, the increased precision lowers the complexity of the overall call-graph, since we do not introduce imprecision by considering all subclasses of a virtual method call as potential receivers. Avoiding this imprecision in the call-graph also lowers the number of false positives. The complexity is further reduced by the design decision to not follow RPC calls to other entry classes. We complement the call-graph with message-based IPC edges during the control-flow slicing (see below).

Slicing & on-demand msg-based IPC resolution. We conduct a forward control-flow slice for each identified entry point method. The slicer stops at native methods, RPC invocations to classes other than the current one, and when the entry point method returns. During slicing, we perform an on-demand message/handler resolution to add message-based IPC edges to the call-graph, thus avoiding a huge computational overhead of computing all edges in advance when only a subset of them are required for analysis (e.g. if PPEP are analyzed only).

When the slicer reaches a `sendMessage` call, we infer the concrete handler type and add a call edge from the `sendMessage` call to the `handleMessage` method of the receiving handler. We augment this process with inter-procedural backwards slicing for two reasons: First, since existing type inference algorithms (like the ones implemented in `WALA`) work intra-procedurally, type inference fails if `Handler` objects are stored in fields whose declared field type is the

`Handler` base class and not the concrete subtype. Using inter-procedural backwards slicing starting at the message-sending instruction, we obtain a more precise set of possible handler types in AXPLORER. Second, `Messages` are usually not constructed explicitly but indirectly obtained via calls to `Message.obtain` or `Handler.obtainMessage` and contain a public integer field that carries a sender-defined message code that allows the recipient to identify the message type. To statically identify the message code we compute a backwards slice starting from the message-sending instruction and check the resulting set of instructions for calls that construct/obtain a message. We then repeat this approach starting from the message obtain call to infer the concrete message code used to initialize the `Message`.

`Handlers` use `switch` statements to match the provided message code and to transfer control-flow to a specific basic block of the method’s control-flow graph (cf. line 25 et seqq. in Listing 1). To avoid infeasible paths, we have to recreate path-sensitivity intra-procedurally and map the message code(s) to the individual execution path(s). The control-flow slicer then continues at this specific execution path to avoiding a huge number of false positives. `Runnable` types on a `post` call of the `Handler` are resolved in the same way and a call edge to the `Runnable`’s `run` method is added. The approach slightly differs in case of `StateMachines`. Here, there is no single `handleMessage` function. Instead, each `StateMachine` implements its own `processMessage` function. In this case, we recreate path-sensitivity for each of these functions and delegate the control-flow to any matching switch statement.

6 Framework Complexity Analysis

We apply our gained insights from Section 4 to collect complexity information about the application framework. By doing this, we demonstrate how the analysis complexity can be held manageable to allow such in-depth analysis within a reasonable amount of time. Finally, we collect the framework’s protected resources as denoted in our taxonomy and validate the results (a detailed discussion on how security analyses can benefit from this is given in Section 8). Using AXPLORER we analyze four different Android versions: 4.1.1 (API level 16), 4.2.2 (17), 4.4.4 (19), and the latest Lollipop release 5.1 (22).

6.1 Handling Framework Complexity

Table 1 summarizes different complexity statistics generated for the four analyzed versions. Unsur-

prisingly, the complexity in terms of code increases with each version, whereas the gap to the most recent major version is significantly larger as between the minor version changes due to new features like Android TV. The entry class discovery algorithm identified between 242–383 entry classes of which $\approx 25\%$ include at least one PPEP. The evaluation was conducted on a server with four Intel Xeon E5-4650L 2.60 GHz processors with 8 cores each and 768 GB RAM. Initial processing of the frameworks finished in reasonable time, ranging from 14–126 hours. Note that this computation has to be done only once per Android version and that there are no real-time constraints as, e.g., in application vetting. The most time-consuming task (about 85% of the overall time) was generation of the high-precision call-graphs. In the following, we describe the use of entry-class interconnection and IPC analysis to speed up processing time without loosing the precision of our data model.

Entry class interconnection. IPC-interfaces of framework entry classes are not only used by the application layer, but also by other framework services. Analyzing the communication behavior of entry classes does not only provide a deeper understanding of how the framework services are interconnected but also facilitates analyses that rely on permission checks as security indicator (e.g., see Section 7). Exploiting the knowledge about which service EP triggers which RPCs along its control flow enables pre-computation of execution path conditions and restricting the scope of a service analysis to only subsets of dependent services rather than the entire framework (i.e, it allows to efficiently divide and conquer the framework analysis). In a post-processing step the analysis results for distinct services can be stitched together at RPC boundaries. Appendix A illustrates the RPC interconnections for Android 5.1.

Message-based IPC Analysis. A precise model of the message sender to handler relations is crucial for the generation of a static runtime model of the framework with a low number of false connections. The last row in Table 1 shows the prevalence of the message sending pattern. Between 38–52% of PPEP include at least one message sending call. Across API levels we found 300 (API 16) to over 500 (API 22) distinct message sender calls used within PPEP. The evaluation of our IPC analysis showed that in 7% of all cases the message was sent to a `StateMachine`, and in 27% of all cases to a `Handler`. In the remaining 66% a `Runnable` was posted. This ratio remains approximately the same in all versions. Overall, our IPC analysis was able to fully resolve about 76%

Android version	4.1.1 (16)	4.2.2 (17)	4.4.4 (19)	5.1 (22)
# of classes	27,749	29,804	31,023	46,192
- inner classes	14,784	15,936	17,525	28,933
# of entry point classes	242	256	284	383
- with at least one PPEP	64 (26.4%)	73 (28.5%)	75 (26.4%)	81 (21.2%)
# entry methods (EP)	2,583	2,734	2,861	3,225
- with perm check (PPEP)	863 (33.4%)	1,018 (37.2%)	1,227 (42.9%)	1,250 (38.8%)
- incl. message sending	328 (38.0%)	532 (52.2%)	518 (42.2%)	597 (47.8%)

Table 1: Comparing complexity measures for different Android versions (percentages relate to preceding line).

of all message sending instances, yielding already a very valuable data set of the message sender to handler relationships. Reasons for failed resolution are that either the `Handler` (81%) or `Runnable` (5%) could not correctly be inferred while in the remaining 13% of cases the message code could not be inferred. The root cause of most of these failures is the missing/incomplete support of `AsyncChannels` and the `Message.sendToTarget()` API call. At the time of writing this support is work-in-progress.

During our initial analysis run AXPLORER records both an RPC-map per entry class as well as a list of resolved sender-to-handler relationships. This data is then re-applied as expert knowledge in subsequent analysis *re-runs* to significantly reduce the analysis runtime, e.g., for API level 17, the processing time drops by ~75% to about 7 hours. By publishing this data we hope that independent analyses can equally benefit from this by removing the burden to re-implement a comparable IPC resolution algorithm.

Reflection We analyzed reflection usage within framework code by counting the number of calls to methods within the `java.lang.reflect` package. The absolute numbers range from 89 (API 16) to 118 (API 22). Across API levels less than 50% targeted the `Method` class while the remaining calls were distributed among other reflection classes. In many cases reflection is used in utility or debug classes and we found only one entry class that makes use of reflection (`ConnectivityService`), but the respective method was removed in API level 20. In SDK code the total numbers are slightly higher across API levels (115–288). However, the additional usage of reflection is mainly due to `View/Widget` classes. Overall, reflection is only rarely used in framework code and not used at all by main service components.

6.2 Android’s Protected Resources

To validate our established taxonomy, we collect the protected resources for each Android version and classify them with respect to the taxonomy. Across

versions the total number ranges from 6,5k (API 16) to 10k (API 22). Although these numbers seem quite high at first glance, they are reasonable in relation to the overall size and complexity of the framework. AXPLORER recorded the context depth (in terms of method invocations) at which the protected resources were found. While for simple methods that include few (or only even one) resource the call depth is lower than two, the median call depth ranges from 8–11 across Android versions. This emphasizes that approaches that do not perform in-depth analysis are not suitable to detect resources located deeper in the control-flow. The relative distribution of resources per type is stable across all versions. We validated our statement of Section 4.3 that field update instructions are the most prevalent resource type (with a share of about 75%). They are followed by native method calls (about 21–23%), which are most frequently used as a gateway to the device hardware (e.g. file system, audio, nfc). There is a surprisingly low number of PPEP that return a protected value, the absolute number ranges from 51–69 entries. Another unexpected result is that runtime exceptions occur with a frequency that is about as high as protected broadcast senders. Besides the already mentioned example within the `PowerManagerService`, we found occurrences in UI widget classes and even in the default XML parsing library on Android.

Appendix B gives more detailed statistics on protected resources, as well as a manual validation and assessment of the use of RTE in the framework.

7 Permission Analysis

Building on top of our new insights we re-visit an important aspect of Android’s permission specification, that is *permission mapping* between permission check and SDK method, and further introduce *permission locality* to study which framework components perform which permission checks. To this end we extend AXPLORER as follows:

- 1) A PPEP only indicates the presence of a permission check in the control-flow from this

entry-point, but there is no information yet about the number of checks or the concrete permission strings. We extend our slicing-based approach to also resolve the permission strings in common permission check API invocations (e.g., as defined in the `Context` class). Non-constant strings are resolved in a similar way like message codes in Section 5. From 520 distinct permission checks found in API level 16, we were able to resolve 99% of the permission strings. Among the failing cases, one case was located in the `ActivityManagerService$PermissionController` class where the permission string is an argument of the entry point method, which is only called from native code and hence was not statically resolved.

2) Entry class interconnection, i.e., RPC transitions to other PPEP (see Section 6.1), usually accumulates all permissions required by the additionally called entry classes for the UID that called the first entry class in the control-flow. However, those transitions are irrelevant for permission analysis when the RPC is located between calls to `Binder.clearCallingIdentity` and `Binder.restoreCallingIdentity`. Clearing the calling UID in the framework’s bound services resets it from the calling app’s UID to the privileged system server UID. Thus, outgoing IPC edges after clearing and before restoring the UID should be ignored in permission analysis, since the additional PPEP are called with a UID that is different from the calling app’s UID.

3) We add a light-weight SDK analysis to reason about required permissions of documented APIs. To this end, we conduct a reachability analysis from public SDK methods to framework EPs (SDK to framework layer in Figure 1). Combining this mapping with the mapping from framework EPs to permissions creates a permission map for the documented API.

7.1 Re-Visiting Permission Mapping

The *Stowaway* project [32] were the first to generate a comprehensive permission map for Android 2.2. Their dynamic analysis approach (feedback directed API fuzzing) generates precise but incomplete results. Moreover, the involved manual effort makes it difficult to re-use it for newer API versions. *PScout* [7] improved on this situation by statically analyzing the framework code, thus increasing the code coverage. In direct comparison *PScout*’s results contain notably more permission mappings. To handle the complexity induced by the framework size, *PScout* resorts to low-precision data models based on class hierarchy information. In the following, we demon-

strate that this has negative implications for their resulting permission map. Using our insights we provide permission mappings that call the validity of prior mappings into question.

We compare our results with *PScout* using their latest available results (for Android 4.1.1)³. Since we exclude `Intent` and `ContentProvider` permissions, which both require supplemental analysis effort such as manifest or `URI` object parsing, we restrict the comparison to un-/documented APIs. For the evaluation we include the standard system apps and make identical assumptions as *PScout*, i.e., we assume that any permission found for a particular API is indeed required (a more precise analysis would require path-sensitivity). Moreover, like *PScout*, we did not conduct a native code analysis.

7.1.1 Documented API map

Figure 3 shows for our documented API map (SDK EP to permissions) how often a certain permission is required. For some permissions *PScout* reports higher numbers while for others AXPLORER reports higher numbers. Since the results are fairly deviating, we manually inspected various cases, including a full analysis of NFC and bluetooth, to verify correctness of our generated numbers. *PScout*’s higher method count, particularly for the two cases of NFC and bluetooth, originates from adding package-protected methods that are not exposed to app developers and from improper handling of the `@hide` javadoc⁴ attribute, resulting in an overcounting of the documented API methods. Our higher numbers of `BROADCAST_STICKY` and `SET_WALLPAPER` mainly refer to abstract methods from the `Context` class that are implemented in its subclass `ContextWrapper` and then inherited by 18 non-abstract subclasses (for API 16). Instead, *PScout* only lists those methods for the `Context/-Wrapper` class, thus missing to count the non-abstract subclasses.

Figure 4 provides a different view of the mapping by showing the distribution of required permissions per API. The main difference is the smaller number of outliers in our data set: four mappings with three or more required permissions, compared to 58 such outliers in the *PScout* data set. While the different results in Figure 3 mainly originate from technical shortcomings in the SDK analysis, Figure 4 hints at the different quality of the undocumented API map as result of a more precise

³We use *PScout*’s results as published on their website at <http://pscouth.cs.toronto.edu>. Last visited 01/25/2016.

⁴EP methods annotated with the `@hide` attribute are not included in the SDK.

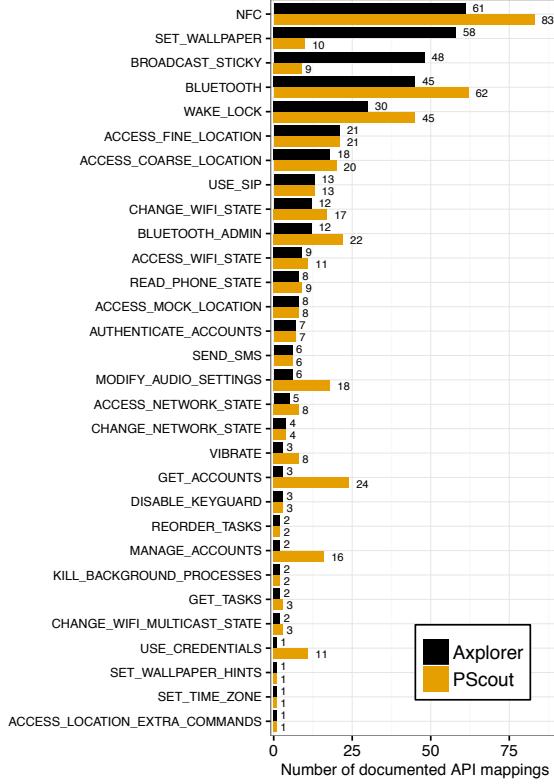

Figure 3: Number of documented APIs per permission.

framework analysis (see next Section 7.1.2). *PScout*'s more light-weight framework analysis results in an over-approximation of permission usage of EPs. For their outliers with more than five permissions in the `ConnectivityManager` class they either overapproximate the receivers of a `sendMessage` call and/or did not resolve the message code and the correct path in the `handleMessage` method. In such cases the over-approximation in the framework analysis negatively influences the quality of the SDK map when IPC calls from the SDK to the application framework are connected. We manually validated all outliers and found that no method actually requires more than three permissions, thus contradicting the *PScout* results. The four outliers in our dataset check at most two permissions, independent of the EP call arguments. Additional permission checks might be required for specific arguments/parameters. For instance the `setNetworkPreference(int)` function of the `ConnectivityService` will tear down a specific type of network trackers depending on a preference integer argument. Some subtypes such as the `BluetoothTetheringDataTracker` require both bluetooth permissions to execute this functionality while other subtypes require no additional permis-

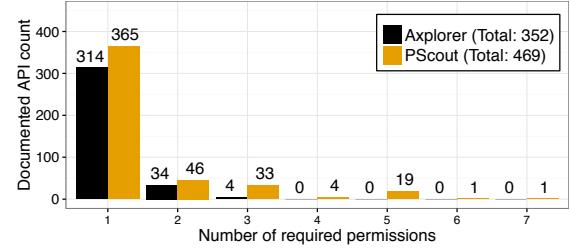

Figure 4: Number of permissions required by a documented API.

sion. Adding parameter-sensitivity to the analysis is required to resolve such cases automatically and to annotate permission checks with conditions.

7.1.2 Undocumented API map

A fair, direct comparison of permission maps for undocumented APIs is unfortunately very difficult due to shortcomings in the original paper. Although *PScout* did not explicitly define the term *undocumented API*, we assume after manual inspection of their results that it refers to the publicly exposed framework interfaces and covers any functionality that can be called from application level (independent of whether it is provided by SDK or system apps). Hence we refer to undocumented API as the entire set of framework entry points (cf. Section 4.1).

In contrast to *PScout*'s documented API map, we discovered different inconsistencies in their undocumented mappings. Besides valid mappings from PPEP to permissions, they also include mappings for unrelated methods. First, public methods of AIDL-based entry classes (which we define as *Entry Points*) are counted up to five times: once in the SDK manager class, in the framework service class, in the AIDL interface class, and in the auto-generated `Stub` and `Proxy` classes. Second, their mapping contains methods of `StateMachine` classes. `StateMachines` are used framework-internally and their functionality is not exposed to apps. Third, synthetic accessor methods as well as methods of anonymous inner classes are reported. We assume that this problem is related to the lack of a concise entry point definition that induces difficulties with the abort criteria during their backwards analysis starting from permission checks. In contrast, our forward analysis seems more suitable in this context, as permission checks are usually closely located to framework EPs.

Table 1 reports on the numbers of entry points per API level. For Android 4.1.1, AXPLORER found 863 PPEP (33.4% of entry points) that require at least one permission. These numbers include signature/

OrSystem permissions since this information, although not interesting for app developers, is of interest for understanding the Android permission model in its entirety. On average we found 1.17 permissions per PPEP, which leads to a total of 1,012 permission mappings that cover 129 distinct permissions. This is a magnitude less than the 32,304 permission mappings reported by *PScout* for normal and dangerous permissions only. However, due to our more concise definition of what constitutes public framework functionality and the inclusion of all permission levels, we argue that our number is more substantiated.

7.2 Permission Locality

The application framework implements a separation of duty: every bound service is responsible for managing a certain system resource and enforcing permissions on access by apps to them. For instance, the `LocationService` manages and protects location related information or the `PhoneInterfaceManager` facilitates and guards access to the radio interfaces. Permission strings already convey a meaning of the kind of system resource they protect and app developers might have an intuition where those permissions are required. We study whether permission checking also follows the principle of separation of duty and permissions are checked by only one particular service. We call this aspect *permission locality*. A low permission locality indicates that a certain permission is enforced at different (possibly unrelated) services. This potentially contributes to the app developer’s permission *incomprehension* that can lead to overprivileged apps [32]. Moreover, a strict separation of duty, i.e., high permission locality, significantly eases the task of implementing (and verifying) authorization hooks for resources, for instance in the design of recent security APIs [21, 8]. Consequently, the permission that protects a set of sensitive operations is ideally checked only in one associated entry class.

To study the permission locality, we analyze the checked permission strings and map them to the enclosing class of the permission check call. In Android v4.1.1 (API level 16) we found that out of 110 analyzed permissions 22 (20%) are checked in more than one class. Among these permissions, 13 are checked in two classes, 5 in three classes and 4 in four classes. An example for seemingly unrelated classes are `LocationManagerService` and `PhoneInterfaceManager` that both check the dangerous permission `ACCESS_FINE_LOCATION`. While the permission is intuitively related to the first service, the connection to the latter one becomes only obvious by looking at the enclosing method that

includes the check (e.g. `getCellLocation`). Interestingly, `PhoneInterfaceManager` is not a framework service but included in the telephony system *app*. Mixing framework services and system apps for enforcing identical permissions complicates permission validation and policy enforcement, since system apps might be vendor-specific. Grouping permissions by protection level results in 22.2% (12/54) of normal/dangerous permissions and 17.9% (10/56) of signature/-OrSystem permissions being checked in distinct classes. This implies that low permission locality equally affects all protection levels. Applying this analysis on API 22 results in an even lower overall permission locality. Focusing on the four outliers in API 16, changes in API 22 include three class renamings, two removals and nine additions (cf. Figure 6 in Appendix C). The permission `CONNECTIVITY_INTERNAL` more than doubled the number of classes (10) in which it is enforced. This evolution of permission checks indicates a disconcerting trend to lower permission locality.

Instead, the permission locality should be increased by, ideally, associating each permission with a single service. Once a designated owner service has been identified for each permission, a dedicated permission check function could be publicly exposed via its `Binder` interface, e.g., a method to check the `ACESSS_FINE_LOCATION` permission could be added to the `ILocationManager` interface. The addition and removal of callers to such methods then no longer affects the number of decision points and preserves the separation of duty for permission checks.

8 Discussion of Other Use-Cases

We briefly discuss further use-cases that can benefit from our work, particularly from our taxonomy of protected resources and the insights from our permission locality analysis.

Permission check inconsistencies. Prior work *Kratos* has shown that the default permission check is inconsistent and can lead to attacks [33]. However, this approach explicitly did not make the attempt to identify protected resources in Android’s application framework but instead relied on arbitrary shared code as heuristic to identify security relevant hotspots in the framework’s code base. While this approach has successfully demonstrated the need for such analysis, we argue that using our definition of protected resources as refinement of shared code can further improve the precision of their analysis, since, by definition, protected resources describe sensitive operations. False positives originating from shared logging

or library code are automatically eliminated then. Distilling a more concise definition of field-update and native method call resources from our high-level taxonomy is a promising future work. An example for such refinement is the removal of non-relevant field updates of a `this` reference within constructors. As there is no prior state for this object, such updates must not be flagged as protected resource.

Authorization hook placement. Different Android framework extensions [26, 46, 29, 12, 21, 8] augment the application framework with authorization hooks in a best effort approach. On commodity systems, a comparable situation for the Linux and BSD kernels has been improved through a long process that established a deeper understanding of the internal control and data flows of those kernels and that allowed development of tools to verify or automate placement of authorization hooks. A similar evolution for Android’s application framework has yet been precluded due to open technical challenges: first, one must be able to analyze control and data flows in the framework across process and service boundaries; second one must be able to track the execution state of the framework service along its internal control and data flows (e.g., tracking the availability of the subject identity); third, one has to establish a clear and very specific understanding of the protected resources of each service. This work at hand addresses the first of these challenges and provides necessary permission locality information to implement comprehensive, coarse-grained enforcement models. Additionally, with our high-level taxonomy of protected resources we made a first step towards solving the third challenge.

9 Conclusion

In this paper, we studied the internals of the Android application framework, in particular challenges and solutions for static analysis of the framework, and provided a first high-level classification of its protected resources. We applied our gained insights to improve on prior results of Android permission mappings, which are a valuable input to different Android security research branches, and to introduce permission locality as a new aspect of the permission specification. Our results showed that Android permission checks violate the principle of separation of duty, which might motivate a more consolidated design for permission checking in the future. To allow app developers and independent research to benefit from our results, we published our data sets as

well as lint rules for our permission mappings for the Android Studio IDE at <http://www.axplorer.org>.

Appendix

A Entry Class Interconnection

A standard call graph gives information about the enclosing method/class of function calls. However, this information is insufficient to provide information about the interconnection of framework entry classes. Instead, the interesting information is the originating entry class that leads to an RPC rather than the actual class that encloses the RPC. To provide better information on the RPC dependencies of entry classes, AXPLORER creates an RPC map by recording RPCs to other entry classes and mapping them to the original entries during control-flow slicing. Figure 5 shows a subgraph of the overall RPC interconnections between flows from different entry classes on Android 5.1 that AXPLORER generated. Nodes correspond to entry classes and are weighted by in-/out-degree, thus highlighting highly-dependent classes such as `ActivityManagerService`. The source of a directed edge is the originating entry class: the control-flow starts at an entry method of this class and at some point along the flow, not necessarily in the same class, an RPC to the class of the edge target node is invoked.

Across all four investigated Android versions there is a median number of three distinct RPC receivers per entry class in our map. The `ActivityManagerService` is an exceptional case where flows from its entry methods reach 36 different entry classes. These numbers emphasize that large parts of the framework are strongly connected and that detailed knowledge about the communication behavior greatly simplifies further framework analyses as explained above.

B Evaluation of protected resources

B.1 Statistics on protected resources

Table 2 provides absolute numbers of protected resources by API version and the distribution by resource types.

B.2 Manual investigation of RTE

Due to the surprisingly high number of runtime exceptions and the fact that uncaught RTE might potentially crash the system, we manually investigated the corresponding code locations to better understand their security implications. The

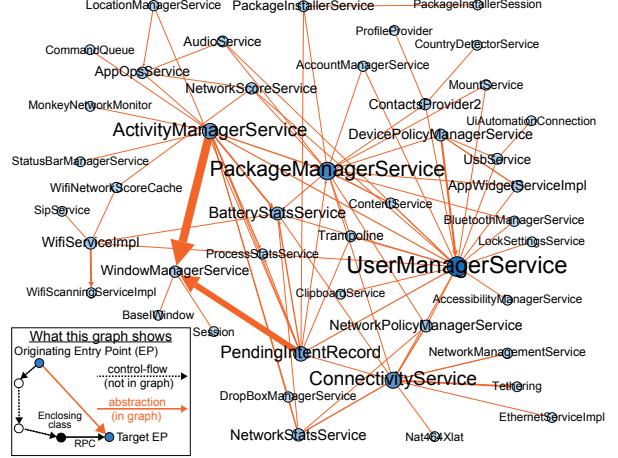

Figure 5: Subgraph of overall entry class interconnection via RPCs in Android 5.1. Directed edges show an RPC to an exposed `IInterface` method of target node.

source code analysis revealed that these instructions reside both in Android’s code base and in external library code. Android, similar to other operating systems, relies on external libraries for specific tasks, such as XMLPullParser, Bouncy Castle, and J-SIP. Integrating library code into such a complex system usually raises the question on how to handle unchecked exceptions that are thrown by library functions. Either the library code is patched, which might be a tedious maintenance task, or exceptions are caught at caller site. Although the latter case is considered bad practice in case of runtime exceptions, using generic catch handler around library call sites is the easiest and most reliable approach in this situation.

Runtime exceptions in the Android code are thrown to indicate precondition violations, like crucial class fields being null, unrecoverable IO errors, or security violations. The implications of a runtime exception differ with respect to code location in which they are thrown. Exceptions in the application layer, i.e. in system applications, cause the respective app to crash. Similarly as for normal apps, they can be restarted by the user. Sticky system app services are restarted automatically by the system. Exceptions thrown in bound services of the `SystemServer` are handled in a special way: A system watchdog thread `com.android.server.Watchdog` constantly monitors the core services like `PowerManagerService` and `ActivityManagerService`. In case of a crash or deadlock, it reboots the entire system. Uncaught runtime exceptions in unmonitored system services cause the Android Runtime, including Zygote and

Android version	4.1.1 (16)	4.2.2 (17)	4.4.4 (19)	5.1 (22)
# of protected resources	6,490	6,969	7,488	10,044
- field updates	4,891 (75.36%)	5,268 (75.59%)	5,675 (75.79%)	7,520 (74.87%)
- native method calls	1,433 (22.08%)	1,499 (21.51%)	1,643 (21.94%)	2,305 (22.95%)
- return value	51 (0.79%)	60 (0.86%)	54 (0.72%)	69 (0.69%)

- throw runtime exception	50 (0.77%)	70 (1.01%)	63 (0.84%)	72 (0.71%)
Median context depth	8	9	11	9

Table 2: Numbers on protected resources by type and Android version.

the SystemServer to be restarted (hot reboot) while the kernel keeps running—effects also described in recent research [22].

C Statistics on permission locality

Table 3 shows a detailed statistic about the number of permissions in API 16 that are checked in more than one class, grouped by their protection level. These numbers imply that there is no apparent correlation about the relative frequency and the protection level, in particular between the permissions available to third-party apps (normal+dangerous) and the ones reserved for the system. Hence, low permission locality cases occur across all permission protection levels.

Protection level	# permissions
normal	2/16 (12.5%)
dangerous	10/38 (26.3%)
signature	2/25 (8%)
signatureOrSystem	8/31 (25.8%)

Table 3: Number of permissions in API 16 that are checked in more than one class grouped by permission protection level.

Figure 6 lists all four permissions that are checked in four distinct entry classes in API level 16 (colors denote changes in API 22). In case of READ_PHONE_STATE, those four classes even reside in four distinct packages of which one is part of the telephony system app. Although it may not always be easy to identify one dedicated service as the permission owner, an effort might be desirable to centralize permission checks into as few services as possible (in best case into a single service). Besides renamed classes (blue color) as result of a code refactoring process, the number of additions and removal for this small number of examples clearly confirms that permission checks are violating the separation of duty and underline the need for central enforcement points.

```

Abstract

Smartphone users often use private and enterprise data with untrusted third party applications. The fundamental lack of secrecy guarantees in smartphone OSes, such as Android, exposes this data to the risk of unauthorized exfiltration. A natural solution is the integration of secrecy guarantees into the OS. In this paper, we describe the challenges for decentralized information flow control (DIFC) enforcement on Android. We propose context-sensitive DIFC enforcement via *lazy polyinstantiation* and practical and secure network export through *domain declassification*. Our DIFC system, *Weir*, is backwards compatible by design, and incurs less than 4 ms overhead for component startup. With *Weir*, we demonstrate practical and secure DIFC enforcement on Android.

1 Introduction

Application-based modern operating systems, such as Android, thrive on their rich application ecosystems. Applications integrate with each other to perform complex user tasks, providing a seamless user experience. To work together, applications share user data with one another. Such sharing exposes the user’s private and enterprise information to the risk of exfiltration from the device. For example, an email attachment opened in a third party document editor (e.g., *WPS Office*) could be exported if the editor was malicious or compromised.

Android’s permission framework is used to protect application data. However, permissions are only enforced at the first point of access. Data once copied into the memory of an untrusted application can be exported. This problem is generic in OSes that provide only data protection, but not data secrecy, and can be solved by integrating information flow secrecy guarantees.

Classic information flow control (IFC) [8] only captures well-known data objects through a centralized policy. On Android, data is often application-specific (e.g.,

email attachments, notes). Therefore, Android requires decentralized IFC (DIFC) [21, 26, 44, 49], which allows data owners (i.e., applications) to specify the policy for their own data objects.

Although DIFC systems have been proposed for Android [19, 28, 46], existing enforcement semantics cannot achieve both security and practicality. For instance, an Android application’s components are instantiated in the same process by default, even when executing separate user tasks. Since the various secrecy contexts from the tasks share state in process memory, DIFC enforcement on the process is hard, as the combined restrictions from all secrecy contexts would make individual components unusable. Prior approaches solve this problem by eliminating Android’s default behavior of application multitasking, and in ways detrimental to backwards compatibility, i.e., 1) killing processes per new call, which could result in dangling state, or 2) blocking until the application voluntarily exits, which could lead to deadlocks.

Similarly, different secrecy contexts may share state on storage through common application files (e.g., application settings). Proposals to separate this shared state on storage (e.g., Maxoid [46]) either deny access to application resources or require applications to be modified. To summarize, prior DIFC proposals for Android cannot separate shared state in memory and on storage while maintaining security and backwards compatibility.

In this paper, we present *Weir*,¹ a practical DIFC system for Android. *Weir* allows data owner applications to set secrecy policies and control the export of their data to the network. Apart from the data owners, and applications that want to explicitly use *Weir* to change their labels, all other applications can execute unmodified. *Weir* solves the problem of shared state by separating memory and storage for different secrecy contexts through *polyinstantiation*. That is, *Weir* creates and manages instances of the application, its components, and its stor-

¹Weir: A small dam that alters the flow of a river.

age for each secrecy context that the application is called from, providing availability along with context-sensitive separation. Our model is transparent to applications; i.e., applications that do not use *Weir* may execute oblivious to *Weir*'s enforcement of secrecy contexts.

We term our approach as “*lazy*” *polyinstantiation*, as *Weir* creates a new instance of a resource only if needed, i.e., if there is no existing instance whose secrecy context matches the caller's. Additionally, *Weir* provides the novel primitive of *domain declassification* for practical and secure declassification in Android's network-driven environment. Our approach allows data owners to articulate trust in the receiver of data (i.e., trusted network domain). This paper makes the following contributions:

- We identify the challenges of integrating DIFC into Android. Using these challenges, we then derive the goals for designing DIFC enforcement for Android.
- We introduce the mechanism of “*lazy*” *polyinstantiation* for context-sensitive separation of the shared state. Further, we provide the primitive of *Domain Declassification* for practical declassification in Android's network-driven environment.
- We design and implement *Weir* on Android. *Weir* incurs less than 4ms overhead for starting components. *Weir*'s design ensures backwards compatibility. We demonstrate *Weir*'s utility with a case study using the *K-9 Mail* application.

While *Weir* presents a mechanism that is independent of the actual policy syntax, our implementation uses the policy syntax of the Flume DIFC model [21]. *Weir* extends Flume by allowing implicit label propagation, i.e., *floating labels*, for backwards compatibility with unmodified applications. Since floating labels are *by themselves* susceptible to high bandwidth information leaks [8], we show how *Weir*'s use of floating labels is inherently resistant to such leaks. Note that while language-level IFC models [40–42] often incorporate checks that prevent implicit flows due to floating labels, our solution addresses the challenges faced by OS-level floating label DIFC systems [19, 44]. Finally, we note that *Weir* provides practical DIFC enforcement semantics for Android, and the usability aspect of DIFC policy and enforcement will be explored in future work.

In the remainder of this paper, we motivate the problem (Section 2), and describe the challenges in integrating DIFC on Android (Section 3). We then describe the design (Section 4), implementation (Section 5) and security (Section 6) of *Weir*, followed by the evaluation (Section 7), and a case study (Section 8). We then discuss the limitations (Section 9), related work (Section 10) and conclude (Section 11).

2 Motivation and Background

We now motivate the need for data secrecy on Android. This is followed by background on DIFC and Android.

2.1 Motivating Example and Threat Model

Consider Alice, an enterprise user in a BYOD (bring your own device) context. Alice receives an email in the enterprise *OfficeEmail* application with an attached report. She edits the report in a document editor, *WPS Office*, and saves a copy on the SD card, accessible to all applications that have the READ_EXTERNAL_STORAGE permission. Later, Alice uses the *ES File Explorer* to browse for the report, edits it in *WPS Office*, and then shares it with *OfficeEmail* to reply to the initial email.

To perform their functions, untrusted third party data managers such as *ES File Explorer* require broad storage access. Even without direct access, user-initiated data sharing grants data editors like *WPS Office* access to confidential data. If *ES File Explorer* or *WPS Office* were malicious or compromised, they could export Alice's confidential data to an adversary's remote server.

Threat Model and Assumptions: We seek to enable legitimate use of third party applications to process secret user data, while preventing accidental and malicious data disclosure to the network. For this purpose, our solution, *Weir*, must mediate network access, and track flows of secret data 1) among applications and 2) to/from storage.

Weir's trusted computing base (TCB) consists of the Android OS (i.e., kernel and system services), and core network services (e.g., DNS). *Weir* assumes a non-rooted device, as an adversary with superuser privileges may compromise OS integrity. Further, we assume correct policy specification by the data owner applications, specifically regarding declassification. To prevent timing and covert channels based on shared hardware resources (e.g., a hardware cache), the only alternative is denying data access to secret data or the shared resource. *Weir* does not defend against such channels, which are notoriously hard to prevent in DIFC OSes in general.

2.2 Why Information Flow Control (IFC)?

Android uses its permission framework to protect user data. While permissions provide protection at the first point of access, the user or the data owner application (e.g., *OfficeEmail*) have no control over the flow of data once it is shared with another application (e.g., *WPS Office*). Unauthorized disclosure is an information flow problem that permissions are not designed to solve.

Information flow control (IFC) [8] can provide data secrecy and prevent unauthorized disclosure, through the definition and enforcement of the allowable data flows in the system. In an IFC system, subjects (e.g., processes)

and objects (e.g., files) are labeled with predefined security classes (e.g., top-secret, secret, confidential). The secrecy policy determines the data flow (i.e., ordering) between any two classes based on a partially ordered finite lattice. Labels may also be joined to form a higher label in the lattice. For secrecy, data can only flow up, i.e., to a higher security class [6], and violating flows require declassification by the policy administrator.

2.3 What is DIFC?

A centralized IFC policy can only describe the secrecy constraints for well-known data objects (e.g., location, IMEI). Decentralized IFC (DIFC) [26] extends the IFC lattice to include unknown subjects and objects, and is appropriate for protecting application-specific data, such as Alice’s secret report received by *OfficeEmail*. We now describe some fundamental aspects of DIFC.

Label Definition: In a DIFC system, security principals create labels (i.e., security classes) for their own secret data. On Android, decentralized label definition would allow apps to control the flow of their data by creating and managing labels for their data. Note that while DIFC also provides integrity, our description is for data secrecy as it is the most relevant to the problem in Section 2.1.

Label Changes and Floating Labels: The finality of subject and object label assignment is called *tranquility* [6], a property of mandatory protection systems. Tranquility constraints have to be relaxed for DIFC policy. Subjects may then change (raise or lower) their labels “safely”, i.e., with authorization from the data owners whose security classes are involved in the change.

Explicit label changes offer flexibility over immutable labels, but are not practical in environments where communication is user-directed and unpredictable a priori. *Floating* labels (e.g., in Asbestos [44]) make DIFC compatible with unmodified apps in such cases, by allowing seamless data flows through implicit label propagation. That is, the caller’s and the callee’s labels are joined, and the resultant label is set as the callee’s label.

Declassification: The network is considered to be public, and any network export requires declassification by the data owner. Data owners may choose to explicitly declassify every request to export their data, or allow trusted third parties to declassify on their behalf. While the former is impractical when frequent declassification is required, the latter bloats the data owner’s TCB.

System Integration: One of the first steps while integrating data secrecy into an existing OS is the selection of the subject for data flow tracking. Fine-grained dynamic taint tracking (e.g., TaintDroid [13]) labels programming language objects to provide precision, but does not protect against implicit flows. OS-based DIFC

approaches [21, 49] adopt the better mediated OS process granularity, but incur high false positives; i.e., functions sharing the process with unrelated functions that read secret data may be over-restricted. While secure process-level labeling is desired, practical DIFC enforcement must minimize its impact on functionality.

2.4 Android Background

The Android application model consists of four components, namely *activities* for the user interface (UI), *services* for background processing, *content providers* to provide a uniform interface to application data, and *broadcast receivers* to handle broadcast events.

Component Instantiation: Services and content providers run in the background, and have one active instance. Activities can have multiple instances, and the default “standard” launch behavior for activities is to start a new instance per call. Developers use Android’s “`android:launchMode`” manifest attribute to manage activity instances as follows: *SingleTop* activities are resumed for new calls if they already exist at the top of the activity stack. *SingleTask* and *SingleInstance* activities are similar in that they are allocated an instance in a separate user task and every call to such an activity resumes the same instance; the only difference being that the latter can be the only activity in its task.

Inter-Component Communication: Inter-component communication on Android can be 1) indirect or 2) direct. Indirect communication is an asynchronous call from one component to another, through the *Activity Manager* service (e.g., `startActivity`, `bindService`). Direct communication involves a synchronous *Binder* remote procedure call (RPC) to the callee using the callee’s “*Binder object*”. While direct communication bypasses the Activity Manager, its setup involves one mediated indirect call to retrieve the callee’s Binder object. For example, the first operation executed on a content provider (e.g., `query`, `update`) by a caller is routed through the Activity Manager, which retrieves the content provider’s Binder object and loads it into the caller’s memory. Future calls are routed directly to the content provider.

3 DIFC Challenges on Android

In this section, we discuss the four aspects of Android that make DIFC enforcement challenging. Further, we describe how previous Android DIFC systems fare with respect to the challenges, and state the design goals for practical DIFC enforcement on Android.

1. Multitasking on Android: Android’s UI is organized into user tasks representing the user’s high-level objectives. An application can be involved in multiple tasks

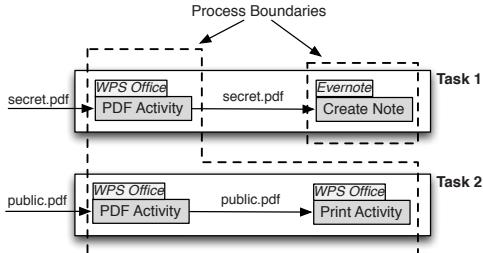

Figure 1: Shared state in memory: Instances of *WPS Office* performing different tasks in the same process.

by default. Further, a default activity can be instantiated multiple times in one or more concurrent tasks [3].

Figure 1 shows two tasks. In *Task 1*, the user opens a secret PDF (e.g., a contract) with *WPS Office*, which loads it in its *PDF Activity*, and shares it with the *Evernote* app. In *Task 2*, the user opens a non-confidential PDF (e.g., a published paper) in another instance of *WPS Office*'s *PDF Activity*. Further, in *Task 2*, the user chooses to print the PDF, which is then sent to *WPS Office*'s internal *Print Activity*. As seen in Figure 1, multiple activities of the *WPS Office* app as well as multiple instances of the *PDF Activity* run in the same process, and may share data in memory (e.g., via global variables).

As the two instances of the *PDF Activity* are instantiated with data of different secrecy requirements (i.e., *secret.pdf* and *public.pdf*), they run in different *secrecy contexts*. Enforcing the DIFC policy on the process due to the sensitive nature of *Task 1* would also unjustifiably restrict the non-sensitive *Task 2*. A naive solution of forcing every component to start in a separate process may break components; e.g., *Print Activity* may try to access a global variable initialized by the *PDF Activity*, and may crash if the *PDF Activity* is not in the same process. To summarize, component instances in various secrecy contexts often share state in process memory, making process-level enforcement challenging.

2. Background components: As described in Section 2.4, service and content provider components have only one active instance, which is shared among all of an application's instances, and may also communicate with other applications. As a result, various secrecy contexts may mix in a single background component instance.

If floating labels (described in Section 2.3) are applied, then the background component may accumulate the labels of all the secrecy contexts it communicates with, and then propagate its new label back to the components connected to it. This results in a *label explosion*, where the entire system acquires a large, restrictive label that cannot be declassified by any single security principal. Note that background components may run in the shared application process by default. Therefore, restarting a background component's process for each new call is infeasible, as it would crash the other components (e.g., a

foreground activity) running in that process.

3. Internal and External Application storage: Android provides each application with its own internal (i.e., private) storage shared amongst all of its runtime instances, irrespective of the secrecy context. For example, both the sensitive and non-sensitive instances of *WPS Office* may access the same user settings in the application's private directory. For availability from all secrecy contexts, storage access enforcement uses floating labels. The propagation of sensitive secrecy labels through shared application files (i.e., shared state on storage) may cause label explosion. The risk and impact of label explosion is higher on the external storage (i.e., the SD card) shared by all applications.

4. Internet-driven environment: Android applications are often connected to the Internet. In such an environment with frequent network export, explicit declassification by the data owner is inefficient. Delegation of the declassification privilege to allow export without the owner's intervention would bloat the application's TCB. Additionally, existing declassification mechanisms described in Section 2.3 make the policy decision based on the identity of the security principal performing the export. On Android, such mechanisms would limit the user to using a small subset of applications for data export (i.e., out of the 2 million applications on Google Play [39]), which would be detrimental to adoption of DIFC on Android.

3.1 Prior DIFC Proposals for Android

We discuss three prior DIFC proposals for Android, namely Aquifer [28], Jia et al. [19] and Maxoid [46], all of which are OS-level DIFC systems. Our objective is to understand the design choices made by these systems, with respect to the challenges described previously.

1. Aquifer: Our prior work, Aquifer [28], provides protection against accidental data disclosure, by tracking the flow of data through applications, and enforcing the declassification policy for network export.

For seamless data sharing between applications, Aquifer uses the floating labels described in Section 2.3. To limit label explosion, Aquifer does not label background components, and hence can only prevent accidental data disclosure. On the other hand, Aquifer labels storage, but does not claim to mitigate label explosion on storage. Further, to prevent different secrecy requirements for data in the memory of a single process, Aquifer disables Android's multi-tasking and restarts the process of the existing instance when the application is called from another secrecy context. Finally, Aquifer's declassification policy allows the data owner to explicitly specify the security principal that may export data,

or a condition on the call chain for implicit export.

2. Jia et al.: The DIFC system by Jia et al. [19] also uses floating labels to support general-purpose applications, but supports strict secrecy policies (i.e., relative to Aquifer) that may restrict data sharing among applications if needed.

Contrary to Aquifer, the system propagates labels to background components, providing stronger protection against malicious data exfiltration. At the same time, the system makes no claims of controlling label explosion via background components or storage. The system uses Flume’s capabilities [21] for declassification. This work also acknowledges the challenge of multi-tasking along with DIFC enforcement, and disallows multi-tasking by blocking new calls to an application until all of its components voluntarily exit. Since Android components do not exit by themselves like conventional OS programs, such blocking could potentially lead to deadlocks.

3. Maxoid: Xu and Witchel [46] provide an alternate approach to file system labeling to prevent label explosion in Maxoid, by using file system polyinstantiation [22] to separate differently labeled data on disk.

Maxiod addresses new calls to existing labeled instances in a manner similar to Aquifer’s; i.e., by restarting the instance. Additionally, Maxoid prevents access to background components from labeled instances, thereby preventing label explosion, although at the cost of backwards compatibility. On the other hand, Maxoid considers overt data flows through Binder IPC as declassification, unlike the system by Jia et al. that mediates such communication. Finally, Maxoid modifies system content providers (e.g., Contacts) to use a SQL proxy, in order to extend its label separation into system content providers. As a result, Maxoid’s storage separation is unavailable for use by content providers in unmodified third party applications.

Takeaways: Prior approaches demonstrate the possibility of DIFC on Android, and make convincing arguments in favor of using floating labels, mainly for backwards compatibility with Android’s unpredictable data flows. At the same time, we observe that in prior systems it becomes necessary to relax either security or backwards compatibility in order to use floating labels on Android (e.g., with background components). Additionally, prior approaches recognize the need to separate different secrecy contexts in process memory, but the proposed solutions disable Android’s default multi-tasking.² Finally, in systems that aim to address label explosion on storage, only separating the shared state on storage without addressing the shared state in memory may be insufficient to support unmodified applications.

²Killing existing processes or blocking can result in the killing of unrelated components sharing the process, or deadlocks, respectively.

3.2 Design Goals

Our objective is to design DIFC enforcement that provides security, and is backwards compatible with unmodified applications. Our design goals are as follows:

- G1** *Separation of shared state in memory.* DIFC enforcement must ensure that data from different secrecy contexts is always separated in memory, preferably in the memory of different processes. Process-level enforcement can then be used to mediate flows between differently labeled data.
- G2** *Separation of shared state on storage.* DIFC enforcement must ensure that data from different secrecy contexts is separate on persistent storage. For mediation by the OS, the separation must be at the level of OS objects (e.g., files, blocks).
- G3** *Transparency.* A naive implementation of goals **G1** and **G2** would affect the availability of components and storage. Our system must be transparent, i.e., applications that do not use the DIFC system must be able to operate oblivious to the enforcement.
- G4** *Secure and practical declassification for network export.* A DIFC system on Android should provide a declassification primitive that is both feasible (i.e., does not hinder the use of applications) and secure.

4 Weir

In this paper, we propose *Weir*, a practical and secure DIFC system for Android. *Weir*’s design is guided by the security and backwards compatibility goals described in Section 3.2. We now briefly describe the specific properties expected from our design, followed by an overview of *Weir* and design details.

Design Properties: Taking a lesson from prior work in Section 3.1, our system must allow seamless data sharing between applications for backwards compatibility with Android’s application model. Data flows must be tracked using implicit label propagation (i.e., floating labels), while mitigating the risk of label explosion. More specifically, our system must not deny data access, unless an application explicitly changes its label and fails a label check. Since our goal is to prevent unauthorized data export, network access may be denied if an application tries to export sensitive data to the network in violation of the declassification requirements of the data owner. Finally, our system must mediate all overt data flows, but covert channels existing in Android are not the targets of our system (discussed further in Section 9).

4.1 Overview

In *Weir*, applications define the policy for their data by creating their own *security classes*. *Weir* labels files (as

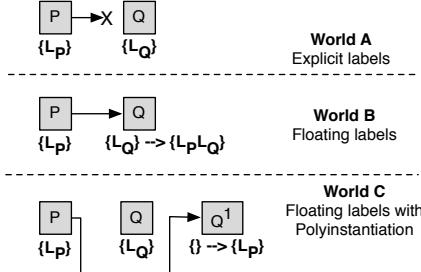

Figure 2: Overview of floating labels w/ polyinstantiation relative to explicit and floating labels.

objects) and processes (as subjects), granting the kernel complete mediation over all data flows among subjects and objects. As *Weir*'s contributions are in its policy-agnostic mechanism, we use the generic terminology from Section 2.3 in policy-related discussions. Section 5.1 describes our implementation's policy model.

Weir uses floating labels (described in Section 2.3), as explicit labels are hard to assign a priori in Android, where data flows are often user-directed and unpredictable. However, naive (i.e., context-insensitive) floating label propagation can cause certain components to acquire more labels due to involvement in multiple secrecy contexts, and eventually become unusable. We propose polyinstantiation to make floating labels context sensitive, and hence separate the shared state from different secrecy contexts in memory (**G1**) and on storage (**G2**). Our approach is in principal similar to context sensitive inter-procedural analysis that adds precision by considering the calling context when analyzing the target of a function call (e.g., summary functions and call strings [36], k-CFA [37], and CFL-reachability [31]). To our knowledge, context sensitivity has not been explored in the scenario investigated in this paper. Further, the approach of secure multi-execution [11] also uses multiple executions of the program, but is fundamentally different in many aspects, as we describe in Section 10.

We describe polyinstantiation relative to explicit and floating labels with the example scenario in Figure 2, where an instance of component *P* with label $\{L_P\}$ tries to send a message to an instance of component *Q* with a label $\{L_Q\}$, and where $\{L_P\} \neq \{L_Q\}$. In World A where only explicit labels are allowed, the message would be denied as *Q* would not be able to explicitly change its label to $\{L_P\}$ without a priori knowledge of *P*'s intention to send a message. In World B with floating labels, the flow would be automatically allowed, with *Q*'s new label implicitly set to a join of the two labels. While World B allows seamless communication, it does not prevent the two secrecy contexts (i.e., $\{L_P\}$ and $\{L_Q\}$) from mixing, leading to the challenges we explored in Section 3. In World C, we use polyinstantiation along with floating labels, and a new instance of *Q* denoted as Q^1 is created

in the caller's context (i.e. with the caller's label $\{L_P\}$), separate from the original instance of *Q* with label $\{L_Q\}$. Thus, our approach allows the call to take place, without the mixing of secrecy contexts. The “lazy” aspect of our approach (not represented in the figure) is that we would reuse a previously created instance of *Q*, denoted Q^{past} , if its label matched the caller's label (i.e., $\{L_P\}$). Additionally, while the new instance has an empty label (i.e., $\{\}$) as the base (compile-time) label in our prototype, our model can be adapted to support a different base label.

Weir uses lazy polyinstantiation for all indirect inter-component calls (e.g., starting an activity, querying a content provider) (described in Section 2.4). *Weir* polyinstantiates processes, Android components and the file system, creating new instances of each for different secrecy contexts. Floating labels allow legacy apps to integrate into *Weir* without modification for making or receiving calls, while polyinstantiation adds context sensitivity. *Weir*'s use of floating labels supports process-level labeling along with application multi-tasking (**G3**), a more practical solution than the alternatives of killing existing instances [28, 46] or indefinite blocking [19].

We now describe *Weir*'s polyinstantiation of memory, followed by storage. We then discuss how *Weir* supports explicit label changes. Finally, we describe how *Weir*'s domain declassification satisfies goal **G4**.

4.2 Polyinstantiation of Memory

To satisfy goal **G1**, *Weir* must ensure that no two component instances with mismatching labels execute in the same process. At the same time, *Weir* must make components available if the underlying Android enforcement (i.e., permission framework) allows. Therefore, our approach polyinstantiates both components and processes to make them available in multiple secrecy contexts.

For backwards compatibility, our approach refrains from affecting developer configurations (e.g., by forcing the “multi-process” manifest attribute). Instead, *Weir* polyinstantiates components within the application’s own context. Specifically, *Weir* upholds the process assignments made for components by the developer, through the “android:process” manifest attribute (i.e., the component’s *processName*). That is, *Weir* ensures that components that were meant to run together (i.e., assigned the same *processName*), still run together. We now describe our approach, followed by an example.

Our approach: On every call, *Weir* retrieves the label of the caller (i.e., the *callerLabel*). *Weir* then checks if an instance of the desired component is running in a process whose label matches *callerLabel*. If one is found, the call is delivered to the matching instance. If not, *Weir* creates a new instance of the called component.

When the target component instance is assigned, *Weir*

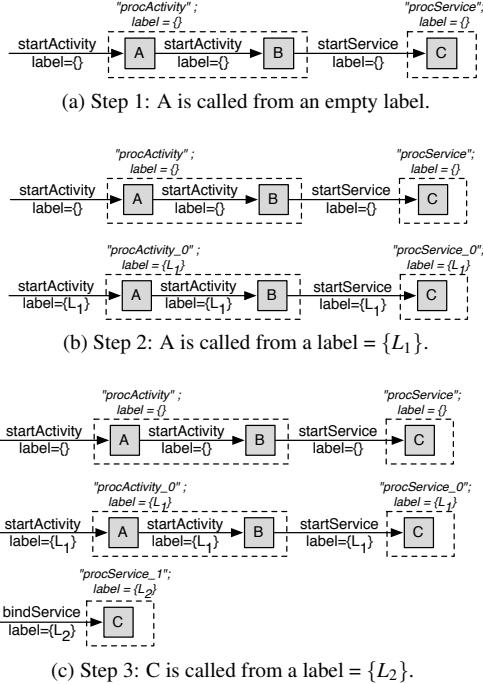

Figure 3: *Weir*'s lazy polyinstantiation of three app components; activities A and B, and a service C.

must find a process to execute it. If the process associated with this component (i.e., *processName*) has a different label, *Weir* cannot execute the new instance in it, and has two options: a) assign a polyinstantiated process that is associated with *processName* and has the label *callerLabel* or 2) create a new process associated with the *processName* with label *callerLabel*. As it is evident based on the first option, *Weir* keeps track of a *processName* and all its instances created for various secrecy labels. *Weir* can then reuse a previously instantiated process that is associated with the original *processName* and already has the required label (i.e., *lazy* polyinstantiation). Additionally, *Weir* can ensure adherence to the developer's process assignment; i.e., that component instances only execute in the process associated with their *processName*. If a matching process is not available, *Weir* creates a new process for *callerLabel*, and internally maintains its association with the original *processName*.

Example: Consider an app with three components, activities A and B, and a service C. The developer sets the *processName* for A and B to be “*procActivity*”, whereas the *processName* for C is set to “*procService*”. This means that A and B are expected to run in the same process, while C runs in a separate process. The app is programmed such that when A is started, it starts B, following which B starts C. Using Figure 3, we describe *Weir*'s instantiation of A, B, and C and their processes.

In Step 1 (Figure 3a), A is first called by an unlabeled caller; i.e., the *callerLabel* is empty. A new instance of A

is created, and a new process by the name “*procActivity*” is started for it. Then, A calls B. The label of A's process is empty, so B is also instantiated with an empty label, in the matching process, i.e., “*procActivity*”. B then calls C, which is instantiated in the new process “*procService*”.

In the Step 2 (Figure 3b), A is called from a caller with *callerLabel* = {*L*₁}. *Weir* cannot deliver the call to the existing instance of A, as its process has a mismatching label (i.e., *callerLabel* = {*L*₁} ≠ {}). Thus, *Weir* creates a new instance of A for this call. As there are no processes associated with “*procActivity*” and with the label {*L*₁}, *Weir* also allocates a new process “*procActivity_0*” to host this instance. Thus, for this call, a new instance of A is started in a new process “*procActivity_0*”, whose label is set to {*L*₁}. When this instance of A calls B, the call is treated as a call to B with *callerLabel* = {*L*₁}, the caller being A's new instance with label {*L*₁}. As *Weir* keeps records of all the processes created for polyinstantiation, it starts a new instance of B in the process that is associated with B's original process “*procActivity*”, and has a matching label {*L*₁}, i.e., “*procActivity_0*”. Reusing an existing process instance is an example of “*lazy*” polyinstantiation. When this instance of B starts C, *Weir* creates a new instance of C due to mismatching labels, in a new process “*procService_0*” with label {*L*₁}.

In Step 3 (Figure 3c), *bindService* is called on C with the label *callerLabel* = {*L*₂}. Since the caller's label {*L*₂} mismatches with the two existing instances of C that are running with labels {} and {*L*₁}, a new instance of C is created. As there are no processes associated with “*procService*” that have a label matching {*L*₂}, a new process “*procService_1*” is created to host the new instance. Note that all of these instances and processes exist simultaneously, as shown in the figures. If C is called again with the label *callerLabel* = {*L*₂}, *Weir* will not have to create a new instance, and the call will be delivered to the existing instance of C running in process “*procService_1*” with the matching label {*L*₂} (i.e., “*lazy*” polyinstantiation).

Weir's approach maintains context-based separation in memory (**G1**), and also ensures that components configured to run in the same process still run together; i.e., our approach is transparent to the application, satisfying goal **G3**. For example, instances of A and B exist together, both in the labeled as well as the unlabeled contexts. *Weir* supports all Android components declared in the application manifest, i.e., activities, services, content providers and broadcast receivers. An exception is broadcast receivers registered at runtime, which are instantiated at registration in the secrecy context of the registering process, and hence not subject to further instantiation. Any future broadcasts to such receivers are treated as direct calls subject to strict DIFC label checks.

4.3 Polyinstantiation of Storage

To prevent restrictive labeling of shared storage by processes running in sensitive contexts, *Weir* extends context-based separation to the storage as well (**G2**). *Weir* achieves this separation without denying access to instances in sensitive secrecy contexts (**G3**).

Our approach: *Weir* separates shared state in the internal and external storage using file-system polyinstantiation via a *layered* file system approach [29]. Our approach is similar to Solaris Containers [22], and more recently, Docker [24]. Context-sensitive storage separation has also been used previously in DIFC, for *known* persistent data objects. For example, in their DIFC system for the Chromium Web browser, Bauer et al. create context-specific copies of bookmarks to prevent a restrictive label from making bookmarks unusable [5].

In *Weir*, every secrecy context receives its own copy-on-write file system layer. Processes running in a particular secrecy context have the same view of the file system, which may be different from those running in other contexts. All file operations are performed on the context-specific layer attached to a process, which relays them to the underlying file system (i.e., the default layer). Unlabeled processes are assigned the default layer.

For simplicity, new layers are always created from the default layer, and never from existing labeled layers. That is, for any layer with label L , the copy-on-write always occurs from the default layer (with label $\{\}$), and not another lower layer (say label L_1), even if L_1 is lower than L (i.e., $L_1 \subseteq L$). An alternate design choice of using a non-default lower layer for copy-on-write could lead to conflicts due to incompatible copies of data at different, but similarly labeled lower layers. For example, two labels L_2 and L_3 might be at the same level below L in the DIFC lattice, but may have different copies of the same file. For resolving such conflicts, the system may have to either involve the user or the application. The backwards compatibility and usability effects of choosing a lower layer need further exploration, although it may be a more flexible option. Hence, our design simplifies the potential choice between contending layers by always choosing to copy from the default layer.

For efficiency, a layer only stores the changes made to the default layer by processes in the layer’s secrecy context (i.e., copy-on-write). When a file present in the default layer is first written by a process attached to a non-default layer, the file is first copied to the non-default layer and then modified. Future accesses for the file from that context are directed to its own copy. When a process attached to a non-default layer tries to read a file that has never been modified in the calling process’s layer, it reads the original file on the default layer. *Weir*’s storage approach is an extension of its *lazy* polyinstantiation, i.e.,

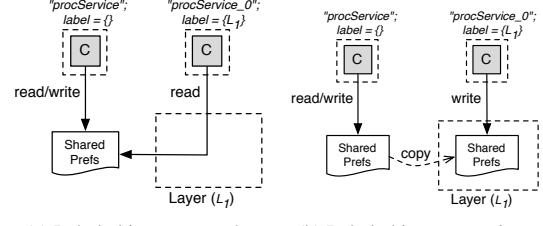

Figure 4: *Weir*’s storage polyinstantiation using layers.

new layers are created only when a process with a previously unknown secrecy context is initialized. Applications transparently access storage using any file system API, and *Weir* directs the accesses to the correct files.

Weir stores the files copied to layers in layer-specific copy-on-write directories. While creating such directories, *Weir* accounts for the security and availability requirements of applications and users. For application-specific internal storage, copy-on-write directories are created in an area that is accessible only to instances of the particular application. For public external storage, *Weir* creates common label-specific copy-on-write directories in an area accessible to all apps. This approach ensures that when an application is uninstalled, its data on external storage is still available to the user.

Example: Figure 4 shows two instances of the component C , one of which is running in the unlabeled secrecy context (i.e., label $\{\}$), while the other has a label $\{L_1\}$. *Weir* sets up a file system layer, i.e., $Layer(L_1)$, to mediate all file accesses by the labeled instance. $Layer(L_1)$ is only attached to processes with label $\{L_1\}$.

As seen in Figure 4a, initially, both the unlabeled and labeled instances of C read from the shared preferences file (i.e., *SharedPrefs*). That is, $Layer(L_1)$ relays all the read requests by the labeled instance of C for unmodified *SharedPrefs* file to the default storage. Once the labeled instance of C attempts to write to the *SharedPrefs* file, *Weir* copies it to $Layer(L_1)$. This copy is used for all future read or write accesses by instances with label $\{L_1\}$.

Security of copy-on-write directories: *Weir* ensures the security of the layered directories through a combination of file labeling and Linux permissions. File labels are initialized when first written, to the writing process’s label. *Weir* uses strict DIFC label checks for all successive file accesses. Further, *Weir* prevents the implicit flows due to the presence or number (i.e., count) of such copy-on-write directories. To address flows through the presence of specific copy-on-write directories, *Weir* uses random directory names known only to the system. To prevent flows that make use of the number of such directories, *Weir* creates the copy-on-write directories inside a parent directory owned by *Weir*. The Linux permissions of this parent directory are set to deny the read operation on it, and hence cannot be used to list or count subdirectories.

Together with the polyinstantiation in memory, *Weir*'s approach enables transparent separation of different secrecy contexts without modifying legacy apps.

4.4 Label Changes and Binder checks

A component instance's label is implicitly set when it is instantiated. Similarly, a file's label is initialized when it is first written to. For all successive accesses (i.e., direct Binder IPC and file reads/writes respectively), *Weir* does not apply floating labels, but performs a strict DIFC label check (i.e., data may not flow to a "lower" label). Hence, any label changes after initialization can only be explicit.

An application aware of *Weir* may change the label of its instances by raising it (to read secret data), or lowering it (to declassify data), provided the change is legal with respect to the policy for the security classes involved in the change, as described in Section 2.3. For example, to read secret data labeled with label $\{L_1\}$, a component instance may raise its label to $\{L_1\}$, if it has authorization (e.g., a capability) from the owner of $\{L_1\}$ (see Section 5.1 for the policy syntax). We now describe the problem caused by explicit label changes.

Problem of explicit label change: A component instance may establish Binder connections with other instances through the Activity Manager, and then use direct Binder RPC. When an instance changes its label, its existing Binder RPC connections (established via indirect communication, see Section 2.4) may be affected. That is, its new label may be higher or lower relative to the instances it is connected to. Hence, it may not be able to send or receive data on existing connections due to the strict DIFC check on Binder transactions. An explicit label change may also make the component instance's context inconsistent with its attached storage layer. At the same time, explicit label changes are unavoidable in applications that use *Weir*.

Our solution: *Weir* provides applications with the *intent labeling* mechanism, i.e., components can label calls (i.e., intent messages), before they are sent to the Activity Manager service, ensuring that the target component is instantiated with the label set on the intent. In fact, a component may instantiate itself with the desired secrecy label by specifying itself as the intent's target. Intent labeling eliminates the need for explicit label changes.

Security of Intent Labeling: *Weir* does not blindly trust the label set on the intent, as applications may otherwise abuse the mechanism for unauthorized declassification. For example, a malicious component with the label $\{L_1\}$ may add secret data to an intent, and set an empty label (i.e., $\{\}$) on the intent before calling itself with it. To account for such malicious use cases, *Weir* checks if the calling application would be authorized to explicitly change its current label to the label on the intent, as per

the policy (see Section 5.1). A call with a labeled intent may proceed only if the caller passes the check.

While we have not encountered use cases that cannot be expressed using intent labeling, our implementation allows explicit label changes, mainly for expert developers who may want to make temporary changes to their instance labels. Explicit label changes must be used with caution, as our design does not account for the problems due to label change after instantiation (e.g., dropped Binder calls), since labels do not float to existing Binder connections and files to prevent label explosion (explained in Section 3).

4.5 Domain Declassification

Problems with traditional network declassification are rooted in the decision to declare trust in the exporting subject, as discussed in Section 3. More precisely, in an internet-driven environment, it may be more practical for the data secrecy enforcement to reason about *where* the data is being delivered, rather than *who* is performing the export. *Weir* introduces the alternative of *domain declassification* to allow data owners to articulate trust in terms of the receiver, i.e., the target Web domain. *Weir* allows the data owner to associate a set of network domains (t^D) with its security class (t). When the data in context $\{t\}$ is to be exported to the network, *Weir*'s enforcement implicitly declassifies t , if the destination domain is in t^D . The data owner is neither required to explicitly declassify nor trust the exporting application.

In Section 8, we discuss an example where the enterprise only wants data to be exported to a set of enterprise domains, irrespective of the application exporting it. Such a policy allows the user to use the same email application for both the personal and work account, but prevents accidental export of work data to the personal SMTP server. Domain declassification not only addresses the goal of practical declassification in a network driven environment (**G4**), but also prevents the user from accidentally exporting data from a trusted application, but to an untrusted server.

Weir is not the first IFC system to use domains for declassification, although most prior systems to do so consider domains as security principals (e.g., COWL [41], Bauer et al. [5]). For instance, COWL confines JavaScript using a declassification policy analogous to the well-known same origin policy (SOP), i.e., code executes in the context of its origin, and hence possesses the declassification privilege for export to the origin's Web domain. In this case, the origin Web domain is a first class security principal, as it has physical presence on the device in the form of the code running in its context. Thus, in COWL, the declassification privilege is still expressed in terms of the security principal that is sending the data (i.e., the origin). On Android, there is

no direct correlation between Web domains and applications; i.e., Web domains do not have code executing in their context on the device, and hence are not security principals. Thus, *Weir*'s approach of expressing trust in the receiver of the data (i.e., the Web domain) rather than the sender is indeed unique among OS-level DIFC systems where Web domains may not be security principals [1, 21, 28, 49]. Hails [15], an IFC web framework for user privacy, may be closer to *Weir*'s approach, as it allows users to declassify their data for specific domains. Hails users are prompted to explicitly declassify when network requests to disallowed domains are first made, which may not be feasible on Android (see Section 3).

Weir's enforcement is limited to the device, and may not defeat an adversary controlling the network. While we leave this aspect relaxed for our threat model, we note that DNSSEC or IPsec could be used in such scenarios.

5 Implementation

We implemented *Weir* on Android v5.0.1, and the Android Kernel v3.4. This section describes the essential aspects of our implementation. The source code can be found at <http://wspr.csc.ncsu.edu/weir/>.

5.1 Weir's DIFC Policy

Weir derives its policy structure from the Flume DIFC model [21], which consists of *tags* and *labels*. A *data owner* (O) application defines a security class for its sensitive data in the form of a secrecy tag (t). A set of tags forms a secrecy label (S). *Weir* enforces the IFC secrecy guarantee, i.e., “no read up, no write down” [6]. Information can flow from one label to another only if the latter dominates, i.e., is a superset of the former. For instance, data can flow from a process P to a process Q if and only if $S_P \subseteq S_Q$. *Weir* applies this strict DIFC check to direct Binder communication and file accesses.

Each tag t has associated capabilities, namely t^+ (for reading) and t^- (for declassification), which data owners delegate to specific apps, or all other apps (i.e., the global capability set G). At any point of time, a process P has an effective capability set composed of the capabilities delegated to its application (C_P), and the capabilities in G . P can change its label S_P to S_P^+ by adding a tag t if and only if $t^+ \in C_P \cup G$. Similarly, P can change its label S_P to S_P^- by removing a tag t if and only if $t^- \in C_P \cup G$.

As the network interface is untrusted, it has an empty label, i.e. $S_N = \{\}$. Thus, a process P must have an empty label (i.e., $S_P = \{\}$), or the ability to change its label to $S_P = \{\}$ to create a network connection, i.e., $\forall t \in S_P, t^- \in C_P \sqcup G$. Additionally, *Weir* extends Flume's syntax with the domain declassification capability t^D , which is a set of trusted Web domains for tag t specified by the owner O . For a network export to a domain $d \in t^D$, t is implicitly declassified.

5.2 Component Polyinstantiation

When a component calls (i.e., sends an intent message or queries a content provider), the Activity Manager resolves the target component to be called using the static information present in the application manifest. *Weir* does not interfere with this *intent resolution* process. Then, the Activity Manager chooses the actual runtime instance of the resolved component, which is where *Weir*'s polyinstantiation takes effect. That is, *Weir* controls component instantiation, without modifying the components themselves. Hence, *Weir* is compatible with all developer manifest options, except ones that control instantiation. Section 7.2 provides a compatibility evaluation for such options. For a detailed explanation on Android's component startup workflow and *Weir*'s component instantiation logic, see Appendix A.

5.3 File-system Layering

We chose OverlayFS [29] over alternatives (e.g., aufs), as it is in the Linux kernel (since v3.18). As the current OverlayFS patch is incompatible with SELinux, we set SELinux to monitoring mode. This is a temporary limitation, as OverlayFS developers are working towards full integration [45], which is on SELinux's Kernel ToDo list as well [10]. Additionally, we could use a fine-grained block-level copy-on-write file system (e.g., BTRFS [32]). There are advantages to using such file systems, as we describe in the trade-offs (Section 9). Note that while we could get the Android Linux kernel to compile with BTRFS, the build system support tools that are required to build Android's sparse-images for BTRFS (e.g., `ext4_utils` for ext4) are missing. Therefore, our prototype opts for OverlayFS, as it does not require user-space support.

5.4 Process Initialization

On Android, the *zygote* process forks and prepares new processes for applications. When a new process is forked, *Weir* sets its secrecy label in the kernel, and uses zygote to mount the appropriate storage *layer* to the process's mount namespace based on its label. If the process has a non-empty label, *Weir* separates the process's mount namespace from the global mount namespace using the *unshare* system call, and mounts the appropriate OverlayFS copy-on-write layer based on the label on top of the unlabeled file system. New layers are allocated when new labels are first encountered. *Weir* maintains the mapping between a label, its assigned layer and the specific copy-on-write directories used for it.

5.5 Kernel Enforcement

Weir uses a Linux security module (LSM) to track the security contexts of processes and files in the kernel. We

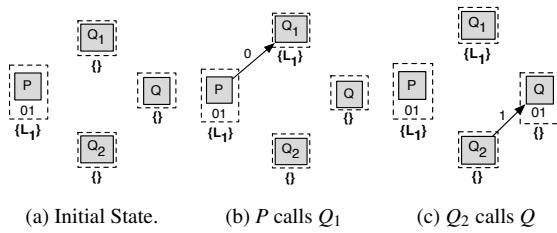

Figure 5: Floating label DIFC system: Q receives 1 and guesses 0 for every reply not received.

integrated the multi-LSM patch [35] to enable concurrent SELinux and *Weir* enforcement. The security context of a process contains its secrecy label and capabilities, while that of a file only contains a secrecy label. We now describe the enforcement for file access, Binder communication and network access, as follows:

1. Files: *Weir* uses the *file_permission* LSM hook to mediate each file read and write access. The secrecy label of a file (stored in the xattrs) is initialized from the label of the process that first writes it.

2. Binder: *Weir* mediates Binder transactions in the kernel using the Binder LSM hooks. For compatibility, *Weir* whitelists Binder communication with Android system services in the kernel. To prevent apps from misusing whitelisted services as implicit data channels, we manually analyzed all system service API, and modified API that may be misused, e.g., the Clipboard Manager service provides label-specific clipboards in *Weir*.

3. Network: *Weir* mediates the socket *connect* and *bind* operations in the kernel. The tags in the calling process’s label that cannot be declassified using its capability set are sent to *Weir*’s system service in the userspace via a synchronous upcall, along with the IP address of the destination server. *Weir*’s system service then resolves the domain name from the IP address, which is challenging, as a reverse DNS lookup may not always resolve to the same domain used in the initial request. Fortunately, Android proxies all DNS lookups from applications to a separate system daemon. We modify the daemon to notify *Weir* when a process performs a DNS lookup, including the domain name and the IP address returned. During the domain declassification upcall, this mapping is referenced to identify the destination domain. *Weir* allows the connection only if all the tags in the upcall can be declassified for that domain.

6 Security of Polyinstantiation

Floating labels were first predicted to be prone to information leaks by Denning [8]. While language-level floating label IFC models (e.g., COWL [41] and LIO [40,42]) can mitigate such leaks, securely using floating labels is

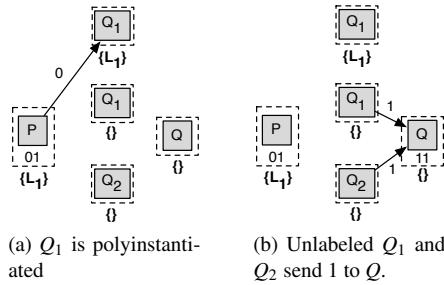

Figure 6: *Weir*: Q always receives data “11”

still a challenge for OS-level DIFC systems (e.g., IX [23] and Asbestos [44]). We discuss an attack on an OS-level floating label DIFC system, described in Krohn and Tromer’s paper on the non-interference of Flume [20], and show how *Weir* is resistant to such data leaks. We use Android’s terminology to describe the attack.

We describe the attack twice; once in a floating label system without polyinstantiation (Figure 5) and once in *Weir* (Figure 6). Figure 5a shows the malicious components (e.g., services) P , Q , Q_1 and Q_2 . P has obtained the data “01”, and the accompanying label $\{L_1\}$. P wants to transfer the data to Q , without Q obtaining the label $\{L_1\}$. Note that Q , Q_1 and Q_2 initially have the empty label $\{\}$. Additionally, P and Q have a prior understanding that P will call the i^{th} service of Q to indicate “0” at the i^{th} bit. Q ’s components are programmed to send a message to Q after a predetermined time if they do not receive a message from P (i.e., indicating a “1”). Since the first data bit is “0”, P sends “0” to Q_1 , whose label floats to $\{L_1\}$ (Figure 5b). After a predefined time, the component that did not receive a message from P , i.e., Q_2 , sends a “1” to Q (Figure 5c). The data leak is successful, as Q knows that the second bit is “1”, and assumes the first to be “0”, all without acquiring the label $\{L_1\}$. As Android does not place any limits on the number of components, a wider n bit channel is possible with n components.

Weir’s polyinstantiation defeats this attack by creating a new instance of Q_1 in a separate process to deliver a call from a label that mismatches its own (Figure 6a). Next, the unlabeled instance of Q_1 and Q_2 both call Q with data “1”, as shown in Figure 6a. In fact, for n components of Q , Q will always get n calls with data “1”, as *Weir* will polyinstantiate all the components that have been called by P with the label $\{L_1\}$. *Weir*’s use of floating labels is resistant to implicit flows inherent to regular floating labels, as labels do not float to the original instance, but to a new instance created in the caller’s context.

Jia et al [19] attempt to solve a similar problem,³ by making the raised label the component’s base (i.e., static) label. This defense allows the existing leak, but makes the components that received the message (e.g., Q_1) un-

³Refer to page 8 of the paper by Jia et al. [19] for details.

usable for future attacks. Attackers can be expected to beat this defense by coordinating the components used for every attack, and transferring significant data before all the components have restrictive static labels.

Finally, while polyinstantiation is resistant to data leaks in floating labels, we leave the complete formalization of this idea as future work. The intuition behind the formalization is described as follows: Let \mathcal{L} be the type system corresponding to the labels (e.g., type-system for floating labels) and \mathcal{S} be the type system corresponding to information about stacks (e.g., for k -CFA analysis strings of size k that capture information about last k calls). Assume that we have inferencing/propagation rules for both type systems and they are sound. We have an intuition that the combined system (denoted by $\mathcal{L} \times \mathcal{S}$) is sound (the inferencing/propagation rules are basically a combination of both rules).

7 Evaluation

Our evaluation answers the following questions about *Weir*'s performance and compatibility:

Q1 Is *Weir* compatible with developer preferences that manipulate component instantiation?

Q2 What is *Weir*'s performance overhead?

Q3 Is *Weir* scalable for starting components?

We now provide an overview of the experiments and highlight the results. The rest of this section describes each experiment in detail.

7.1 Experiment Overview and Highlights

Weir does not modify components, but only modifies their instantiation. Thus, we evaluate compatibility with options that control component instantiation (**Q1**), i.e., the singleTop, singleTask and singleInstance activity launch modes described in Section 2.4. We trigger the launch modes in popular Android apps from Google Play, and record application behavior in unlabeled and labeled contexts. We did not observe any crashes or unexpected behavior. Every launch mode worked as expected, while the underlying polyinstantiation ensured delivery of calls to instances in the caller's context.

We measure the performance overhead of *Weir* over an unmodified Android (AOSP) build (**Q2**) with microbenchmarks for common operations (e.g., starting components). Our comparison between the unmodified build, *Weir* (unlabeled instance), and *Weir* (labeled instance) in Table 1 shows negligible overhead. Even in cases where the overhead percentage is large, the absolute overhead value is negligible (<4ms). Further, the negligible difference in the values of *Weir*'s labeled and unlabeled instances (i.e., relative to the error) would make a noisy covert channel at best.

As described in Section 5, for every call, Android's intent resolution gets the target component. The OS then chooses a runtime instance from available instances of the target. Hence, the total number of a component's runtime instances only affects its own start time. We evaluate the scalability of a component's start time, when a certain number of its instances already exist (**Q3**). Our results in Figure 7 show a linear increase in the start time with increase in the number of concurrent instances, and low absolute values (e.g., about 56 ms for 100 instances).

7.2 Compatibility with Launch Modes

We randomly pick 30 of the top applications on Google Play (i.e., 10 per launch mode, complete list available at <http://wspc.csc.ncsu.edu/weir/>).

Methodology: For each launch mode, we first launch each application from two separate unlabeled components, and navigate to the specific activity we want to test. With this step, we confirm that the application and specifically the singleTask/Top/Instance activity works as expected. Without closing existing instances, we start the same application from a labeled context and repeat the prior steps. We record any unexpected behavior.

Observations: We did not observe any unexpected behavior, and activities started in their assigned tasks. In the case of singleTask and singleInstance activities, two instances of the same activity ran in the designated task instead of one; i.e., one labeled and the other unlabeled. Intent messages were delivered to the activity instance with the caller's label. This behavior is compatible with singleTask and singleInstance activities, and also maintains label-based separation in memory.

7.3 Microbenchmarks

We evaluate the performance of the operations affected by *Weir* (i.e., file/network access, component/process start), on a Nexus 5 device. We perform 50 runs of each experiment, waiting 200 ms between runs. Table 1 shows the mean with 95% confidence intervals. Cases with negative overhead can be attributed to the high error in some operations. Specific experimental details are as follows:

Component and Process start: We measure the component start time as the time from the placement of the call (e.g., `startActivity`) till its delivery. The component is stopped between runs. To measure the process start time, we kill the process between subsequent runs. While the overhead percentages may be high (e.g., for providers), the absolute values are low, and would not be noticeable by a user. Further, the process start time that includes file-system layering in zygote shows minimal overhead.

File access: We perform file read and write operations on

Table 1: Performance - Unmodified Android (AOSP), Weir in unlabeled context, Weir in labeled context.

Operation	AOSP (ms)	Weir (ms)		Overhead (ms)	
		Weir w/o label	Weir w/ label	Weir w/o label	Weir w/ label
Activity start	20.06±4.47	22.22±4.69	20.82±4.87	2.16 (10.77%)	0.76 (3.79%)
Service start	13.94±2.87	14.96±2.85	17.36±4.78	1.02 (7.32%)	3.42 (24.53%)
Broadcast Receiver start	12.92±3.96	11.42±4.44	11.86±3.34	-1.5 (-11.6%)	-1.06 (-8.2%)
Content Provider start	4.54±2.28	7.26±5.32	7.9±4.73	2.72 (59.91%)	3.36 (74.01%)
Process start	127.18±5.62	130.28±5.63	132.98±6.66	3.1 (2.44%)	5.8 (4.56%)
File Read (1MB)	42.38±6.05	43.46±5.44	41.32±5.39	1.08 (2.55%)	-1.06 (-2.5%)
File Write (1MB)	46.8±5.79	47.84±5.42	47.16±5.85	1.04 (2.22%)	0.36 (0.77%)
Network	66.98±3.62	65.68±2.78	69.00±7.04	-1.3 (-1.94%)	2.02 (3.02%)

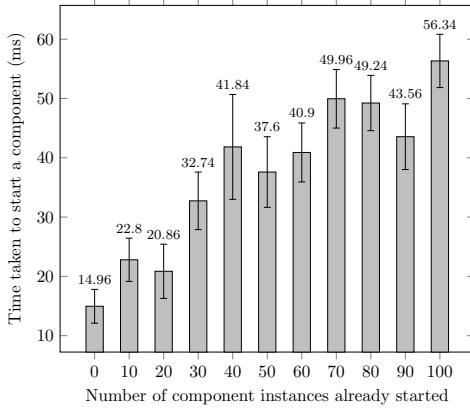

Figure 7: Linear increase in component start time when $0 \rightarrow 100$ instances (in steps of 10) already exist.

a 1MB file using a 8KB buffer. Since the entire check is performed using the process and file labels in the kernel, the overhead value is negligible (e.g., about 0.77% for a labeled file write). We also measure the cost of copying the 1MB file to the labeled layer, i.e., repeating the file write experiment on *Weir* but deleting the file between runs. The extra time taken to copy relative to AOSP is 5.98 ms (about 13% overhead). RedHat’s evaluation of OverlayFS further demonstrates its scalability [18].

Network access: We measure the time to establish a network connection using the *HTTPUrlConnection* API, using domain declassification for the labeled instance. The labeled instance’s overhead includes the kernel upcalls and the DNS proxy lookup. The overhead for the labeled instance (2.02 ms or 3.02%) includes the time taken by the DNS proxy to inform *Weir* of the lookup, as well as the synchronous kernel upcalls.

7.4 Scalability of Component Instantiation

We create up to 100 simultaneous instances (in steps of 10) of a service component, each with a different label. At each step, we then invoke the last instance, i.e., from a caller with the last instance’s label, and measure the component start time. Note that this experiment presents the worst case scenario; i.e., our prototype does not implement any particular strategy (e.g., least recently used (LRU)) for matching a call with a list of available in-

```

1 // Creating the tag 't'
2 domains={ ``www.bcloud.com'', ``smtp.bcloud.com'', ... };
3 createTag(``t'', domains);

```

Listing 1: *BCloud*’s policy configuration

```

1 addTag(``t''); //raise own label to {t}
2 //perform sharing action ...
3 removeTag(``t'')//lower own label

```

Listing 2: *BCloud* raises its label

stances, and a request with the last instance’s label will always result in a label comparison with *all* available instances. Figure 7 shows linear scalability, with the highest absolute value being less than 57 ms.

8 Case Study

We investigated the use of labeled enterprise data with an unmodified third party email (*K-9 Mail*) application [9]. With this case study, we demonstrate *Weir*’s utility, and motivate the trade-off discussion in Section 9.

Application Setup: We created an enterprise cloud application, *BCloud* that allows the user to sync her work data (e.g., contacts, documents) to the device. Further, we used the popular email application *K-9 Mail* with both user and enterprise data. The setup is as follows:

1. *BCloud*. We assume that the enterprise policy is to enable the use of third party applications with work data, but to allow export to only enterprise domains. For example, work data must only be emailed using the work SMTP server *smtp.bcloud.com*.⁴ Thus, *BCloud* creates a tag *t* as shown in Listing 1. To set the policy before sharing its data or saving it to storage, *BCloud* may temporarily raise its label to $\{t\}$ (Listing 2), or start itself or other applications with $\{t\}$ using intent labeling (Listing 3). For instance, *BCloud* raises its label before copying the work contacts to Android’s *Contacts Provider*.

2. *K-9 Mail*. We configured *K-9 Mail* for both personal and work email accounts. Like most modern email clients, *K-9 Mail* allows the user to send an email using the work or the personal account, using the *send as* email field. Internally, *K-9 Mail* uses the SMTP server *smtp.gmail.com* for the personal account, and

⁴We used *mail.yahoo.com*, *smtp.mail.yahoo.com* and *imap.mail.yahoo.com* as *BCloud*’s trusted domains.

`smtp.bcloud.com` for the work account. To assist the user in composing an email, *K-9 Mail* retrieves contacts from the *Contacts Provider* app, and makes suggestions as the user types into the “to” (i.e., sender) field.

Experiment: We opened a document from *BCloud* in the *WPS Office* application. Then, from the *WPS Office* app, we shared the document with *K-9 Mail*. *K-9 Mail*’s “compose” window was displayed. We then chose to *send as* the work account, and picked a contact to add to the “to” field. We tried to attach another file, and the “attach” action opened Android’s system file browser. We selected a file and returned to *K-9 Mail*’s compose screen. We then switched to the home screen without sending the work email. We repeated the entire experiment in the default (i.e., unlabeled) context, with the *send as* field set to the personal account. We then sent both emails. Throughout the experiment, we watched the system log for important events (e.g., network denial).

Observations: We made the following observations, and verified them using the system log:

1. *Context-specific instances.* As we shared work data (in the context $\{t\}$) with *WPS Office* and subsequently *K-9 Email*, instances of these applications (i.e., processes and components) were started in the work context $\{t\}$, and attached to the internal and external (SD card) storage layer $Layer(t)$. The unlabeled context resulted in separate instances with the empty label $\{\}$, attached to the default storage layer. Instances in both contexts existed concurrently, without any crashes or abnormal behavior.
2. *Context-specific data separation.* While attaching another document in the work $\{t\}$ instance of *K-9 Mail*, we could see all the documents on the default storage layer (i.e., unlabeled files), and documents in work $Layer(t)$ (i.e., added from *BCloud*). On the contrary, in the default context, we could only see the files on the default layer. Further, in the default context, *K-9 Mail* suggested from all of the user’s unlabeled contacts, but none of the work contacts. In the work context, *K-9 Mail* suggested from all the work contacts, and the unlabeled contacts that existed before *BCloud* synced its labeled contacts. That is, *K-9 Mail* could not see new records created in the default layer’s contacts database after it was copied over to $Layer(t)$.
3. *Domain Declassification.* In the work context, *K-9 Email* was unable to connect to the SMTP and IMAP sub-domains of `gmail.com`, but could only connect with the domains declassified by tag t . Unmodified *K-9 Email* silently handled these network access exceptions, without crashing or displaying errors messages.

9 Trade-offs and Limitations

This section describes the trade-offs of our approach, motivated in part by the observations in the case study.

```

1 Intent intent = new Intent();
2 // Add 't' to the intent's label.
3 intent.addLabel('t');
4 // Add data to the intent ...
5 startActivity(intent); //Call self

```

Listing 3: *BCloud* starts itself with new label

1. Centralized perspective: The user cannot view both labeled and unlabeled data together, unless an application is started in the labeled context (e.g., *K-9 Mail* in context $\{t\}$). We envision modified application launchers and phone settings that allow the user to start applications (e.g., File Browsers) with a certain label by default, for making labeled and default data available together. Our test apps use similar techniques; hence such launchers should not be hard to create. On the other hand, a centralized perspective on more than one non-default context (e.g., $\{t1, t2, t3, \dots\}$) may require a trusted OS application exempt from polyinstantiation (but subject to only floating labels), as floating labels by themselves are vulnerable to information leaks (Section 6).

2. Updates to default layer: While context-specific versions of files may be generally acceptable, in case of database files (e.g., contacts read by *K-9 Mail* in the work context) the user may expect new records in the unlabeled context to be propagated to the copy in the labeled context. The lack of updates is mainly a trade-off of our file-level copy-on-write implementation (i.e., OverlayFS). As mentioned in Section 5, a block-level copy-on-write file system (e.g., BTRFS [32]) may mitigate this trade-off, as it would only copy the blocks modified by the labeled context, and newly allocated blocks in the default context would be accessible to the labeled context, although this aspect needs further exploration.

3. Access control denials: Floating labels ensure that inter-component communication is never denied, and that resources (e.g., files, other components) are available in all secrecy contexts. Although apps may be denied network access, research has addressed this challenge in the past (e.g., AppFence [17]). Further, most IDEs (e.g., Eclipse) enforce compile-time checks for proper exception handling, and it is uncommon for apps to crash due to network denial, as observed in the case study as well.

4. Instance Explosion: *Weir* creates separate context-specific *K-9 Mail* instances, *only for the contexts in use*. The theoretical worst-case count of component instances is equivalent to the number of components multiplied by the number of all existing contexts (not just those in use). Our event-based and “lazy” instantiation makes this worst case practically improbable, unlike approaches that execute *all existing* contexts (see Section 10). On the other hand, a denial of service attack on a particular application component may be feasible, by starting a very large number of its instances in a short amount of time for noticeable impact on the lookup time of that compo-

ment. Our implementation can be modified to detect and prevent unusual rates of component instantiation. Note that polyinstantiation of a component only affects its own lookup time (as discussed in Section 7.1), and cannot be used for an attack with a device-wide impact.

5. Resource Overhead: Polyinstantiation may cause resource overhead in terms of the memory, battery and storage. The memory overhead is manageable as Android’s out of memory manager automatically reclaims memory from low priority components. Further, any measurement of the battery or storage use is bound to be subjective with respect to the number of labels, number of apps/components, type of apps (e.g., game vs. text editor), aspects of the user scenario (e.g., user-initiated flows, scenario-specific storage access). An objective large-scale study will be explored in the future.

6. Consistency Issues: To a remote server, the instances of an application in *Weir* are analogous to instances running on different devices (e.g., a user logged in from two devices). Hence, any data consistency issues in such scenarios are not a result of polyinstantiation.

7. Covert Channels: *Weir* mediates overt communication between subjects and objects, but does not address covert channels existing in Android. A clearance label [6, 40, 44] can be used to defend against adversaries using covert channels by preventing access to certain tainted data in the first place. While a clearance label can be easily incorporated into *Weir*, setting the clearance policy for third party applications with unpredictable use cases is hard, and needs further exploration from a policy specification standpoint. Finally, unlike IFC systems that focus on preventing untrusted code within a program from exfiltrating data (e.g., Secure multi-execution [11]), *Weir*’s focus is inter-application data sharing. Hence, compartmentalizing an application using clearance is outside the scope of this paper.

8. Explicit labeling of messages and files: On Android, an indirect message through the OS (e.g., intent message) is required before a bi-directional Binder connection can be established between two instances. *Weir* allows floating labels on such indirect communication (but not on direct Binder calls), and polyinstantiation ensures that the two instances at the end of a bidirectional Binder connection have the same label, which is sufficient for synchronous Binder messages. Hence, labeling of individual Binder messages does not provide additional flexibility, unlike in explicit labeling DIFC systems (e.g., COWL [41], Flume [21]). Note that *Weir* allows explicit labeling of indirect messages (i.e., intent labeling). Further, explicit labeling of a file with a label that is different from its creating process instance would place it on an incorrect layer. Such incorrectly stored files will not be visible to future instances started with matching labels,

and may cause unpredictable application behavior. Thus, our design trades the flexibility in explicitly labeling files for stable context-sensitive storage.

10 Related Work

In Section 3.1 we described prior DIFC proposals for Android (i.e., Aquifer [28], Jia et al. [19] and Maxoid [46]). We now describe other relevant prior research.

DIFC: Myers and Liskov presented the Decentralized Labeling Model (DLM) [26] that allowed security principals to define their own labels. Since then, numerous DIFC systems have been proposed that provide valuable policy and enforcement models [20, 21, 25–27, 33, 44, 49, 50]. Language-based DIFC approaches (e.g., JFlow [25] and Jif [27]) provide precision within the program, but rely on the OS for DIFC enforcement on OS objects (e.g., processes, files, sockets). On the contrary, coarse-grained OS-level approaches (e.g., HiStar [49] and Asbestos [44]) provide security for flows between OS objects, but cannot reason about flows at the granularity of a programming language variable. While *Weir* is also an OS-level DIFC approach, which means it cannot achieve precision at the program variable level, context sensitive enforcement ensures that *Weir* always has higher precision than traditional OS-level DIFC. Further, while Laminar [30, 33] provides both language-level as well as the OS-level enforcement, it requires applications to be modified to use the precise language-level enforcement. This is not an option for backwards compatible DIFC on Android. Finally, *Weir* does not require general-purpose applications to explicitly define flows as in Laminar, HiStar and Flume [20, 21], as inter-application communication in Android tends to be unpredictable.

Secure multi-execution: Secure multi-execution [11] was proposed to determine and enforce that a program’s execution is noninterferent, i.e., to eliminate unlawful data flows by untrusted code *within* a program. The approach achieves noninterference using multiple concurrent executions at all points in the lattice, removing statements that do not match the labels of specific executions. On the contrary, lazy polyinstantiation creates only one instance in the security context of the caller. Unlike secure multi-execution where the multiple executions are treated as a part of the same program instance, polyinstantiation treats multiple executions as unrelated context-specific instances separated in memory and storage. Our approach is more suitable for Android’s inter-application data sharing abstractions, while secure multi-execution may be useful to prove non-interference for a general program. Further, secure multi-execution only assumes a finite, predefined label set. This assumption is violated in DIFC systems, where the label set is often

large and not known a priori, and executing all labels at once is impractical.

Faceted Execution: Jeeves [48] and Jacqueline [47] ensure that security principals see different views of data based on their secrecy contexts, using a technique defined as faceted execution. The result of *Weir*'s approach is similar; i.e., each security principal can only see data at its own secrecy context. For faceted execution, the copies of data have to be specified by the programmer a priori, which is acceptable if the security of different users using a single program (e.g., a conference submission site) is to be defined. On the contrary, on Android, *Weir*'s approach of allowing applications to operate unmodified, and creating context-specific copies on the go, is more practical. To elaborate, data in terms of *Weir* is not the value(s) of a programming language variable, but the instances of components in memory and file system layers per label. Finally, just like secure multi-execution, faceted execution is more suitable when the IFC lattice is small (e.g., two labels) or finite, and may not be feasible for DIFC, where tags can be created at runtime.

Coarse-grained Containers: Approaches such as Samsung Knox [34] and Android for Work [2] protect enterprise data by isolating groups of applications into different containers. Containers cannot compensate for the lack of data secrecy guarantees, as they do not address threats within the container, i.e., the accidental export of secret data by a trusted application or the potential compromise of a trusted application. Virtual phones (e.g., Cells [4]) are similarly inadequate for data secrecy.

Transitive Enforcement on Android: Android permissions lack transitive enforcement, and are susceptible to privilege escalation attacks [7, 16]. IPC Inspection [14] enforces transitivity by reducing the caller's effective permissions to those of the least privileged component in the call chain. Quire [12] provides the call chain information to applications being called, to prevent confused deputy attacks. Like floating labels, privilege reduction is additive, and may severely restrict shared components.

Fine-grained Taint Tracking on Android: Taint-Droid [13] detects private data leaks via fine-grained taint tracking on Android, but is vulnerable to implicit flows. CleanOS [43] and Pebbles [38] use fine-grained taint tracking on memory and storage to evict and manage private data respectively. For tracking data in databases, both approaches rely on modification to the database library, which may not be secure as the library executes in the memory of the enforcement subject.

11 Conclusion

Android's component and storage abstractions make secure and practical DIFC enforcement challenging. To ad-

dress these challenges, we present *lazy polyinstantiation* and *domain declassification*. We design and implement a DIFC system, *Weir*, and show a negligible performance impact as well as compatibility with legacy applications. In doing so, we show how secure and backwards compatible DIFC enforcement can be achieved on Android.

A Component Polyinstantiation Logic

In this section, we describe *Weir*'s changes to the Activity Manager service's component and process assignment logic. Figure 8 shows the workflow inside the Activity Manager when a component *C* is called. The

shaded blocks form *Weir*'s label checks and polyinstantiation logic. Note that the figure portrays the high level steps followed by the Activity Manager, common to all components. When a call arrives, *Weir* first gets the label for the caller's process from the kernel and stores it in *callerLabel*. The Activity Manager then resolves the target component *C* using the information in the call. At this point the Activity Manager only knows the name and type of the target component (e.g., the content provider *C*). The Activity Manager then checks if there is a runtime instance of *C* in its records. If a runtime instance exists and is executing in a process with a matching label, the call is delivered to the running instance. Otherwise, *Weir* forces the Activity Manager to create another runtime instance, for this new *callerLabel*.

Without *Weir*, the Activity Manager would always deliver the call to the existing instance.⁵ *Weir* modifies the Activity Manager's internal bookkeeping structures to be consistent with its polyinstantiation; i.e., it enables the Activity Manager to manage multiple runtime records for the same component. For example, the ActivityManager uses a direct mapping between a service's name and its runtime instance, to store records of running services. *Weir* modifies this mapping to one between the name and a set of services.

At this stage, the system has a new component instance that needs to be executed in a process. The Activity Manager selects the process based on the *processName* extracted from the “android:process” manifest attribute. A runtime record of the resolved process *P* is then sent to *Weir* for process matching (i.e., the *Match_Weir_Proc (P, callerLabel)* subroutine). *Weir* first checks the label of the existing process *P*, and if it matches, returns *P* itself. If not, *Weir* retrieves its internal list of processes associated with *P*. This list constitutes the processes that were created in the past to be assigned instead of *P* for specific caller labels. *Weir* checks if the list contains a process with a label matching the current *callerLabel*; this step ensures that components with the same *processName* as well as *callerLabel* are executed in the same process. If *Weir* fails to find a matching process in the list, it allocates a new process for the *callerLabel*, and adds it to the list of existing processes mapped to the specific *processName*. This process is then returned as *P* to the Activity Manager. The Activity Manager then starts *P*, if it is not already started, and *Weir* sets its label in the kernel. Note that if the process is already started (i.e., the original *P* was matching, or a matching process was found in *Weir*'s *pList (P.processName)*, the Activity Manager does not restart it. Finally, the component instance is executed in the assigned process, and the call is delivered to it.

⁵Except in the case of standard and multi-process activities.

Screen After Previous Screens: Spatial-Temporal Recreation of Android App Displays from Memory Images

Abstract

Smartphones are increasingly involved in cyber and real world crime investigations. In this paper, we demonstrate a powerful smartphone memory forensics technique, called RetroScope, which recovers multiple previous screens of an Android app — in the order they were displayed — from the phone’s memory image. Different from traditional memory forensics, RetroScope enables *spatial-temporal* forensics, revealing the progression of the phone user’s interactions with the app (e.g., a banking transaction, online chat, or document editing session). RetroScope achieves near perfect accuracy in both the recreation and ordering of reconstructed screens. Further, RetroScope is app-agnostic, requiring no knowledge about an app’s internal data definitions or rendering logic. RetroScope is inspired by the observations that (1) app-internal data on previous screens exists much longer in memory than the GUI data structures that “package” them and (2) each app is able to perform context-free re-drawing of its screens upon command from the Android framework. Based on these, RetroScope employs a novel interleaved re-execution engine to selectively reanimate an app’s screen redrawing functionality *from within a memory image*. Our evaluation shows that RetroScope is able to recover full temporally-ordered sets of screens (each with 3 to 11 screens) for a variety of popular apps on a number of different Android devices.

1 Introduction

As smartphones become more pervasive in society, they are also increasingly involved in cyber and real world crimes. Among the many types of evidence held by a phone, an app’s prior screen displays may be the most intuitive and valuable to an investigation — revealing the intent, targets, actions, and other contextual evidence of a crime. In this paper, we demonstrate a powerful forensics capability for Android phones: recovering *mul-*

tiple previous screens displayed by each app from the phone’s memory image. Different from traditional memory forensics, this capability enables *spatial-temporal* forensics by revealing what the app displayed over a time interval, instead of a single time instance. For example, investigators will be able to recover the multiple screens of a banking transaction, deleted messages from an online chat, and even a suspect’s actions before logging out of an app.

Our previous effort in memory forensics, GUITAR [35], provides a related (but less powerful) capability: recovering the most recent GUI display of an Android app from a memory image. We call this GUI display *Screen 0*. Unfortunately, GUITAR is *not* able to reconstruct the app’s previous screens, which we call *Screens -1, -2, -3...* to reflect their reverse temporal order. For example, if the user has logged out of an app before the phone’s memory image is captured, GUITAR will only be able to recover the “log out” screen, which is far less informative than the previous screens showing the actual app activities and their progression.

To address this limitation, we present a novel spatial-temporal solution, called RetroScope, to reconstruct an Android app’s previous GUI screens (i.e., Screens 0, -1, -2... -N, N > 0). RetroScope is *app-agnostic* and does not require any app-specific knowledge (i.e., data structure definitions and rendering logic). More importantly, RetroScope achieves near perfect accuracy in terms of (1) reconstructed screen display and (2) temporal order of the reconstructed screens. To achieve these properties, RetroScope overcomes significant challenges. As indicated in [35], GUI data structures created for previous screens get overwritten almost completely, as soon as a new screen is rendered. This is exactly why GUITAR is unable to reconstruct Screen -i (i > 0), as it cannot find GUI data structures belonging to the previous screens. In other words, GUITAR is capable of “spatial” — but not “spatial-temporal” — GUI reconstruction. This limitation motivated us to seek a fundamentally different ap-

proach for RetroScope.

During our research, we noticed that although the GUI data structures for app screens dissolve quickly, the actual *app-internal data* displayed on those screens (e.g., chat texts, account balances, photos) have a much longer lifespan. Section 2 presents our profiling results to demonstrate this observation. However, if we follow the traditional memory forensics methodology of searching for [16, 25, 26, 41] and rendering [35–37] instances of those app data, our solution would require app-specific data structure definitions and rendering logic, breaking the highly desirable app-agnostic property.

We then turned our attention to the (app-agnostic) display mechanism supplied by the Android framework, which revealed the most critical (and interesting) idea behind RetroScope. A smartphone displays the screen of one app at a time; hence the apps’ screens are frequently switched in and out of the device’s display, following the user’s actions. Further, when the app is brought back to the foreground, its entire screen must be redrawn from scratch: by first “repackaging” the app’s internal data to be displayed into GUI data structures, and then rendering the GUI data structures according to their layout on the screen. Now, recall that the “old” app-internal data (displayed on previous screens) are still in memory. Therefore, we propose redirecting Android’s “draw-from-scratch” mechanism to those old app data. Intuitively, this would cause the previous screens to be rebuilt and rendered. This turns out to be both feasible and highly effective, thus enabling the development of RetroScope.

Based on the observations above, RetroScope is designed to trigger the re-execution of an app’s screen-drawing code in-place within a memory image — a process we call *selective reanimation*. During selective reanimation, the app’s data and drawing code from the memory image are logically interleaved with a live *symbiont app*, using our *interleaved re-execution engine* and *state interleaving finite automata* (Section 3.2). This allows RetroScope (within a live Android environment) to issue standard GUI redrawing commands to the interleaved execution of the target app, until the app has redrawn all different (previous) screens that its internal data can support. In this way, RetroScope acts as a “puppeteer,” steering the app’s code and data (the “puppet”) to reproduce its previous screens.

We have performed extensive evaluation of RetroScope, using memory snapshots from 15 widely used Android apps on three commercially available phones. For each of these apps, RetroScope accurately recovered multiple (ranging from 3 to 11) previous screens. Our results show that RetroScope-recovered app screens provide clear spatial-temporal evidence of a phone’s activities with high accuracy (only missing 2 of 256 re-

coverable screens) and efficiency (10 minutes on average to recover all screens for an app). We have open-sourced RetroScope¹ to encourage reproduction of our results and further research into this new memory forensics paradigm.

2 Problem and Opportunity

Different from typical desktop applications, frequent user interactions with Android apps require their screen display to be highly dynamic. For example, nearly all user interactions (e.g., clicking the “Compose Email” button on the Inbox screen) and asynchronous notifications (e.g., a pop-up for a newly received text message) lead to drawing an entirely new screen. Despite such frequent screen changes, an earlier study [35] shows that every newly rendered app screen destroys and overwrites the GUI data structures of the previous screen.

This observation however, seems counter-intuitive as Android apps are able to very quickly render a screen that is similar or identical to a previous screen. For example, consider how seamlessly a messenger app returns to the “Recent Conversations” screen after sending a new message. Given that the previous screen’s data structures have been destroyed, the app must be able to *recreate* GUI data structures for the new screen. More importantly, we conjecture that the raw, app-internal data (e.g., chat texts, dates/times, and photos) displayed on previous screens must exist in memory long after their corresponding GUI data structures are lost.

To confirm our conjecture about the life spans of (1) GUI data structures (short) and (2) app-internal data (long), we performed a profiling study on a variety of popular Android apps (those in Section 4). Via instrumentation, we tracked the allocation and destruction (i.e., overwriting) of the two types of data following multiple screen changes of each app. Figure 1 presents our findings for TextSecure (also known as Signal Messenger). It is evident that the creation of every new screen causes the destruction of the previous screen’s GUI data, whereas the app-internal data not only persists but accumulates with every new screen. We observed this trend across all evaluated apps.

Considering that a memory image reflects the memory’s content at one time instance, Figure 1 illustrates a limitation of existing memory forensics techniques (background on memory image acquisition can be found in Appendix A). Specifically, given the memory image taken after Screen 0 is rendered (as marked in Figure 1), our GUITAR technique [35] will only have access to the GUI data for Screen 0. Meanwhile, the app’s internal

¹RetroScope is available online, along with a demo video, at: <https://github.com/ProjectRetroScope/RetroScope>.

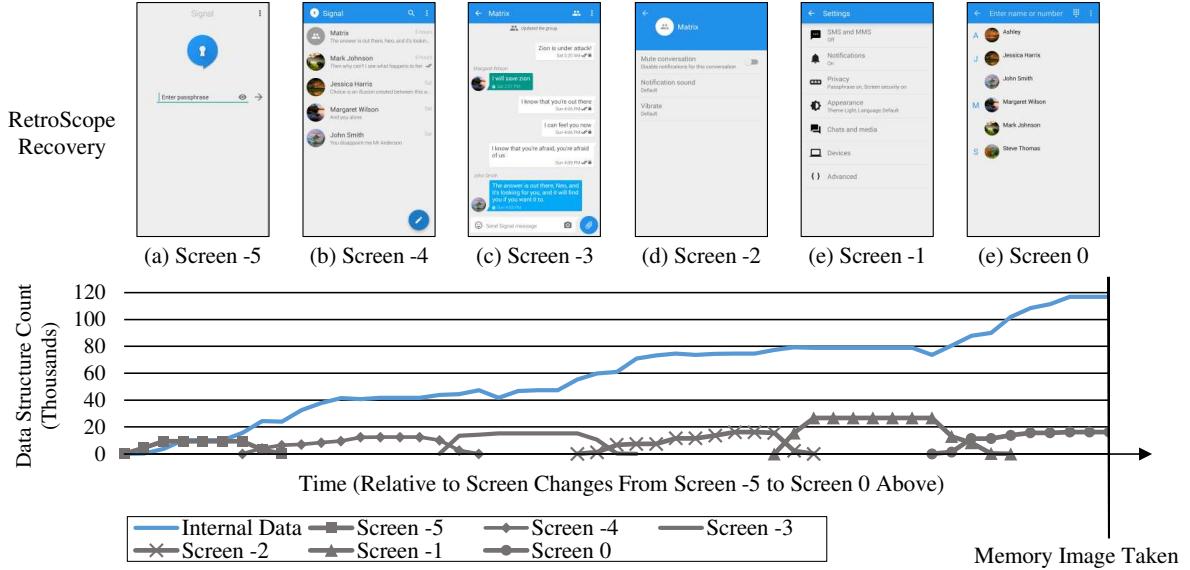

Figure 1: Life Cycles of GUI Data Structures Versus App-Internal Data Across Multiple Screen Changes.

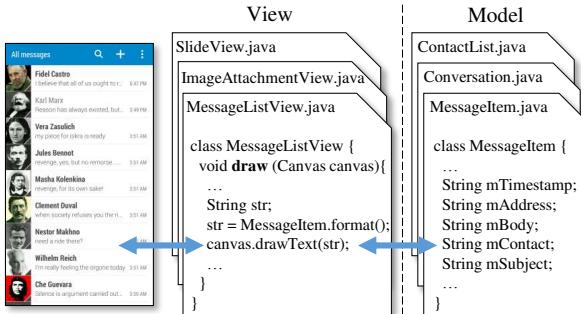

Figure 2: The Typical Model/View Implementation Split of Android Apps.

data are maintained by the app itself for as long as the app’s implementation allows (e.g., we never observed TextSecure deallocating its messages because they may be needed again). However, without app-specific data definitions or rendering logic, it is impossible for existing app-agnostic techniques [6, 36, 41] to meaningfully recover and redisplay the app’s internal data on Screens -1 to -5 in Figure 1.

It turns out that the Android framework instills the “short-lived GUI structures and long-lived app-internal data” properties in all Android apps. Specifically, Android apps must follow a “Model/View” design pattern which intentionally separates the app’s logic into *Model* and *View* components. As shown in Figure 2, an app’s Model stores its internal runtime data; whereas its View is responsible for building and rendering the GUI screens that present the data. For example, the *MessageItem*, *Conversation*, and *ContactList* (Model) classes in Figure 2 store raw, app-internal data, which are then

formatted into GUI data structures, and drawn on screen by the *MessageListView* class. This design allows the app’s View screens to respond quickly to the highly dynamic user-phone interactions, while delegating slower operations (e.g., fetching data updates from a remote server) to the background Model threads.

Further, the Android framework provides a Java class (aptly named *View*) which apps must extend in order to implement their own GUI screens. As illustrated by Figure 2’s *MessageListView* class, each of the app’s screens correspond to an app-customized *View* object and possibly many sub-*Views* drawn within the top-level *View*. Most importantly, each *View* object defines a *draw* function. *draw* functions are prohibited from performing blocking operations and may be invoked by the Android framework whenever that specific screen needs to be redrawn. This makes any screen’s GUI data (e.g., formatted text, graphics buffers, and drawing operations which build the screen) easily disposable, because the Android framework can quickly recreate them by issuing a *redraw command* to an app at any time. This design pattern provides an interesting opportunity for RetroScope, which will intercept and reuse the context of a live *redraw command* to support the reanimation of *draw* functions in a memory image.

3 Design of RetroScope

RetroScope’s operation is fully automated and only requires a memory image from the Android app being investigated (referred to as the *target app*) as input. From this memory image, RetroScope will recreate as many

previous screens as the app’s internal data (in the memory image) can support. However, without app-specific data definitions, RetroScope is unable to locate or understand such internal data. But recall from Section 2 that the Android framework can cause the app to draw its screen by issuing a redraw command, without handling the app-internal data directly. This is possible because the app’s `draw` functions are invoked in a *context-free* manner: The Android framework only supplies a buffer (called a `Canvas`) to draw the screen into, and the `draw` function obtains the app’s internal data via previously stored, global, or static variables — analogous to starting a car with a key (the redraw command) versus manually cranking the engine (app internals). Thus, RetroScope is able to leverage such commands, avoiding the low-level “dirty work” as in previous forensics/reverse engineering approaches [36, 37].

RetroScope mimics this process *within* the target app’s memory image by selectively reanimating the app’s screen drawing functions via an *interleaved re-execution engine* (IRE). RetroScope can then inject redraw commands to goad the target app into recreating its previous screens. An app’s `draw` functions are ideal for re-animation because they are (1) functionally closed, (2) defined by the Android framework (thus we know their interface definition), and (3) prevented from performing I/O or other blocking operations which would otherwise require patching system dependencies. Finally, RetroScope saves the redrawn screens in the temporal order that they were previously displayed, unless the `draw` function crashes — indicating the app-internal data could not support that screen.

To support selective reanimation, RetroScope leverages the open-source Android emulator to start, control, and modify the execution of a *symbiont app*, a minimal implementation of an Android app which will serve as a “shell” for selective reanimation.

3.1 Selective Reanimation

Before selective reanimation can begin, RetroScope must first set up enough of the target app’s runtime environment for re-executing the app’s `draw` functions. Therefore RetroScope first starts a new process in the Android emulator, which will later become the symbiont app and the IRE (Section 3.2). RetroScope then synthetically recreates a subset of the target app’s memory space from the subject memory image. Specifically, RetroScope loads the target app’s data segments (native and Java) and code segments (native C/C++ and Java code segments) back to their original addresses (Lines 1-4 of Algorithm 1) — this would allow pointers within those segments to remain valid in the symbiont app’s memory space. RetroScope then starts the symbiont app which

will initialize its native execution environment and Java runtime. Note that the IRE will not be activated until later when state interleaving (Section 3.2) is needed.

Isolating Different Runtime States. The majority of an Android app’s runtime state is maintained by its Java runtime environment². For RetroScope, it is not sufficient to simply reload the target app’s memory segments. Instead the symbiont app’s Java runtime must also be made aware of the added (target app’s) runtime data prior to selective reanimation. Later, the IRE will need to dynamically switch between the target app’s runtime state and that of the symbiont app to present each piece of interleaved execution with the proper runtime environment.

RetroScope traverses a number of global Java runtime data structures from the subject memory image with information such as known/loaded Java classes, app-specific class definitions, and garbage collection trackers (Lines 5–9 of Algorithm 1). Such data are then copied and isolated into the symbiont app’s Java runtime by inserting them (via the built in Android class-loading logic) into duplicates of the Java runtime structures in the symbiont app. Note that, at this point, the duplicate runtime data structures will not affect the execution of the symbiont app, but they must be set up during the symbiont app’s initialization so that any app-specific classes and object allocations *from the memory image* can be handled later by the IRE.

At this point, the symbiont app’s memory space contains (nearly) two full applications (shown in Figure 4). The symbiont app has been initialized naturally by the Android system with its own execution environment. In addition, RetroScope has reserved and loaded a subset of the target app’s memory segments (those required for selective reanimation) and isolated the necessary old (target app’s) Java runtime data into the new (symbiont app’s) Java runtime. The remainder of RetroScope’s operation is to (1) mark the target app’s View `draw` functions so that they can receive redraw commands and (2) reanimate those drawing functions inside the symbiont app via the IRE.

Marking Top-Level Draw Functions. RetroScope traverses the target app’s loaded classes to find top-level Views (Lines 10–17 in Algorithm 1). Top-level Views are identified as those which inherit from Android’s parent View class `ViewParent` and are not drawn inside any other Views. As described in Section 2, top-level Views are default Android classes which *contain* app-customized sub-Views. Further, we know that all Views must implement a `draw` function (which invokes the sub-Views’ `draw` functions). Thus RetroScope marks each top-level `draw` function as a reanimation starting point.

²Please see Section 5 regarding Dalvik JVM versus ART runtimes.

Algorithm 1 RetroScope Selective Reanimation.

Input: Target App Memory Image M
Output: GUI Screen Ordered Set S

```

1: for Segment  $S \in M$  do           ▷ Rebuild the Target App runtime environment
2:   if isNeededForReanimation( $S$ ) then
3:     Map( $S.startAddress$ ,  $S.length$ ,  $S.content$ )
4: SymbiontApp.initialize()          ▷ Set up Symbiont App
5: JavaGlobalStructs  $G \leftarrow \emptyset$  ▷ Isolate the Target App runtime state.
6: for Segment  $S \in M$  do           ▷ Find Java control data
7:   if containsJavaGlobals( $S$ ) then
8:      $G \leftarrow \text{getJavaGlobals}(S)$ 
9:   break
10:  ▷ Register reanimation points with the IRE.
11: View Set  $V \leftarrow \emptyset$           ▷ Top-level Views.
12: for Class  $C \in G \rightsquigarrow \text{Classes}$  do      ▷ Find top-level Views.
13:   if  $C <: \text{ViewParent}$  then        ▷ ' $<:$ ' denotes subtype.
14:     if not isSubView( $C$ ) then
15:       IRE.beginOn( $C.draw$ )          ▷ Register drawing function.
16:     View Set  $views \leftarrow C.instances$ 
17:      $V \leftarrow V \cup views$ 
18: View  $T \leftarrow \text{SymbiontApp.getTopLevelView}()$ 
19:  $T.invalidate()$                   ▷ Cause screen redraw command to be issued.
20: procedure CATCHREDRAWCOMMAND
21:   for View  $view \in V$  do
22:      $T \leftarrow view$  ▷ Override the Symbiont App's top-level View.
23:     largestID  $\leftarrow \max_{v \in view.\text{subViews}} v.getField(ID)$  ▷ Record largest subView ID.
24:     deliverRedrawCommand()        ▷ IRE handles re-execution of redrawing code.
25:   Screen  $s \leftarrow T.\text{copyGUIBuffer}()$ 
26:    $S.insert(largestID, s)$ 
27: end procedure

```

Selective Reanimation. Once all top-level draw functions are identified, RetroScope can begin selective reanimation of each. First, RetroScope invalidates the symbiont app’s current View (Line 19 of Algorithm 1). This will cause Android to set up and issue a redraw command to the symbiont app along with a buffer to draw into. However, RetroScope first intercepts this command and replaces the symbiont app’s top-level View with one of the target app’s top-level Views identified previously (Lines 20–27 in Algorithm 1). Note that RetroScope does not distinguish between different instances of top-level Views, it simply reissues redraw commands for every previously identified top-level View instance, even if duplicates exist.

Since the top-level Views of the symbiont app and the target app are both default instances of (or inherit from) the same Android View class, they are interchangeable as far as the Android framework is concerned (both with the same functionality). Now RetroScope can inject the redraw command into the symbiont app which, upon receiving this command, will naturally invoke the target app’s top-level draw function (previously marked for re-animation).

This will trigger the IRE to begin logically interleaving

the draw function execution with the symbiont app’s GUI drawing environment. Most importantly, this will direct input code/data accesses (i.e., queries to the target app’s Model) to the appropriate target app functions and output code/data accesses (i.e., drawing of screens) to the symbiont app’s running GUI framework. Upon successful completion of each draw function reanimation, RetroScope retrieves and stores the symbiont app’s (now filled) screen buffer, switches the top-level View to another marked target app View, and re-injects the redraw command — reloading the memory image in between to avoid side effects.

Finally, RetroScope reorders the redrawn screens to match the temporal order in which they were displayed. This is done via comparison of View ID fields in the target app’s Views (recovered from the memory image). A View’s ID is an integer that identifies a View. The ID may not be unique, as some Views may alias others, but it is always set from a monotonically increasing counter. This yields the property that app screens can be ordered temporally by comparing the largest ID among their sub-Views. Intuitively, the most recently modified portion of the screen (sub-View) will yield an increasingly large ID.

3.2 Interleaved Re-Execution Engine

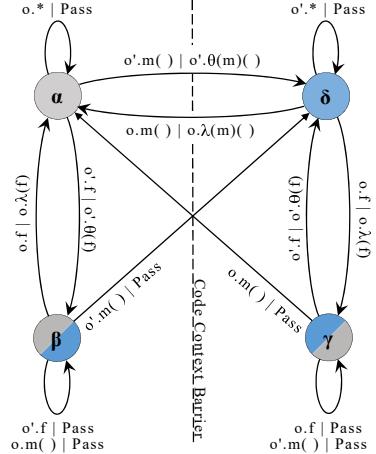

Figure 3: State Interleaving Finite Automata.

The key enabling technique behind RetroScope is its IRE which logically interleaves the state of the target app into the symbiont app just before it is needed by the execution. To monitor and interleave the execution contexts, the IRE intercepts the execution of Java byte-code instructions corresponding to function invocations, returns, and data accesses (i.e., instance/static field reads/writes). The IRE’s operation is similar to parsing a lexical context-free grammar: The current byte-code instruction (i.e., token) and the context of its operands (e.g., new/old data) are matched to a *state interleaving*

finite automata (Figure 3), where each state transition defines which runtime environment the IRE should present to that instruction.

In RetroScope, state interleaving begins at the invocation of one of the marked top-level draw functions within the target app. As a running example, Figure 4 shows a snippet of a draw function’s code along with the live memory space (containing both the symbiont app and the target app’s execution environment).

IRE State Tracking. For each byte code instruction, the IRE tracks two pieces of information: (1) if the code being executed is from the memory image (*old code*) or from the symbiont app (*new code*) and (2) if the current runtime information (i.e., loaded classes, object layouts, etc.) originates from the memory image (*old runtime*) or the symbiont app (*new runtime*). Based on that, the execution context may be in any of four possible states:

$$\begin{aligned} (\text{new code, new runtime}) &= \alpha \\ (\text{new code, old runtime}) &= \beta \\ (\text{old code, new runtime}) &= \gamma \\ (\text{old code, old runtime}) &= \delta \end{aligned} \quad (1)$$

In Figure 4, we have denoted which state the IRE is in before and after executing each line of code. For ease of explanation, Figure 4 presents source code, but RetroScope operates on byte-code instructions only. For example, before executing Line 1, the IRE is in α because no old code or data has been introduced yet. Likewise, after Line 1, the IRE is in δ as the IRE is then executing the target app’s draw function (old code) within the target app’s top-level View object (old runtime). However, note that the context of runtime data may not (and often does not) match the context of the code: For example, in Line 4, fetching the `mDensity` field from the new Canvas requires using the new runtime data but is being performed by old code (resulting in state γ).

Modeling State-Transitions. In Figure 3, we generalize the state-transition rule matching to two primitive operations: Given an object o , state transitions may occur when accessing a field f within o ($o.f$) or when invoking a method m defined by o ($o.m()$). Further, o may be an object loaded from the target app’s memory image or allocated by the target app’s code (i.e., interacting with this object requires the old runtime data), thus we denote such *old objects* as o' in Figure 3. Note that our discussion will follow Java’s object-oriented design, but the transitions in Figure 3 are equally applicable to static (i.e., $o == \text{NULL}$) execution.

The state transitions in Figure 3 are modeled as a Mealy machine [29] with the input of each state-transition being a matched operation and the output being the corresponding state correction performed by the IRE. These state corrections (i.e., transition outputs) fall into

three categories: (1) a transition from the new runtime data to the old runtime data (the function θ), (2) a transition from old to new runtime data (the function λ), and (3) no change in runtime data (“Pass”). For example, the transition from α to δ is represented as:

$$\alpha \rightarrow \delta : o'.m() \mid o'.\theta(m)() \quad (2)$$

where the input to this transition is a match on $o'.m()$ (invoking an old object’s method) and the output state correction is to switch to the old runtime prior to invoking the method ($o'.\theta(m)()$). This is exactly the IRE’s transition before executing Line 1 in Figure 4 as the IRE must switch to the old runtime prior to invoking the old View object’s draw function to look up the method’s implementation. Conversely, the transition from γ to α is represented as:

$$\gamma \rightarrow \alpha : o.m() \mid \text{Pass} \quad (3)$$

because this transition occurs when a new object’s method is invoked ($o.m$) but the IRE is already using the new runtime data, thus no runtime data correction is needed (i.e., “Pass”). This case is observed in Line 11 of Figure 4. At the beginning of Line 11, the IRE is in state γ due to the lookup of the new Canvas’s `mDensity` field on Line 4. Thus, the invocation of `getClipBounds` on Line 11 does not require the runtime to change (a “Pass” transition), but does change from old code to new.

Another important corrective action in Figure 3 is whether or not a transition crosses the code context barrier (i.e., a horizontal transition). Crossing the code context barrier signifies a switch between fetching new code (from the symbiont app) to old code (from the memory image) or vice versa. Although crossing the context barrier alone does not require active correction by the IRE (e.g., the old runtime’s method definitions will naturally direct the execution to the old code), the IRE must note that the change occurred.

Monitoring which context the code is fetched from is essential for a number of runtime checks and corrections that the IRE must perform. Firstly, objects allocated while executing old code should use the class definitions from the target app (as the Android framework classes may be vendor-customized or the class may be defined by the target app itself). Secondly, type comparisons (e.g., the Java `instanceof` operator) executed by old code must consider both new and old classes but prefer old classes. This is because new objects (which are instances of classes loaded by the symbiont app’s runtime) will be passed into old code functions — which use the target app’s loaded classes that contain “old duplicates” of classes common to both executions (e.g., system classes). The reverse is true for new code type comparisons. Lastly, exceptions thrown during interleaved execution should be catchable by both old and new code.

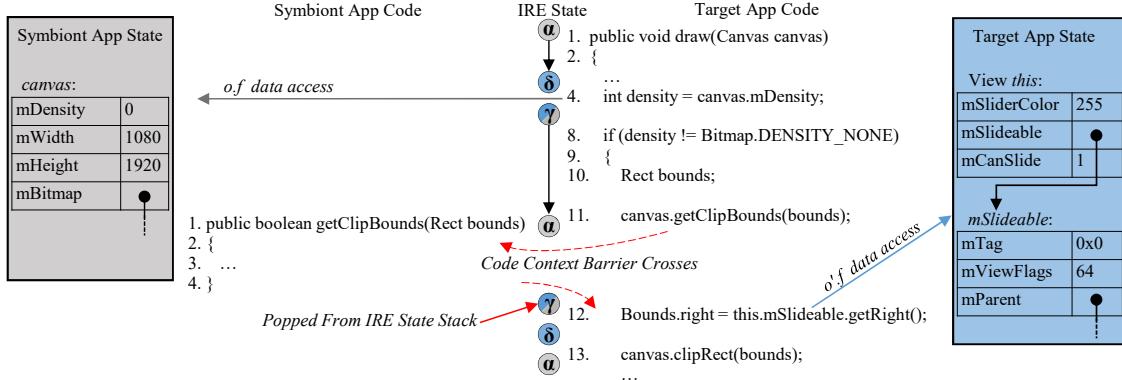

Figure 4: Example of Interleaved Re-Execution.

Interestingly, we find a number of test cases in Section 4 *purposely* throw exceptions inside their inner drawing functions, and allowing new code to catch old code exceptions (or vice versa) requires patching type lookups (as before) and stack walking.

Return Transitions. Although Figure 3 does not illustrate state transitions for return instructions, the IRE does perform state correction for them. Unlike the transitions in Figure 3 (which rely on the current IRE state to determine a new state), method returns simply restore the IRE state from before the matching invocation. This is tracked by a stack implemented in the IRE which pushes the current IRE state before invoking a method and pops/restores that IRE state upon the method’s return. This behavior is seen in Line 12 in Figure 4. Before the invocation of `getClipBounds` (Line 11), the IRE is in state γ . Function `getClipBounds` executes in state α , and upon its return the IRE pops state γ from the stack and restores that state prior to executing Line 12.

Another notable simplification of the IRE’s design is that it is sufficient to only perform state correction at function invocations, returns, and field accesses. Intuitively, this is because other “self-contained” instructions (e.g., mathematical operations) do not require support from the runtime. But another advantage is that state-interleaving tends to occur after bunches of instructions. Our evaluation shows that on average 10.24 instructions in a row will cause loop-back transitions before a state correction is needed. Further, many functions execute entirely in state α or δ because no data from the other environment enter those functions.

Native Execution. The IRE operates on the Java bytecode instructions of the functions marked for selective reanimation. However, it is possible that app developers utilize the Java Native Interface (JNI) to implement some of their app’s functionality in native C/C++ code. Further, the Android framework heavily uses JNI functions. When the IRE observes an invocation of a C/C++

function, it follows the same state transitions defined in Figure 3 (i.e., new code only invokes new C/C++ functions and vice versa).

Luckily, due to the tightly controlled interaction between C/C++ functions and the Java runtime data, the IRE’s state correction can be further simplified. To access data or invoke methods from the Java runtime, C/C++ functions must use a set of helper functions defined by the Java runtime. The IRE hooks these functions and checks if the data or method being requested is in the old or new context. The IRE can then properly patch the helper function’s return value and allow the C/C++ function to execute as intended. Note that, because all the target app’s native code and data segments have been mapped back to their original addresses, all pointers (code and data) in those segments remain valid.

Lastly, although the IRE executes app-specific code, it does so on a *syntactic* basis *without* understanding the code’s semantics, hence maintaining RetroScope’s app-agnostic property.

3.3 Escaping Execution and Data Accesses

To monitor and interleave the target app’s reanimation, the IRE must accurately track the current state of the execution environment. However, due to the relative complexity of Android apps, it is possible that the target app’s control flow causes the IRE to miss a state transition, potentially failing to correct the execution environment despite the actual execution being in a different state. We call such missed state transitions *escaping execution* or *escaping data accesses*.

Escaping Execution. This occurs when the target app’s reanimation invokes a function but the IRE is unable to determine which context to transition to. This is primarily due to the invocation of a static method which exists in both the old and new environments — leading to an *ambiguous state-transition*, where the IRE does not have

sufficient information at the function invocation site to determine which state (α) or (δ) to transition to. Simply put, the IRE must discover if the execution intended to invoke the old or new method. To decide that, the IRE performs a simple data flow analysis on each version. If the method writes data to a static variable, then the IRE always invokes the method in state α , otherwise the IRE keeps the same state that the method was invoked by (to avoid an unnecessary transition). This ensures that any accesses to static values which exist in both old and new environments are always directed to the new one. Note that app-defined static variables will only exist in the old environment, and thus their accesses do not lead to ambiguous transitions.

Escaping Data Accesses. This occurs when an app implements a non-standard means of accessing an object’s fields. For example, the two most common causes of escaping data accesses we observed are: (1) C/C++ code using a hard-coded Java object layout to access an object’s fields and (2) old Java code which has cached an old version of an object which RetroScope is trying to replace with a new version (e.g., some Views will save and reuse a reference to the previously drawn on Canvas). Although escaping data accesses are caused by app implementation differences, they can be handled uniformly by the IRE.

Escaping data accesses caused by Java code can be identified automatically when the fields of the object are accessed incorrectly. For example, there should not exist any old Canvas objects during selective reanimation and thus the IRE will identify its field accesses and replace the object with the new instance. Escaping data accesses caused by C/C++ code are handled by preventing C/C++ code from directly accessing Java objects. Instead, the IRE requires all pointers to Java objects to be encoded before they are given to C/C++ code. These pointers can be decoded when they are used in the standard JNI field access helper functions, but will cause a segmentation fault when dereferenced erroneously. This segmentation fault can then be handled by RetroScope to patch the field access with the appropriate JNI helper function. In fact, support for encoded/decoded JNI pointers already exists but may be avoided in Android, so the IRE only needs to require that all JNI pointers are encoded/decoded and handle the segmentation fault for those that previously avoided this functionality.

4 Evaluation

Evaluation Setup. Our evaluation of RetroScope involved three Android phones (a Samsung Galaxy S4,

HTC One, and LG G3)³ as evidentiary devices. On each phone, we installed and interacted with 15 different apps to cause the generation, modification, and deletion of as many screens as possible. The interactions took an average of 16 minutes per app, and we installed and interacted with the apps on each phone at random times over a 4-day period. Then, for each phone, we waited 60 minutes for any background activity of the 15 apps to complete, after which we took a memory image from the phone (as described in Appendix A).

The set of 15 apps was chosen to represent both typical app categories (to highlight RetroScope’s generic applicability) and diverse app implementation (to evaluate the robustness of RetroScope’s selective reanimation). Based on the importance of personal communication in criminal investigations, we included Gmail, Skype, WeChat, WhatsApp, TextSecure (also known as Signal, notable for its privacy-oriented design which limits evidence recovery [4]), Telegram (whose encrypted broadcast channels are popular with terrorist organizations [3]), and each device’s default MMS app (implemented by the device vendor). We also included the two most popular social networking apps: Facebook (known for its highly complex/obfuscated implementation) and Instagram. Finally we consider several apps which, by nature, display sensitive personal information: Chase Banking, IRS2Go (the official IRS mobile app), MyChart (the most popular medical record portfolio app), Microsoft Word for Android, and the vendor-specific Calendar and Contacts/Recent Calls apps.

We then used RetroScope to recreate as many previous app screens as still exist in the memory images of the 45 (15 × 3) apps. The recovery results are reported in Table 1. Table 1 presents the device and app name in Columns 1 and 2, respectively. Column 3 shows the ground-truth number of screens that RetroScope should recover, and Column 4 reports the number of screens recovered. Columns 5 through 9 present several metrics recorded over the selective reanimation of all screen redrawing functions for each app: Column 5 shows the number of reanimated Java byte-code instructions, Column 6 reports the number of JNI invocations (i.e., C/C++ functions invoked from Java code) observed, and Columns 7 and 8 report the total number of newly allocated Java objects and C/C++ structures that made up the new screens. Column 9 shows RetroScope’s runtime for each case.

Selective Reanimation Metrics. Table 1 provides interesting insights into the complexity and scale of screen redrawing via selective reanimation. From Table 1, we learn that an average of 231,867 byte-code instructions

³These devices all run vendor-customized versions of Android Kitkat (the most widely used Android version [17]).

Device	App	Expected # of Screens	RetroScope Recovery	Metrics for Evaluating Selective Reanimation				
				Byte-Code Instructions	JNI Invocations	Allocated Java Objects	New C/C++ Structures	Runtime (seconds)
Samsung S4	Calendar	8	8	259196	4699	930	79119	502
	Chase Banking	9	9	424336	9318	1905	106168	1610
	Contacts	5	5	199755	4606	928	49322	369
	Facebook	6	6	338195	7928	1432	45420	1059
	Gmail	5	5	188463	4185	826	80808	487
	Instagram	7	7	240139	5191	482	86319	672
	IRS2Go	5	5	195413	4450	790	21027	674

Table 1: Overall Results of RetroScope Evaluation.

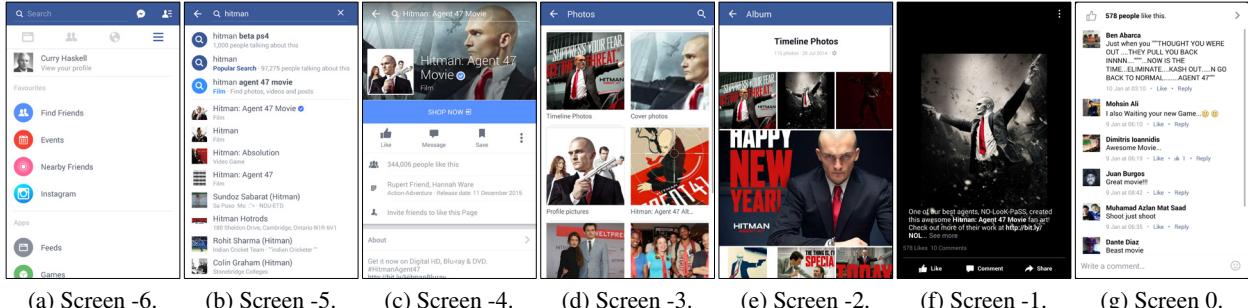

and 5,047 JNI function invocations are required to redraw all of the screens for a single app. This yields an average of 41,078 byte-code instructions and 894 JNI function invocations *per screen*. Higher than our initial expectations, these numbers attest to the complexity of the screen drawing implementation and robustness of RetroScope’s IRE.

Another metric above our expectation was the number of data structures that had to be *newly allocated* to redraw each screen. While redrawing all previous screens of each app, the reanimated code allocated an average of 891 Java objects and 76,397 C/C++ structures per app,

and an average of 158 Java objects and 13,535 C/C++ structures *per screen*. These numbers confirm the claim in GUITAR [35] that each screen is made of “thousands of GUI data structures.” Most importantly, as also shown in [35], only the structures for Screen 0 may still exist in a memory image, whereas RetroScope actively triggers the *rebuilding* of the lost data for Screens 0, -1, -2, … -N.

4.1 Spatial-Temporal Evidence Recovery

Ground Truth. We now evaluate how accurately RetroScope recreates the screens displayed during our last

(a) Screen -6. (b) Screen -5. (c) Screen -4. (d) Screen -3. (e) Screen -2. (f) Screen -1. (g) Screen 0.

Figure 5: LG G3 Facebook Recovery.

interaction session with each app. However, obtaining the ground truth (how many previous screens RetroScope *should* recover) is not straightforward because the screens’ recoverability is decided by the availability of the app’s internal data in the memory image. Therefore, to identify the recoverable previous screens, we instrumented each app to log any *non-GUI-related* data allocations and accesses performed by each screen-drawing function. We then compared this log to the content of the final memory image to identify which screens’ *entire* app-internal data still existed⁴. This gives us a strict lower bound on the number of screens that RetroScope should recover (i.e., all the internal data for those screens exist in the memory image). *Without* app-specific reverse engineering efforts, it is impossible to know the upper bound that the app’s internal data could support. But as we discuss later, screen redrawing is often “all or nothing” and adheres closely to this lower bound.

Highlights of Results. RetroScope recovered a total of 254 screens for the 45 apps, from a low of 3 to a high of 11 screens — ironically for the privacy sensitive Chase Banking app on the HTC One phone (Figure 6). Overall, Table 1 shows that RetroScope recovers an average of 5.64 screens per app, with the majority of the test cases (33 out of 45) having 5 or more screens.

Table 1 highlights the depth of *temporal* evidence that RetroScope makes available to forensic investigators, but even more intriguing is the clear progression of user-app interaction portrayed by the recovered screens. Figure 5 shows the 7 screens recovered for the Facebook app on the LG G3 phone. From these screens we can infer the “suspect’s” progression: from his own profile (Screen -6), to search results for “hitman” (Screen -5), to the Facebook profile (Screen -4), Photos screen (Screen -3), a photo album (Screen -2) of the Hitman movie, to a single photo (Screen -1), and lastly to that photo’s comments (Screen 0). Such powerful spatial-temporal recov-

ery — from a single memory image — is not possible via any existing memory forensics technique.

Another interesting observation from Table 1 is that, although RetroScope’s recovery is app-agnostic, the apps’ diverse implementations lead to very different redrawing procedures. For example, for both Skype and Facebook apps on the Samsung S4, RetroScope reproduced all 6 screens from each app. However, Facebook’s redrawing implementation appears much more complex, requiring 338,195 byte-code instructions and 7,928 JNI invocations, compared to Skype’s 236,213 byte-code instructions and 5,256 JNI invocations. This also leads to varied RetroScope run times: from the shortest, Samsung S4’s MyChart, at 259 seconds to the longest, LG G3’s Chase Banking, at 1731 seconds. The average runtime across all apps is 655 seconds (10 minutes, 55 seconds).

Lastly, Table 1 shows that in two cases (Rows 26 and 34), RetroScope missed a single screen. Manual investigation of these cases revealed that the app-specific drawing functions for the missed screens had thrown unhandled Java exceptions. For the HTC One device’s Facebook case, we found that the app had stored a pointer to the Thread object which handled its user interface and during redrawing the app failed on a check that the current Thread (handled by RetroScope during reanimation) is the same as the previously stored Thread (from the memory image). For the LG G3 Skype case, when drawing the “video call” screen, a saved timer value (in the memory image) was compared against the system’s current time, which also failed during reanimation. These were addressed by reverse engineering to determine which field/condition in the app caused the fault, and RetroScope can be instructed to set/avoid them during interleaved execution. Also of note, several cases required recovering on-screen elements (e.g., user avatars) which were cached on persistent storage until they are loaded on the screen. Currently, RetroScope attempts to detect (e.g., via the unhandled exception) but can not automatically correct such implementation-specific semantic constraints. We leave this as future work.

⁴Note that RetroScope did not have access to nor could benefit from this ground truth information. Further, we utilized in-place binary instrumentation (which does not interact nor interfere with the app’s execution or memory management) to ensure the accuracy of our experiments.

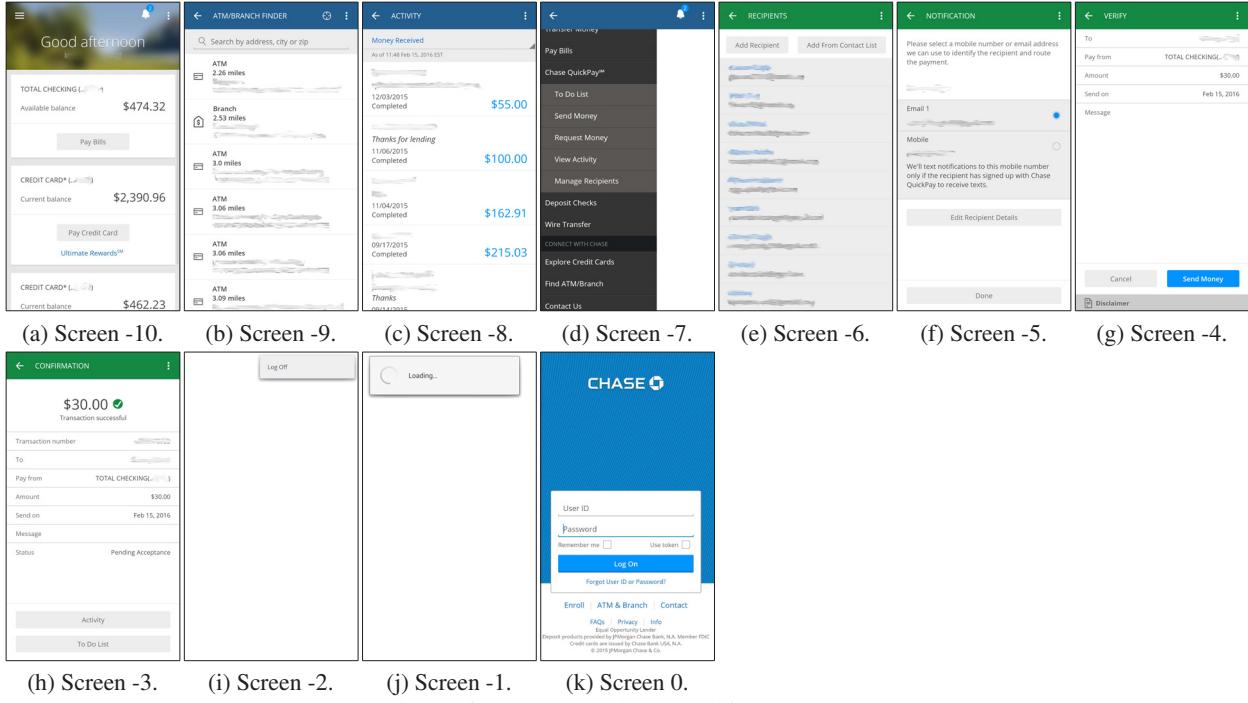

Figure 6: HTC One Chase Banking Recovery.

4.2 Case Study I: Behind the Logout

We now elaborate on the Chase Banking app case and highlight RetroScope’s ability to recreate an app’s previous screens *even after the user has logged out*. Table 1 Row 32 shows that RetroScope recovered 11 out of 11 screens (the highest of all cases). Not surprisingly, the recovery required the most reanimated byte-code instructions (584,587) and JNI function invocations (12,591), as well as the most re-allocated Java objects (2,091) and C/C++ structures (266,965).

The recovered screens are shown in Figure 6. Starting from the Account screen (Screen -10), the “suspect” looks up a nearby ATM (Screen -9). He then reviews his recent money transfers (Screen -8) and begins a new transfer to a friend via the app’s options menu (Screen -7). Screens -6 to -4 fill in the transfer’s recipient and amount. Screen -3 asks the user to confirm the transfer. Screen -2 shows the app’s “Log Out” menu, Screen -1 presents a loading screen while the app logs out, and Screen 0 is (as expected) the app’s log in screen.

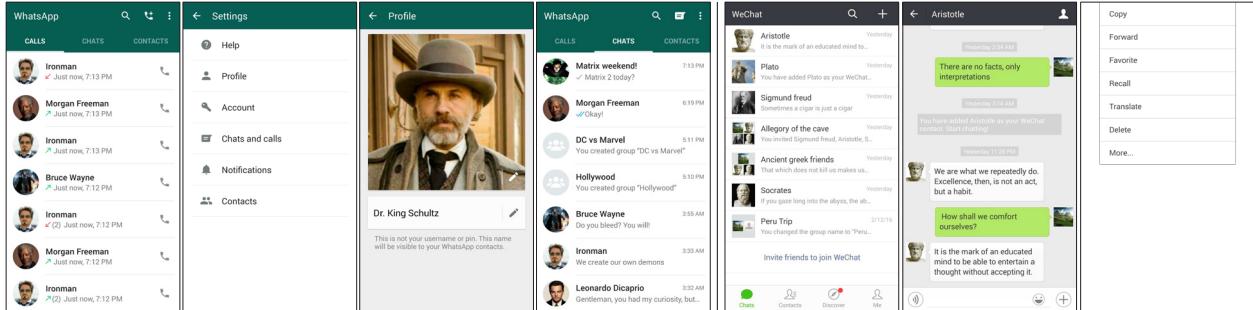

This case yields some interesting observations: First, it highlights the robustness of RetroScope to recover a large number of screens when an app’s internal data continues to accumulate. More importantly, the case shows that, after logging out, the Chase app (as well as many others we have tested) does not clear its internal data. This is not surprising because programmers usually consider their app’s *memory* to be private (compared to network communications or files on persistent storage). This is further evidenced by the TextSecure app, which

also allows for a significant post-logout recovery (of pre-logout screens), despite the app’s message database being locked in the device’s storage.

4.3 Case Study II: Background Updates

Another interesting case is WhatsApp Messenger on the Samsung S4. Table 1 Row 15 shows that RetroScope re-animated 402,536 byte-code instructions and 8,186 JNI functions in 23 minutes, 10 seconds, yielding an average of 50,317 instructions and 1,023 JNI functions per screen. What was unexpected however is that RetroScope recovered an *extra* screen (8 out of the 7 expected screens) from the memory image.

Our investigation into this extra screen found that it was not a screen we had previously seen during our phone usage. Instead, after we had finished interacting with WhatsApp, the app received a new chat message *while it was in the background* and, to our surprise, this prompted the app to prepare a new chat screen that appended the newly received message to the chat. Figure 7 presents the screens recovered by RetroScope, and again we see a clear temporal progression through the app by the “suspect.” First, Screen -6 shows the call log screen. The app’s Settings screen is seen in Screen -5 followed by a screen that is only accessible through the Settings: the device owner’s profile (our fictitious device owner is Dr. King Schultz) in Screen -4. Screen -3 shows the recent chats; Screen -2 shows the “suspect’s” chat with a friend; then Dr. Schultz places a call to that friend

(a) Screen -6.

(c) Screen -4.

(d) Screen -3.

(e) Screen -2.

(f) Screen -1.

(g) Screen 0.

(h) Screen +1.

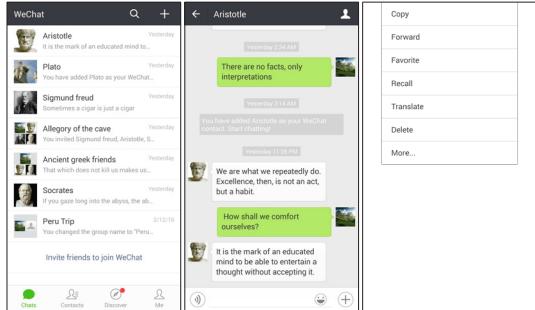

Figure 7: Samsung S4 WhatsApp Recovery.

in Screen -1. Lastly, Screen 0 shows the friend’s profile. Then, the extra *Screen +1* shows the chat screen as prepared by the app while in the background. Indeed it shows the newly received message, even time-stamped (“TODAY” and “4:51 AM” in Figure 7(h)) after the previous chat had taken place.

To ensure that this result was not an accident, we repeated the experiment (receiving chat messages while the app was in the background) six more times (twice per device). In every test, we found that RetroScope recovered the additional pre-built chat screen containing the new message. Strangely, after testing the other apps which can receive background updates, we found that WhatsApp is the only app, among our 15 apps, that exhibited this behavior. We suspect that this is a WhatsApp-specific implementation feature to speed up displaying the chat screen (*Screen +1*) when the device user clicks the “New Message” pop-up notification.

4.4 Case Study III: Deleted Messages

In addition to the WhatsApp case above, RetroScope recovered *extra screens* for four other cases in Table 1: Telegram (Row 12), WeChat (Row 29), WhatsApp (Row 30), and TextSecure (Row 43). However, the extra screens here are for a different reason: RetroScope can recover *explicitly deleted* chat messages. In these tests, we began a chat in each app and then explicitly deleted one of the messages (as a suspect would do in an attempt to hide evidence), and then used RetroScope to

(a) Screen -4.

(b) Screen -3.

(c) Screen -2.

(d) Screen -1.

(e) Screen 0.

Figure 8: LG G3 WeChat Recovery.

recover the deleted message. Additionally, RetroScope also recovered proof of the suspect’s intent to delete the message: For WeChat and WhatsApp, RetroScope recovered the app’s pop-up menu (just prior to the deleted message) which displays the “Delete Message” option. For TextSecure, RetroScope recovered both the pop-up menu and a loading screen showing the text “Deleting Messages.”

Figure 8 shows one example: RetroScope’s recovery for the WeChat app on the LG G3. Screen -4 shows the “suspect’s” recent chats followed by a chat conversation with a friend in Screen -3. Screen -2 is the pop-up menu displaying the “Delete” option. The deleted message (now disconnected from the previous chat window) is displayed in Screen -1, and the friend’s profile page (which the “suspect” navigated to last) is shown in Screen 0.

This result, in particular, highlights one of the most powerful features of RetroScope, given that it works for many apps and even provides proof of the suspect’s intent. Further, all four apps tout their *encrypted* communication and some (e.g., TextSecure) even encrypt the message database in the device. In light of this, law enforcement has routinely had trouble convincing developers of such apps to backdoor their encryption in support of investigations [4, 5]. Despite the few hardening measures discussed in Section 5, RetroScope can provide such alternative evidence which would otherwise be unavailable to investigators.

5 Privacy Implications and Discussion

RetroScope provides a powerful new capability to forensic investigators. But despite being developed to aid criminal investigations, RetroScope also raises privacy concerns. In digital forensics practice, the privacy of device users is protected by strict legal protocols and regulations [9, 21], the most important of which is the requirement to obtain a search warrant prior to performing “invasive” digital forensics such as memory image analysis. Outside the forensics context, even some of the authors were surprised by the *temporal depth* of screens that RetroScope recovered for many privacy-sensitive apps (e.g., banking, tax, and healthcare). In light of this, we discuss possible mitigation techniques which, despite their significant drawbacks, might be considered worthwhile by privacy-conscious users/developers.

RetroScope’s recovery is based on two fundamental features of Android app design: (1) All apps which present a GUI must draw that GUI through the provided View class’s `draw` function and (2) The Android framework calls drawing functions on-demand and prevents those drawing functions from performing blocking operations (file/network reads/writes, etc.). As such, an app that aims to disrupt RetroScope’s recovery would need to hinder its own ability to draw screens.

Previous *anti-memory-forensics* schemes focused on encrypting in-memory data after its immediate use. This ensures that traditional memory scanning or data structure carving approaches (e.g., [25, 26, 37, 41]) would not find any useful evidence beyond the few pieces of decrypted in-use data. However, these solutions cannot hinder RetroScope’s recovery because RetroScope recovers evidence via the app’s existing `draw` functions, which would have to include decryption routines as part of building the app screen. App developers may add state-dependent conditions to their `draw` functions which would crash when executed by RetroScope, but as seen in Section 4 these can still be handled via additional debugging/reverse engineering efforts to skip/fix the conditions.

One approach that may disable RetroScope’s recovery is to overwrite (i.e., zero) all app-internal data immediately after they are drawn on screen. By doing so, RetroScope would find that the app’s internal state could not support the execution of any of its `draw` functions. Unfortunately, this approach would significantly degrade usability and increase implementation complexity: First, frequently overwriting app-internal data would incur execution overhead (especially during screen changes which are expected to be fast and dynamic). More importantly, this would require the app to download its internal data from a remote server *every time the app needs to draw a screen*. An app may

attempt to amortize these overheads (e.g., only zeroing a prior session’s memory upon logout) but this would require: (1) tracking used/freed memory throughout the session (to be zeroed later) and (2) users to regularly log out, which is uncommon and inconvenient for frequently used apps such as email, messengers, etc.

Current vs. Future Android Runtimes. It is worth noting that Google has begun shifting the Android framework’s runtime from the Dalvik JVM to a Java-to-native compilation and native execution environment (named ART). Our implementation of RetroScope was based on the original (and still the most widely used by far [17]) Dalvik JVM runtime. However, during our development of RetroScope, specific care was taken to design RetroScope to utilize only features present in *both* runtimes. Specifically, ART still provides the same Java runtime tracking and support as Dalvik does (implemented now via C/C++ libraries) and all apps’ implementations (e.g., their `Views` and `draw` functions) remain unchanged. Our study of ART revealed that the only engineering effort required to port RetroScope is the interception of state-changing instructions in the compiled byte-code, rather than the literal byte-code as it exists in Dalvik. We leave this as future work.

6 Related Work

RetroScope is most related to GUITAR [35] which, by recovering the remaining “puzzle pieces” (GUI data structures) from a memory image, is able to piece together an app’s Screen 0. Motivated by GUITAR’s “Screen 0-only” limitation (i.e., spatial recovery), RetroScope enables the fundamentally more powerful capability of recovering Screens 0, -1, -2, ... -N (i.e., spatial-temporal recovery). Technically, GUITAR is based on geometric matching of GUI pieces; whereas RetroScope is based on selective reanimation of GUI code and data.

A number of other (spatial) memory forensics tools have also been developed recently for Android. Many of these approaches recover raw instances of app-specific data structures to reveal evidence: App-specific login credentials were recovered by Apostolopoulos et al. [8]. Macht [28] followed by Dalvik Inspector [6] involved techniques to recover Dalvik-JVM control structures and raw Java object content. Earlier, Thing et al. [42] found that text-based message contents could be recovered from memory images. Most recently, our VCR [36] technique made it possible to recover images/video/preview frames from a phone’s camera memory.

In a mobile device-agnostic effort, DEC0DE [44] involved an effective technique to carve plain-text call logs and address book entries from phone storage using probabilistic finite state machines.

RetroScope shares the philosophy of leveraging existing code for memory content rendering with our prior memory forensics technique DSCRETE [37]. However, DSCRETE renders a single application data structure, whereas RetroScope renders full app display screens in temporal order. More importantly, DSCRETE requires *application-specific* (actually, data structure-specific) identification and extraction of data rendering code, while RetroScope is totally *app-agnostic*, requiring no analysis of app-internal data or rendering logic. Finally, DSCRETE works on Linux/x86 whereas RetroScope works on the Android/ARM platform.

Many prior memory forensics techniques leverage memory image scanning and data structure signature generation approaches [11, 12, 16, 26, 32, 34, 38, 41]. Data structure signatures can be content-based [16] or “points-to” structure-based [13, 15, 25, 26, 30]. For binary programs without source code, a number of reverse engineering techniques have been proposed to infer data structure definitions [24, 27, 39]. As a fundamentally new memory forensics technique, RetroScope requires neither data structure signature generation nor memory scanning.

7 Conclusion

We have presented RetroScope, a spatial-temporal memory forensics technique (and new paradigm) that recovers multiple previous screens of an app from an Android phone’s memory image. RetroScope is based on a novel interleaved re-execution engine which selectively reanimates an app’s screen redrawing functionality without requiring any app-specific knowledge. Our evaluation results show that RetroScope can recover visually accurate, temporally ordered screens (ranging from 3 to 11 screens) for a variety of apps on three different Android phones.

Appendix

A. Memory Image Acquisition

A prerequisite of memory forensics is the timely acquisition of a memory image from the subject device. Memory images typically contain a byte-for-byte copy of the entire physical RAM of a device or the virtual memory of an operating system or specific process(es). Traditionally, acquisition is performed by investigators, before the subject device is powered down, using minimally invasive software (e.g., fmem [22], LiME [7]) or hardware (e.g., Tibble [14], CoPilot [31]) tools. Other notable techniques have used the DMA-capable Firewire port [10] to acquire memory images, existing hibernation or swap files [18, 23, 32, 33], or cold/warm booted devices [19, 20, 43], but such approaches are only employed for highly specialized investigations. A more comprehensive list of memory image acquisition tools can be found in [2].

Android memory forensics was initially proposed during the development of memory acquisition tools for the devices. Most known among these are the software-based LiME [7] and TrustDump [40] techniques. In an alternative approach, Hilgers et al. [20] proposed cold-booting Android phones to perform memory forensics. Our evaluation of RetroScope used both LiME and a ptrace-based tool we developed (also available with the open source RetroScope code). Meanwhile, hardware-based memory acquisition from a mobile device is often performed via the ARM processor's JTAG port [1, 45].

Harvesting Inconsistent Security Configurations in Custom Android ROMs via Differential Analysis

Youssra Aafer, Xiao Zhang, and Wenliang Du

Syracuse University

{yaafer, xzhang35, wedu}@syr.edu

Abstract

Android customization offers substantially different experiences and rich functionalities to users. Every party in the customization chain, such as vendors and carriers, modify the OS and the pre-installed apps to tailor their devices for a variety of models, regions, and custom services. However, these modifications do not come at no cost. Several existing studies demonstrate that modifying security configurations during the customization brings in critical security vulnerabilities. Albeit these serious consequences, little has been done to systematically study how Android customization can lead to security problems, and how severe the situation is. In this work, we systematically identified security features that, if altered during the customization, can introduce potential risks. We conducted a large scale differential analysis on 591 custom images to detect inconsistent security features. Our results show that these discrepancies are indeed prevalent among our collected images. We have further identified several risky patterns that warrant further investigation. We have designed attacks on real devices and confirmed that these inconsistencies can indeed lead to actual security breaches.

1 Introduction

When vendors, such as Samsung, LG and HTC, put Android AOSP OS on their devices, they usually conduct extensive customization on the system. The reasons for customization can be many, including adding new functionalities, adding new system apps, tailoring the device for different models (e.g., phone or tablet), or carriers (e.g., T-mobile and AT&T), etc. Further complicating the process is Android updates pushed to the devices: the updates might target a new Android or app version.

This fragmented eco-system brings in several security risks when vendors change the functionalities and configurations without a comprehensive understanding

of their implications. Previous work has demonstrated some aspects of these changes and the resulting risks. Wu et al. [25] analyze several stock Android images from different vendors, and assess security issues that may be introduced by vendor customization. Their results show that customization is responsible for a number of security problems ranging from over-privileged to buggy system apps that can be exploited to mount permission re-delegation or content leaks attacks. Harehunter [5] reveals a new category of Android vulnerabilities, called Hares, caused by the customization process. Hares occur when an attribute is used on a device but the party defining it has been removed during the customization. A malicious app can “impersonate” the missing attribute to launch privilege escalation, information leakage and phishing attacks. ADDICTED [29] finds that many custom Android devices do not properly protect Linux device drivers, exposing them to illegitimate parties.

All the problems reported so far on Android customization are mainly caused by vendors’ altering of critical configurations. They change security configurations of system apps and Linux device drivers; they also remove, add, and alter system apps. Although the existing work has studied several aspects of security problems in the changes of system/app configurations, there is no work that systematically finds all security configuration changes caused by vendor customization, how likely it can lead to security problems, what risky configuration changes are often made by vendors, etc.

In this work, we make the first attempt to systematically detect security configuration changes introduced by parties in the customization chain. Our key intuition is that through comparing a custom device to similar devices from other vendors, carriers, and regions, or through comparing different OS versions, we might be able to find security configuration changes created unintentionally during the customization. More importantly, through a systematic study, we may be able to find valuable insights in vendor customization that can help ven-

dors improve the security of their future customizations. We propose DroidDiff, a tool that detects inconsistent security configurations in a large scale, and that can be employed by vendors to locate risky configurations.

The first challenge that we face in our systematic study is to identify what configurations are security relevant and are likely to be customized. We start from the Android layered architecture and list access control checks employed at each layer. Then, for each check, we rely on Android documentation and our domain knowledge to define corresponding security features. We further analyze how different configurations of these features across custom images can lead to inconsistencies and thus affect the access control check semantics. As a result, we have identified five categories of features. DroidDiff then extracts these features from 591 custom Android ROMs that we collected from multiple sources. This step produces the raw data that will be used for our analysis.

The next challenge is how to compare these images to find out whether they have inconsistent values for the features that we extracted. Given a set of images, conducting the comparison itself is not difficult; the difficulty is to decide the set of images for comparison. If we simply compare all the 591 images, it will not provide much insight, because it will be hard to interpret the implications of detected inconsistencies. To gain useful insights, we need to select a meaningful set of images for each comparison. Based on our hypothesis that inconsistencies can be introduced by vendors, device models, regions, carriers, and OS versions, we developed five differential analysis algorithms: *Cross-Vendor*, *Cross-Model*, *Cross-Region*, *Cross-Carrier*, and *Cross-Version* analyses, each targeting to uncover inconsistencies caused by customization of different purposes. For example, in the *Cross-Vendor* analysis, we aim to know how many inconsistencies are there among different vendors; in the *Cross-Model* analysis, we attempt to identify whether vendors may further introduce inconsistencies when they customize Android for different models (e.g. Samsung S4, S5, S6 Edge).

DroidDiff results reveal that indeed the customization process leads to many inconsistencies among security features, ranging from altering the protection levels of permissions, removing protected broadcasts definitions, changing the requirement for obtaining critical GIDs, and altering the protection configuration of app components. We present our discoveries in the paper to show the inconsistency situations among each category of features and how versions, vendors, models, region, and carriers customizations impact the whole situation.

Not all inconsistencies are dangerous, but some changes patterns are definitely risky and warrant further investigation. We have identified such risky patterns, and presented results to show how prevalent they are in

the customization process. The inconsistencies expose systems to potential attacks, but if the vendors understand fully the implication of such customization, they will more likely remedy the introduced risks by putting proper protection at some other places. Unfortunately, most of the inconsistencies seem to be introduced by developers who do not fully understand the security implications. Therefore, our DroidDiff can help vendors to identify the inconsistencies introduced during their customization, so they can question themselves whether they have implemented mechanisms to remedy the risks.

To demonstrate that the identified inconsistencies, if introduced by mistakes, can indeed lead to attacks, we picked few cases detected through our differential analysis, and designed proof-of-concept attacks on physical devices¹. We have identified several real attacks. To illustrate, we found that a detected inconsistency on Nexus 6 can be exploited to trigger emergency broadcasts without the required system permission and another similar one on Samsung S6 Edge allows a non-privileged app to perform a factory reset without a permission or user confirmation. Through exploiting another inconsistency on Samsung Note 2, an attacker can forge SMS messages without the SEND_SMS permission. Moreover, an inconsistency related to permission to Linux GID mapping allows apps to access the camera device driver with a normal protection level permission. We have filed security reports about the confirmed vulnerabilities to the corresponding vendors. We strongly believe that vendors, who have source code and know more about their systems, can find more attacks from our detected risky inconsistencies. We also envision that in the future, vendors can use our proposed tool and database to improve their customization process.

Contributions. The scientific contributions of this paper are summarized as the followings:

- We have systematically identified possible security features that may hold different configurations because of the Android customization process.
- We have developed five differential analysis algorithms and conducted a large-scale analysis on 591 Android OS images. Our results produce significant insights on the dangers of vendor customization.
- We have identified risky configuration inconsistencies that may have been introduced unintentionally during customization. Our results can help vendors' security analysts to conduct further investigation to confirm whether the risks of the inconsistencies are offset in the system or not. We have confirmed via our own attacks that some inconsistencies can indeed lead to actual security breaches.

¹Due to resource limitation, we could not design the attacks for all the cases identified in our analysis.

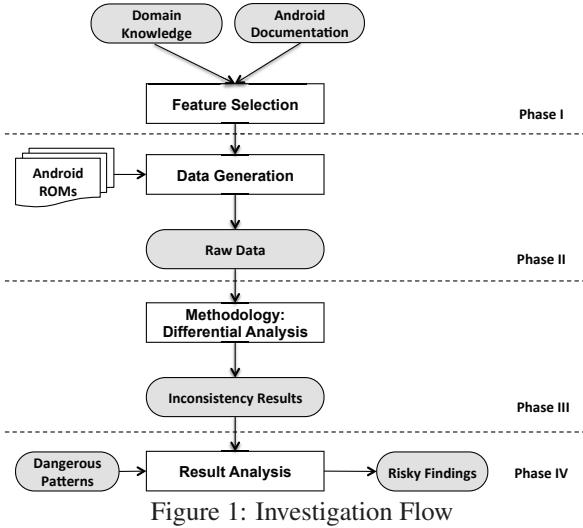

Figure 1: Investigation Flow

2 Investigation & Methodology

In this research work, we investigate Android's security features which are configurable during customization at the level of the framework and preloaded apps. Figure 1 depicts our investigation flow. As our work is data driven, the first and second phase are mainly concerned with locating and extracting meaningful security features from our collected Android custom ROMs. The two phases generate a large data set of configurations of the selected security features per image. The third phase performs differential analysis on the generated data according to our proposed algorithms to find any configuration discrepancies. It should be noted that it is out of our scope to find any security feature that is wrongly configured on all images, as obviously, it would not be detected through our differential analysis.

In the last phase, we analyze the detected discrepancies to pinpoint risky patterns. We have confirmed that they are indeed dangerous through high impact attacks. We discuss in the next sections each phase in details.

3 Feature Extraction

In this phase, we aim to extract security features that can cause potential vulnerabilities if altered inadvertently during the customization process. To systematically locate these security features, we start from the Android layered architecture (Figure 2) and study the security enforcement employed at each layer.

As Figure 2 illustrates, Android is a layered operating system, where each layer has its own tasks and responsibilities. On the top layer are preloaded apps provided by the device vendors and other third parties such as carriers. To allow app developers to access various resources and functionalities, Android Framework layer provides

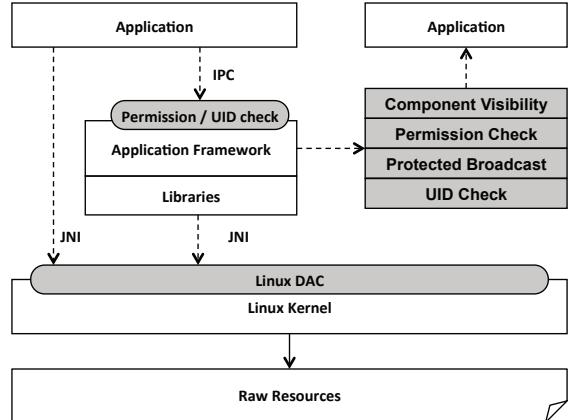

Figure 2: Android Security Model

many high-level services such as Package Manager, Activity Manager, Notification Manager and many others. These services mediate access to system resources and enforce proper access control based on the app's user id and its acquired Android permissions. Additionally, certain services might enforce access control based on the caller's package name or certificate. Right below the framework layer lies the Libraries layer, which is a set of Android specific libraries and other necessary libraries such as libc, SQLite database, media libraries, etc. Just like the framework services, certain Android specific libraries perform various access control checks based on the caller's user id and its permissions as well. At the bottom of the layers is Linux kernel which provides a level of abstraction between the device hardware and contains all essential hardware drivers like display, camera, etc. The Linux kernel layer mediates access to hardware drivers and raw resources based on the standard Discretionary Access Control (DAC).

To encourage collaboration and functionality re-use between apps, Android apps are connected together by Inter-Component Communication (ICC). An app can invoke other apps' components (e.g. activities and services) through the intent mechanism. It can further configure several security parameters to protect its resources and functionalities. As summarized in Figure 2, it can make its components private, require the caller to have certain permissions or to belong to a certain process.

Based on Figure 2, we summarize the Access Control (AC) checks employed by Android in Table 1. We specify the ones whose security features might be altered *statically* during device customization. By *static* modification, we refer to any modification that can be performed through changing framework resources files (including framework-res*.xml which contains most configurations of built-in security features), preloaded apps' manifest files and other system-wide configuration files

(platform.xml and *.xml under /etc/permissions/).

In the following section, we describe in details each configurable AC check and define its security features based on Android documentation and our domain knowledge. We further justify how inconsistent configurations of these features across custom images can bring in potential security risks. Please note that we do not discuss AC checks based on Package Names as previous work [5] has covered the effects of customizing them.

Before we proceed, we present some notations that we will be referring to in our analysis. IMG denotes a set of our collected images. E_P , E_{GID} , E_{PB} and E_C represent a set of all defined permissions, GIDs, protected broadcasts and components on IMG, respectively.

3.1 Permissions

Default and custom Android Permissions are used to protect inner components, data and functionalities. The protection level of a permission can be either Normal, Dangerous, Signature, or SystemOrSignature. These protection levels should be picked carefully depending on the resource to be protected. Signature and SystemOrSignature level permissions are used to protect the most privileged resources and will be granted only to apps signed with the same certificate as the defining app. Dangerous permissions protect private data and resources or operations affecting the user’s stored data or other apps such as reading contacts or sending SMS messages. Requesting permissions of Dangerous levels requires explicit user’s confirmation before granting them. Normal level on the other hand, is assigned to permissions protecting least privileged resources and do not require user’s approval. The following is an example of a permission declaration:

```
<permission android:name="READ_SMS"
    android:protectionLevel="Dangerous">
```

We aim to find if a permission has different protection levels across various images. For example, on vendor A, a permission READ_A is declared with Normal protection level, while on vendor B, the same permission is declared with a Signature one. This would expose the underlying components that are supposed to be protected with more privileged permissions. It would also create a big confusion for developers, as the same permission holds different semantics across images.

Formally, for each defined permission $e \in E_P$, we define the security feature f_{ne} as the following:

$$f_{ne} = \text{ProtectionLevel}(e)$$

The potential values of f_{ne} is in the set {Normal, Dangerous, Signature, Unspecified, 0}. We map

Table 1: Security Checks

AC Checks	Layer	Configurable
UID	Kernel, Framework Library, App	No
GID	Kernel	Yes
Package Name	Framework, App	Yes
Package Signature	Framework, App	No
Permission	Framework, Library, App	Yes
Protected Broadcast	App Layer	Yes
Component Visibility	App Layer	Yes
Component Protection	App Layer	Yes

SignatureOrSystem level to Signature, as both of them cannot be acquired by third party apps without a signature check. An unspecified value refers to a permission that has been defined without a protection level, while 0 refers to a permission that is not defined on an image.

3.2 GIDs

Certain lower-level Linux group IDs (GIDs) are mapped to Android permissions. Once an app process acquires these permissions, it will be assigned the mapped GID, which will be used for access control at the kernel. Permissions to GID mappings for built-in and custom permissions are defined mostly in platform.xml and other xml files under /etc/permissions/. The following is an example of a permission to GID mapping:

```
<permission android:name =
    "android.permission.NET_TUNNELING">
    <group gid="vpn" />
</permission>
```

In the above example, any process that has been granted NET_TUNNELING permission (defined with a Signature level) will be assigned the vpn GID, and consequently perform any filesystem (read, write, execute) allowed for this GID.

Android states that any change made inadvertently to platform.xml would open serious vulnerabilities. In this analysis, we aim to find if the customization parties introduce any modifications to these critical mappings and if so, what damages this might create. More specifically, we want to reveal if vendors map permissions of lower protection levels to existing privileged GIDs, which can result in downgrading their privileges. Following the same example above, assume that on a custom image, the vendor maps a permission vendor.permission (defined with Normal protection) to the existing vpn GID. This new mapping would downgrade the privilege of vpn GID on the custom image as it can be acquired with a Normal permission instead of a Signature one. Thus, any third party app granted vendor.permission will run with vpn GID

attached to its process, which basically allows it to perform any filesystem permissible for vpn GID, usually allowed to only system processes.

To allow discovering vulnerable GID to permission mappings, we extract the minimum permission requirement needed for acquiring a certain GID on a given image; i.e. the minimum protection level for all permissions mapping to it. If the same GID has different minimum requirements on 2 images, then it is potentially vulnerable. For the previous example, we should be able to reveal that vpn GID is problematic as it can be acquired with a Normal permission level on the custom image and with a Signature one on other images.

For each defined GID $e \in E_{GID}$, let P_e denote the permission set mapping to e , we define the feature f_{ne} :

$$f_{ne} = \text{GIDProtectionLevel}(e), \text{ where :}$$

$$\text{GIDProtectionLevel}(e) = \min_{p \in P_e} \text{ProtectionLevel}(p)$$

3.3 Protected Broadcasts

Protected broadcasts are broadcasts that can be sent only by system-level processes. Apps use protected broadcasts to make sure that no process, but system-level processes can trigger specific broadcast receivers. System apps can define protected broadcasts as follows:

```
<protected-broadcast android:name="broadcast.name"/>
```

Another app can use the above defined protected-broadcast through the following:

```
<receiver android:name="ReceiverA">
    <intent-filter>
        <action = "broadcast.name"/>
    </intent-filter/>
<receiver/>
```

The above ReceiverA can be triggered only by system processes broadcasting broadcast.name protected broadcast. The app can alternatively use protected broadcast through dynamically registered broadcast receivers. As it is known, during the customization process, certain packages are removed and altered. We hypothesize that because of this, certain protected broadcasts' definitions will be removed as well. We aim to uncover if these inconsistently non-protected broadcasts are still being used though, as action filters within receivers. This might open serious vulnerabilities, as the receivers that developers assumed to be only invocable by system processes will now be invocable by any third-party app and consequently expose their functionalities.

Formally, for each Protected Broadcast $e \in E_{PB}$, we define the following:

$$f_{ne} = \text{DefineUse}(e),$$

Where DefineUse(e) is defined as the following:

$$\text{DefineUse}(e) = \begin{cases} 1 & \text{if } e \text{ is used on an image but not defined} \\ 0 & \text{for other cases} \end{cases}$$

3.4 Component Visibility

Android allows developers to specify whether their declared components (activities, services, receivers and content providers) can be invoked externally from other apps. The visibility can be set through the `exported` flag in the component declaration within the app's manifest file. If this flag is not specified, the visibility will be implicitly set based on whether the component defines intent filters. If existing, the component is exported; otherwise, it is not as illustrated in the following snippet.

```
// Service1 is private to the app
<service android:name="Service1"/>
// Service2 is not private to the app
<service android:name="Service2">
    <intent-filter> ... </intent-filter>
</service>
```

We would like to uncover any component that has been exposed on one image, but not on another. We assume that if the same component name appears on similar images (e.g. same models, same OS version), then most likely, the component is providing the same functionality or protecting the same data (for content providers). Thus, its visibility should be the same across all images. To account for the cases where a component has been exported but with an added signature permission requirement, we consider them as implicitly unexposed.

Formally, for each defined component $e \in E_C$, we extract the following feature:

$$f_{ne} = \text{Exported}(e)$$

The potential values of f_{ne} is either {true, false, 0}. 0 refers to a non-existing component on a studied image.

3.5 Component Protection

Apps can use permissions to restrict the invocation of their components (services, activities, receivers). In the next code snippet, ServiceA can be invoked if the caller acquires vendor.permissionA. Moreover, an app can use permissions to restrict reading and writing to its content provider, as well as to specific paths within it. `android:readPermission` and `android:writePermission` take precedence over `android:permission` if specified, as shown in the code snippet. Components inherit their parents' permission if they do not specify one.

```
<service android:name="ServiceA"
        android:permission="vendor.permissionA"/>
```

```

<provider android:authorities="providerId"
    android:name="providerB"
    android:Permission="vendor.permissionB"
    android:readPermission="vendor.read"
    android:writePermission="vendor.write">

```

We aim to find if the same component has different protection requirements on similar images. Protection mismatch might not necessarily indicate a flaw if the component is not exposed. That's why, we only consider protection mismatches in case of exported components.

We list three cases where a component can be unintentionally exposed on one image, but protected on other images. First is the permission requirement is removed from the component's declaration. Second is the permission protecting it is of lower privilege compared to other images. Third, the permission used is not defined within the image, which makes it possible for any third-party app to define it and consequently invoke the underlying component. To discover components with conflicting protections, we map used permissions to their declarations within the same image. Any mismatch would indicate a possible security flaw for this component.

Formally, let P_e represents the permission protecting a component $e \in E_c$. We define the following feature:

$$fn_e = \text{Protection}(e);$$

Where $\text{Protection}(e)$ is defined as:

$$\text{Protection}(e) = \begin{cases} 0 & \text{if } e \text{ is not defined} \\ 1 & \text{if } P_e \text{ is None; i.e. } e \text{ is not protected} \\ \text{ProtectionLevel}(P_e) & \text{otherwise} \end{cases}$$

In the case where e is a content provider, we define P_{read} and P_{write} representing its read and write permissions and extract fn_e for both cases.

4 Data Generation

To reveal whether customization parties change the configurations of the mentioned security features, we conduct a large scale differential analysis. We collected 591 Android ROMs from Samsung Updates [4], other sources [3, 1, 2], and physical devices. These images are customized by 11 vendors, for around 135 models, 45 regions and 8 carriers. They operate Android versions from 4.1.1 to 5.1.1. Details about the collected images are in Table 2. In total, these images include on average 157 apps per image and 93169 all together apps. To extract the values of the selected security features on each image, we developed a tool called DroidDiff. For each image, DroidDiff first collects its framework resources Apks and preloaded Apks then runs Apktool to extract the corresponding manifest files. Second, it collects configuration files under /etc/permission/. Then,

Table 2: Collected Android Images

Version	# of Distinct Vendors	# of images
Jelly Bean	9	102
KitKat	9	177
Lollipop	8	312
Total	11	591

Table 3: Security Configurations Map

Image	$e \in E_p$ MIPUSH_RECEIVE	$e \in E_{GID}$ camera GID	$e \in E_c$ sms
I1: Xiaomi RedMi 1 Version: 4.4.2	Signature	Normal	True
I2: Xiaomi Mi 2A Version: 4.1.1	Unspecified	Dangerous	False

DroidDiff searches the extracted manifests and configuration files for the definitions of the targeted entities (E_p , E_{PB} , E_{GID} and E_c). Finally, DroidDiff runs the generated values through our differential analysis methodologies, discussed in the next section.

5 Differential Analysis

In our analysis, we aim to detect any feature fn_e having inconsistent values throughout a candidate set of images. Any inconsistency detected indicates a potential unintentional configuration change introduced by a customization party and requires further security analysis to assess possible consequent damages.

Let $fv(fn_e, img)$ represent the value of the feature fn_e on a given image img . To illustrate fn_e to $fv(fn_e, img)$ mappings, consider this real world example depicted in Table 3. As shown, we extract 3 security features and their corresponding values from 2 Xiaomi images. For the custom permission $e = \text{MIPUSH_RECEIVE}$, our feature extraction step generates the following values $fv(fn_e, I1) = \text{Signature}$, and $fv(fn_e, I2) = \text{Unspecified}$.

Let IMG denote a set of candidate images to be compared, we define a feature fn_e as inconsistent if:

$$\begin{aligned} C(fn_e) = \exists x \exists y [x \in IMG \wedge y \in IMG \\ \wedge x \neq y \wedge fv(fn_e, x) \neq fv(fn_e, y)] \end{aligned}$$

The above statement means that we consider the feature fn_e inconsistent across the set IMG if there exists at least two different images where the value of fn_e is not equal. It should be noted that we do not consider any cases where $fv(fn_e, img) = 0$ for $e \in \{E_p, E_{GID}$ and $E_c\}$.

Sample Selection. To discover meaningful inconsistencies through differential analysis, our collected images should be clustered based on common criteria. A meaningful inconsistency would give us insights about the responsible party that introduced it. For example,

to reveal if inconsistencies are introduced by an OS upgrade, it would not make sense to select images from all vendors, as the inconsistency could be due to customizing the device for a specific vendor, rather than because of the OS upgrade. Similarly, to uncover if a specific vendor causes inconsistencies in a new model, it is not logical to compare it with models from other vendors. Rather, we should compare it with devices from the same vendor. Besides, to avoid detecting a change caused by OS version mismatches, the new model should be compared to a model running the same OS version.

We designed five different algorithms that target to uncover meaningful inconsistencies. Specifically, by carefully going through each party within the customization chain, we designed algorithms that would reveal inconsistencies (if any) caused by each party. Further, for each algorithm, we select our candidate images based on specific criteria that serve the purpose of the algorithm,

We describe each algorithm as well as the sample selection criteria in the next sections.

A1: Cross-Version Analysis. This analysis aims to uncover any inconsistent security features caused by OS version upgrades. We select candidate image sets running similar device models to make sure that the inconsistency is purely due to OS upgrade. For instance, we would pick 2 Samsung S4 devices running 4.4.4 and 5.0.1 as a candidate image set, and would reveal if upgrading this model from 4.4.4 to 5.0.1 causes any security configuration changes. Formally, let IMG_{MODEL} denote the candidate image set as the following:

$$IMG_{MODEL} = \{img_1, img_2, \dots, img_n\}$$

such that $img_i \in IMG_{MODEL}$ if $model(img_i) = MODEL$

Based on our collected images, this algorithm generated 135 candidate image sets (count of distinct model).

Let $fv(fne, img)$ denote a value for a feature fne in $img \in IMG_{MODEL}$. We define the inconsistency condition under Cross-Version analysis algorithm as follows,

$$C_{Version}(fne) = \exists x \exists y [x \in IMG_{MODEL} \wedge y \in IMG_{MODEL} \wedge x \neq y \wedge fv(fne, x) \neq fv(fne, y) \wedge version(x) \neq version(y)]$$

The above condition implies that fne is inconsistent if there exist two same model images running different versions, and where the values of fne is not the same. Droid-Diff runs the analysis for each of the 135 candidate sets and generate the number of inconsistencies detected.

A2: Cross-Vendor Analysis. This analysis aims to reveal any feature fne that is inconsistent across vendors. To make sure that we are comparing images of similar criteria across different vendors, we pick candidate image sets running the same OS version (e.g. HTC M8 and

Nexus 6 both running 5.0.1). Our intuition here is that if an inconsistency is detected, then the vendor is the responsible party. We formally define the candidate image set as the following:

$$IMG_{VERSION} = \{img_1, img_2, \dots, img_n\}$$

such that $img_i \in IMG_{VERSION}$ if $version(img_i) = VERSION$

This algorithm generated 12 candidate image sets (count of distinct OS versions that we collected).

Let $fv(fne, img)$ denote a value for a feature fne in $img \in IMG_{VERSION}$. We redefine the inconsistency condition under Cross-Vendor analysis as follows:

$$C_{Vendor}(fne) = \exists x \exists y [x \in IMG_{VERSION} \wedge y \in IMG_{VERSION} \wedge x \neq y \wedge fv(fne, x) \neq fv(fne, y) \wedge vendor(x) \neq vendor(y)]$$

The last condition implies that fne is inconsistent if there exists two images from different vendors, but running the same OS version, where its value is not equal.

A3: Cross-Model Analysis. In this analysis, we want to uncover any feature fne that is inconsistent through different models. For example, we want to compare the configurations on Samsung S5 and Samsung S4 models, running the same OS versions. To ascertain that any inconsistency is purely due to model change within the same vendor, we pick our candidate image sets running the same OS version, defined as $IMG_{VERSION}$ in the previous example. We further make sure that we are comparing models from the same vendor by adding a new check in the next condition.

Let $fv(fne, img)$ denote a value for fne in $img \in IMG_{VERSION}$. We redefine the inconsistency condition under Cross-Model analysis as follows:

$$C_{Model}(fne) = \exists x \exists y [x \in IMG_{VERSION} \wedge y \in IMG_{VERSION} \wedge x \neq y \wedge fv(fne, x) \neq fv(fne, y) \wedge vendor(x) = vendor(y) \wedge model(y) \neq model(x)]$$

The last condition implies that fne is inconsistent if there exists two images from the same vendor, running the same OS version, but customized for different models, where its value is not equal.

A4: Cross-Carrier Analysis. We aim to uncover any inconsistent security features fne through different carriers (e.g., a MotoX from T-Mobile, versus another one from Sprint). To make sure that we are comparing images running the same OS version, we pick our candidate image sets from $IMG_{VERSION}$. We further make sure that we are comparing images running the same model

as shown in the following inconsistency condition:

$$\begin{aligned} C_{Carrier}(fne) = \exists x \exists y [x \in \text{IMGVERSION} \wedge y \in \text{IMGVERSION} \\ \wedge x \neq y \wedge fv(fne, x) \neq fv(fne, y) \\ \wedge carrier(x) \neq carrier(y) \wedge model(y) = model(x)] \end{aligned}$$

The last conditions in the above definition of $C_{Carrier}$ implies that fne is inconsistent if there exists two images running the same model and OS versions, but from different carriers where its value is not the same.

A5: Cross-Region Analysis. This analysis intends to find any inconsistencies in the configuration of security features fne through different regions (e.g. LG G4, Korean edition versus US edition). Any inconsistencies detected will be attributed to customizing a device for a specific region. We pick our candidate image sets from IMGVERSION to make sure that we are comparing images running the same OS version. We define the inconsistency count under Cross-Carrier analysis as follows:

$$\begin{aligned} C_{Region}(fne) = \exists x \exists y [x \in \text{IMGVERSION} \wedge y \in \text{IMGVERSION} \\ \wedge x \neq y \wedge fv(fne, x) \neq fv(fne, y) \\ \wedge region(x) \neq region(y) \wedge model(y) = model(x)] \end{aligned}$$

The last conditions in the above definition of C_{Region} implies that fne is inconsistent if there exists two images running the same model and OS versions, but from different regions where its value is not the same.

6 Results and Findings

We conduct a large-scale differential analysis on our collected images using the aforementioned methodologies with the help of DroidDiff. The analysis discovered a large number of discrepancies with regards to our selected features. In this section, we present the results and findings.

6.1 Overall Results

Figure 3 shows the overall changes detected from our analysis. We plot the average percentage of inconsistencies detected for each feature category using the five differential analysis algorithms. To provide an estimate of the inconsistencies count, each box plot shows an average number of total common entities (appearing on at least 2 images) in the image sets studied; we depict this number as # total in the graph. Let us use the first box plot as an example to illustrate what the data means: under the Cross-Version analysis (A1), DroidDiff generated on average 673 common permissions per each studied candidate sets. 50% of the candidate image sets contain at least 4.8% of total permissions (around 32 out of 673)

having inconsistent protection levels; those in the top 25 percentile (shown in the top whisker) have at least 6% (40) inconsistent permissions. Figure 3 also depicts the image sets that are outliers, i.e., they have particularly higher number of inconsistencies compared to the other image sets in the same group. For instance, the candidate image set $\text{IMGVersion}=4.4.2$ in the Cross-Vendor analysis (A2) contains around 10% of GIDs whose protections are inconsistent.

As depicted in Figure 3, the Cross-Version analysis (A1) detects the highest percentage of inconsistencies in all 5 categories, which means that upgrading the same device model to a different OS version introduces the highest security configuration changes. An intuitive reason behind this is that through a new OS release, Android might enforce higher protections on the corresponding entities to fix some discovered bugs (e.g. adding a permission requirement to a privileged service). However, we found out that through newer OS releases, certain security features are actually downgraded, leading to potential risks if done unintentionally. We discuss this finding in more details in Section 6.6.

Through the Cross-Vendor analysis (A2), DroidDiff detects that several security features are inconsistent among vendors, even though they are of the same OS version. We have further analyzed the vendors that cause the highest number of inconsistencies. An interesting observation is that smaller vendors, such as BLU, Xiaomi and Digiland caused several risky inconsistencies. In fact, all inconsistent GIDs are caused by these 3 companies. Probably, small vendors may not have enough expertises to fully evaluate the security implications of their actions.

The Cross-Model analysis (A3) also detects a number of inconsistencies, which means that different device models from the same vendor and OS version, might have different security configurations.

Although the Cross-Carrier (A4) and Cross-Region (A5) analyses detect a smaller percentage of inconsistencies, it is still significant to know that the same device model running the same OS version might have some different configurations if it is customized for different carriers or regions. Our results shows that the inconsistencies are less common in North America region, and more prevalent in Chinese editions.

6.2 Permissions Changes Pattern

Protection level mismatch. DroidDiff results confirm that Android permissions may hold different protection levels across similar images. As Figure 3 illustrates, more than 50% of the candidate image sets contain at least 32 (out of 673), 9 (out of 817) permissions having inconsistent protection levels in the Cross-Version (A1) and Cross-Model (A3) analyses, respectively. To reveal

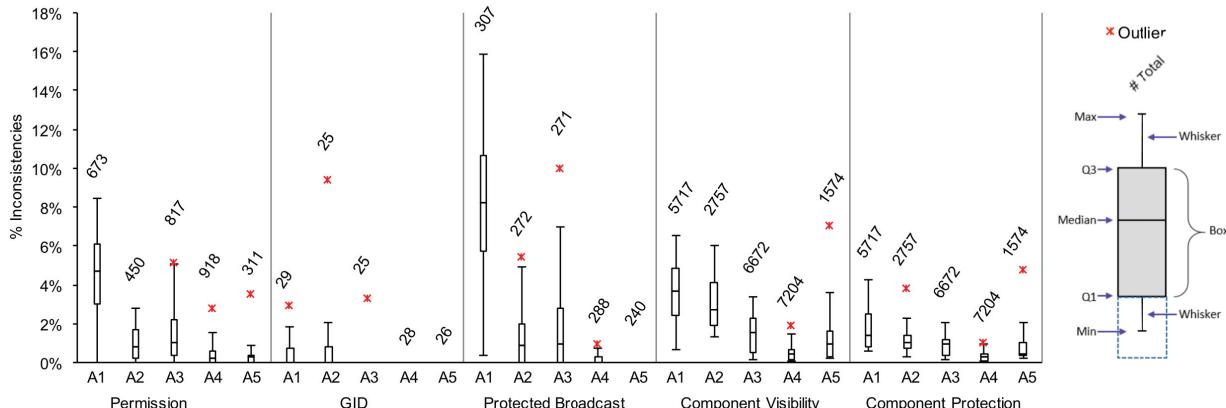

Figure 3: Overall Inconsistencies Detected

A1: Cross-Version, A2: Cross-Vendor, A3: Cross-Model, A4: Cross-Carrier, A5: Cross-Region

more insights, we checked which combination of protection level changes are the most common. That is, which combination out of the following 3 possible combinations is the most common (Normal, Dangerous), (Normal, Signature) or (Dangerous, Signature). We have calculated the occurrence of each pattern, and present the results in Figure 4. As shown, (Normal, Signature) combination is the most common pattern. This is quite serious as several permissions that hold a Signature protection level on some images are defined with a Normal protection level on others. We present here two permissions holding inconsistent protection levels:

- com.orange.permission.SIMCARD_AUTHENTICATION holds Signature and Normal protection on Samsung S4(4.2.2) and Sony Xperia C2105 (4.2.2), respectively.
- com.sec.android.app.sysscope.permission.RUN_SYSCOPE holds Dangerous and Signature protection on Samsung Note4 (5.0.1) and S4(5.0.1).

Usage of unspecified protection level. Android allows developers to define a permission without specifying a protection level, in which case, the default protection level is `Normal`. In our investigation, we found that it is not clear whether developers really intended to use `Normal` as the protection level. We found that a large percentage of these permissions (with unspecified protection level) hold conflicting protections on other images. Overall, 2% of the permissions studied were defined without a specified protection level in at least one image. To check if developers intended to use `Normal` as the protection level, for each permission that has been defined without a protection level, we check its corresponding definitions on other images to see if it has a protection level specified. We then compare the other specification to see if it is `Normal` or not. As Figure 5(a) illustrates, on average, 91% of these permissions holding

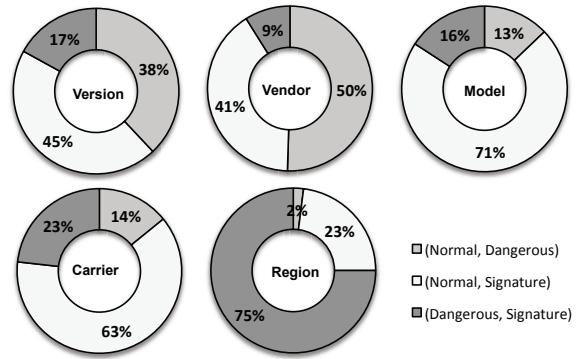

Figure 4: Protection Level Changes Patterns

unspecified protection level hold a `Signature` protection on at least 1 other image, which indicates that developers probably intended to use the `Signature` protection level. We illustrate this finding with 2 permissions:

- com.sec.android.phone.permission.UPDATE_MUTE_STATUS holds Unspecified and `Signature` protections on Samsung E7 (5.1.1) and S6 Edge(5.1.1), respectively.
- com.android.chrome.PRERENDER_URL holds Unspecified and `Signature` protections on LG Vista (4.4.2) and Nexus7 (4.4.2), respectively.

6.3 Permission-GID Mapping

By analyzing the differential analysis results of the mappings between GIDs and permissions, we have confirmed that customization introduces problematic GID-to-permission mappings that can lead to serious vulnerabilities in the victim images. Through the Cross-Vendor analysis (A2), DroidDiff detects 3 inconsistent cases (out of 25 common GIDs), in which vendors mapped less privileged permissions to privileged GIDs. This dangerous pattern leads to downgrad-

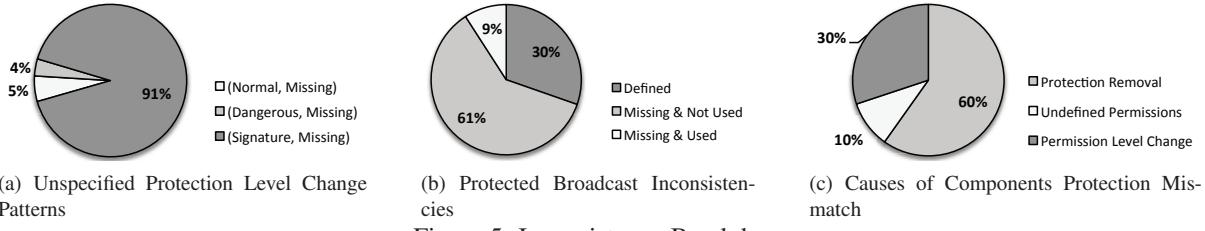

Figure 5: Inconsistency Breakdown

ing the protection level of these GIDs. We illustrate this finding with one detected example. On AOSP images and several customized images (running 4.4.4 and below), camera GID is mapped to a Dangerous level permission (`android.permission.CAMERA`). However, on Neo 4.5 (BLU), we found out that the same GID is mapped to a Normal level permission: `android.permission.ACCESS_MTK_MMHW`. This case indicates that BLU has downgraded the requirement for apps to obtain the camera GID. Our analysis reveals that the requirements for two more GIDs, system GID and media GID, have been downgraded. These two GIDs, protected by a Signature permission on most devices, can be acquired with a Normal permission on the victim devices.

6.4 Protected Broadcasts Changes Pattern

DroidDiff further reveals that protected broadcasts' definitions might be removed from some images during the customization process. As illustrated in Figure 5(b), through the Cross-Version analysis (A1), we detected that 70% of protected broadcast are not defined on at least one vendor. This might not necessarily be problematic if the broadcast is not used. However, our investigation shows that around 9% of these inconsistently unprotected broadcasts (28 on average per image set) are used as intent-filters actions for broadcast receivers. This inconsistency across versions is quite alarming as a privileged receiver that was supposed to be invoked by system processes can be invoked by any unprivileged app on certain versions. As Figure 3 further illustrates, Cross-Vendor (A2) and Cross-Model (A3) analyses reveal that more than 25% of candidate image sets contain at least 2% broadcasts which are inconsistently protected, but still being used as intent-filter actions.

6.5 Component Security Changes Pattern

Visibility mismatch. DroidDiff results confirm that app components may have a conflicting visibility. That is, the component is exposed on one image but not on another. As Figure 3 illustrates, 50% of the candidate image sets contain at least 3.9% components (around 222)

and 2% (133) holding inconsistent visibility through various versions (A1) and models (A3), respectively. To provide insights about which components hold more visibility inconsistencies, we break down our findings to activities, services, receivers, and content providers. We plot the results in Figure 6. As depicted, content providers and activities have the highest visibility mismatch. In fact, 25% of the candidate image sets contain at least 20% (53) and 14% (21) content providers holding a different visibility in different versions (A1) and vendors (A2), respectively. Similarly, 4% (139) and 3% (45) of activities hold a conflicting visibility in 50% of the studied sets based on A1 and A2, respectively.

Permission mismatch. DroidDiff further reveals that components may hold inconsistent protections across images. We break down our findings in Figure 8 (see appendix). Our results show that content providers exhibit the highest number of protection inconsistencies. In fact, more than 25% of the candidate images sets include at least 19% (51) and 10% (33) content providers having different protections in the Cross-Version (A1) and Cross-Model (A3) analyses, respectively. We have further analyzed these inconsistent components and categorized the reason behind the discrepancies. As Figure 5(c) illustrates, in the majority of the cases (60%), the discrepancy is caused by the same component being protected with a permission on one image, but not protected at all on others. The second common reason (30%) is that the same component is protected with permissions holding different protection levels across the studied images. Using non-defined permissions to protect a component is third common reason (10%).

Duplicate components declaration. Based on our analysis of the inconsistent broadcast receivers (particularly high on Lollipop images), we found out that most of them are caused by a non-safe practice that developers follow. Developers declare duplicate broadcast receivers names in the same app, but assign them different protections. After further investigation, we found out that it is not a safe practice to do as it will be possible to bypass any restrictions put on the first defined receiver. To illustrate, consider the following receivers, defined in Samsung's preloaded PhoneErrorService app:

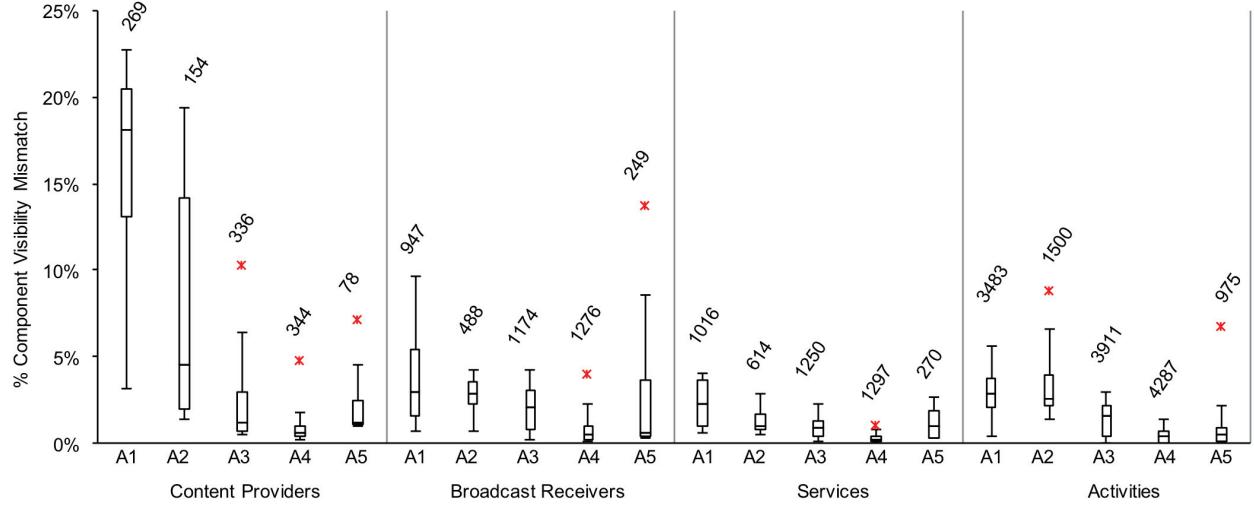

Figure 6: Breaking Down Components: Visibility Mismatch

```

<receiver android:name="PhoneErrorReceiver"
    android:permission="android.permission.REBOOT">
    <intent-filter>
        <action android:name="REFRESH_RESET_FAIL"/>
        ...
    </intent-filter>
</receiver>
<receiver android:name="PhoneErrorReceiver">
    <intent-filter>
        <action
            android:name="DATA_ROUTER_DISPLAY"/>
    </intent-filter>
</receiver>

```

In the above code, the developer decided to protect the functionality triggered when receiving the action `REFRESH_RESET_FAIL` with the permission `REBOOT` (signature level). In the other case, she decided not to require any permissions when invoking the functionality triggered by the action `DATA_ROUTER_DISPLAY`. At first glance, the above duplicate components declaration might look fine. However, we found out that the PackageManagerService does not carefully handle the registration of duplicate receivers. On one hand, it correctly handles mapping each filter to the required permission, used for **implicit** intents routing (e.g., sending the action `REFRESH_RESET_FAIL` requires `REBOOT` permission, while sending `DATA_ROUTER_DISPLAY` does not require any permission). On the other hand, however, it does not correctly map each component name to the required permission, used for **explicit** intents routing (e.g., the first `PhoneErrorReceiver` should require `REBOOT` while the second one should not). In fact, it turns out that the second declaration of the component name replaces the first one. Thus, any protection requirement on the second receiver would replace the first receiver's permission requirement in case of **explicit** invocation. Consequently, in the above example, invoking `PhoneErrorReceiver` explicitly does not require any permission. The explicit in-

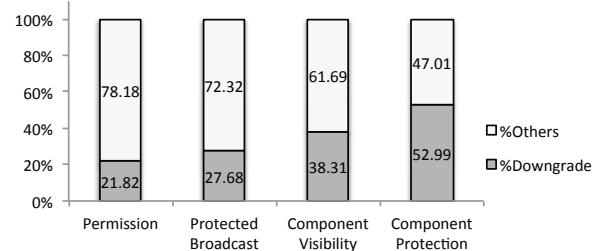

Figure 7: Percentage of Security Features Downgrades

tent can further set the action `REFRESH_RESET_FAIL` and thus trigger the privileged functionality (rebooting the phone) without the required `REBOOT` permission. We have confirmed this dangerous pattern in several preloaded apps and were able to achieve various damages. We filed a bug report about this discovered vulnerability to Android Security team and informed other vendors about it.

6.6 Downgrades Through Version Analysis

A dangerous pattern that we are interested in is whether there are any security downgrades through versions. For example, unlike a security configuration upgrade, possibly attributed to fixing discovered bugs in earlier images, downgrading a security configuration is quite dangerous as it will lead to a potential exposure of privileged resources that were already secured on previous versions. For each security configuration, we report in Figure 7, the percentage of security configuration downgrades out of all detected cases. As Figure 7 illustrates, a large number of configurations are indeed downgraded. For example, 52% of inconsistent component protection mismatch are actually caused by downgrading the protection.

7 Attacks

We would like to find out whether the risky patterns discovered can actually lead to actual vulnerabilities. To do that, we have selected some high impact cases, and tried to design attacks to verify whether these cases can become vulnerabilities. Due to resources limitations, our verification is driven by the test devices that we have, including Samsung Edge 6 Plus (5.1.1), Edge 6 (5.0.1), Nexus 6 (5.1.1), Note2 (4.4.2), Samsung S4 (5.0.1), MotoX (5.0.1), BLU Neo4 (4.2.2), and Digiland DL700D (4.4.0). We have found 10 actual attacks, some of which were confirmed on several devices. We have filed security reports for the confirmed vulnerabilities to the corresponding vendors. We discuss here 6 attacks. At the end of this section, we discuss possible impacts of 40 randomly selected cases in other devices to demonstrate the significance of inconsistent security configurations.

Stealing emails. SecEmailSync.apk is a preloaded app on most Samsung devices. It includes a content provider, called "com.samsung.android.email.otherprovider", which maintains a copy of user's emails received through the default Samsung email app. Our Cross-Model and Cross-Region analyses reveal inconsistent permission protections on this provider among several Samsung images. The Read and Write accesses to this provider are protected with a Signature permission "com.samsung.android.email.permission.ACCESS_PROVIDER" on Samsung Grand On(5.1.1, India), S6 Edge (5.1.1, UAE), and other devices. However, this provider is not protected with any permission on several other devices such as our test device S6 Edge (5.1.1, Global edition). We wrote an attack app that queries this content provider. It was able to access user's private emails on the victim device without any permission.

Forging premium SMS messages. The TeleService package (`com.android.phone`) is preloaded on many Samsung devices, and provides several services for phone and calls management. A notable service is `.TPhoneService`, which performs some major phone functionalities such as accepting voice and video calls, dialing new phone numbers, sending messages (e.g. to inform why a call cannot be received), as well as recording voice and video calls. Our Cross-Model and Cross-Version analyses reveal a permission mismatch on this critical service. On several devices, such as Samsung S5 LTE-A (4.4.2, Korea), the access to this service is protected with the Signature permission `com.skt.prod.permission.OEM_PHONE_SERVICE`, which makes the service unaccessible to third-party apps. However, on several other devices such Samsung Note 2 (4.4.2, Global edition), this service is protected with another permission

`com.skt.prod.permission.PHONE_SERVICE` for which our analysis reveals a missing definition. We built an attack app that defines the missing permission with a `Normal` protection level. Our app was able to successfully bind to `com.android.phone.TPhoneService` and invoke the send-message API on Samsung Note 2, allowing to forge SMS messages without the usually required `SEND_SMS`.

Unauthorized factory reset. The preloaded Samsung app ServiceModeApp_FB.apk performs various functionalities related to sensitive phone settings. It includes a broadcast receiver `ServiceModeAppBroadcastReceiver` that listens to several intent filters including the action filter `com.samsung.intent.action.SEC_FACTORY_RESET_WITHOUT_FACTORY_UI` that allows to factory reset the phone and delete all data without user confirmation. Our Cross-Version analysis reveals a protection mismatch for this critical broadcast receiver. In most devices running Kitkat and below, this receiver is protected with the `Signature` permission `com.sec.android.app.servicemodeapp.permission.KEYSTRING`. However, on several Lollipop images, it is not correctly protected. Further investigation reveals that this is caused by the duplicate receiver pattern discussed in Section 6.5. The declaration of the receiver has been duplicated on the victim images such that the first one requires a `Signature` permission while the second one does not. As discussed in Section 6.5, using this risky pattern allows a caller app to bypass any restrictions on the first declared broadcast receivers through explicit invocation. We wrote an attacking app that invokes the broadcast receiver explicitly with the action `com.samsung.intent.action.SEC_FACTORY_RESET_WITHOUT_FACTORY_UI` and were able to factory reset several victim devices including the latest S6 Edge Plus 5.1.1, S6 Edge 5.0.1, and S4 5.0.1.

Accessing critical drivers with a normal permission. Our Cross-Vendor analysis reveals a critical protection downgrade of the `system` GID. On some images, such as Samsung S5 (4.4.2), this GID is mapped to the `Signature` permission `com.qualcomm.permission.IZAT`. Nevertheless, on other images (e.g., Redmi Note 4.4.2 and Digiland DL700D 4.4.0), this GID is mapped to a `Normal` level permission `android.permission.ACCESS_MTK_MMHW`, indicating that any third-party app can easily get the `system` GID. Table 4 lists the device drivers that are accessible via the `system` GID on the Digiland DL700D Tablet. These are privileged drivers, but they can now be accessible to normal apps.

Triggering emergency broadcasts without permission. CellBroadcastReceiver is a preloaded Google

Table 4: Drivers accessible to System GID

Driver	ACL
booting; devmap; mtk_disp; pro_info; preloader; recovery pro_info; devmap; dkb; gps; gsensor; hdmitx; hwmsensor; kb; logo; misc; misc-sd; nvram; rtc0; sec; seccfg ; stpwmt touch; ttyMT2 ; wmtWifi; wmtdetect	r-
cpuctl	rw-
	r-x

app that performs critical functionalities based on received cell broadcasts. It registers the broadcast receiver `PrivilegedCellBroadcastReceiver` that allows receiving emergency broadcasts from the cell providers (e.g., evacuation alerts, presidential alerts, amber alerts, etc.) and displaying corresponding alerts. This critical functionality can be triggered if the action `android.provider.Telephony.SMS_EMERGENCY_CB_RECEIVED` is received. Our Cross-Vendor and Cross-Version analyses discovered a protection mismatch on this receiver among several devices. For instance, on Nexus S 4G 4.1.1, this receiver is protected with the `Signature` permission `android.permission.BROADCAST_SMS`. However, on other devices (e.g., Nexus6 5.1.1 and MotoX XT1095 5.0.1), it is protected with the `Dangerous` permission `android.permission.READ_PHONE_STATE`. Our investigation reveals that this is also due to the duplicate receivers risky pattern (Section 6.5). On the victim devices, `PrivilegedCellBroadcastReceiver` has been declared twice such that its first declaration requires a `Signature` permission and handles the action `android.provider.Telephony.SMS_EMERGENCY_CB_RECEIVED`, while the second declaration handles less privileged actions and requires a `Dangerous` permission. As discussed, any third-party app can bypass the permission requirement on the first receiver through explicit invocation. We wrote an attack app that was able to trigger this receiver and show various emergency alerts.

Tampering with system wide settings. SystemUI is a preloaded app that controls system windows. It handles and draws a lot of system UIs such as top status bar, system notification and dialogs. To manage the top status bar, the custom Samsung SystemUI includes a service `com.android.systemui.PhoneSettingService`, which handles incoming requests to turn on/off a variety of system wide settings appearing on the top status bar. These settings include turning on/off wifi, bluetooth, location, mobile data, nfc, driving mode, etc; that are usually done with user consent. Our analysis shows a protection mismatch for this service. On S5(4.4.2) and Note8(4.4.2), this service is protected with a signature permission `com.sec.phonesettingservice.permission.PHONE_SETTING`, while on Note 2, 4.4.2, the service is not protected with any permission. We wrote an attack app

that successfully asks the privileged service to turn on all the settings mentioned above without any permission.

Other Randomly Selected Cases. The impact of inconsistent security configurations are significant. In addition to end-to-end attacks we built, we also randomly sampled 40 inconsistencies and manually analyzed what could happen once they were exploited. Note that due to the lack of physical devices, all we could do is just static analysis to infer possible consequences once an exploit succeeds. Such an analysis may not be accurate, but it is still important for understanding the impacts of inconsistent security configurations. The outcomes of our analysis are shown in Table 5. Please note that we could not assess the impact in 5 cases (heavily obfuscated code), while we confirmed that 2 cases have been hardened via runtime checks.

8 Limitations

In this section, we discuss some limitations of our proposed approach.

Components implementation changes. A static change of a component’s security configurations (visibility or permission protection) might not necessarily indicate a security risk all the time. In fact, a developer might *intentionally* decide to export a component or downgrade its permission protection in the following cases: the component’s operations or supplied data are not privileged anymore or the component’s implementation is hardened via runtime checks of the caller’s identity (e.g., `binder.getCallingUid()` or `Context.checkSelfPermission()` APIs). Our solution pinpoints these possibly *unintentional* risky configurations changes and demands further investigation to confirm whether the change was indeed intentional or not.

Components renaming. Our approach would miss detecting inconsistent configurations of components which have been renamed during the customization. In fact, as Android relies heavily on implicit intents for inter-app communication, vendors might rename their components to reflect their organization identity.

9 Related Work

Security risks in Android customization. The extensive Android vendor customization have been proven to be problematic in prior studies. At the Kernel level, ADDICTED [29] finds under-protected Linux device drivers on customized ROMs by comparing them with their counterparts on AOSP images. Our finding on inconsistent GID to permission mappings demonstrates another

Table 5: Impact of Inconsistent Security Configurations

Inconsistent Configuration Category	Impact	Specific Examples
Permission Protection Change	Change System / App Wide Settings	Xiaomi Cloud Settings, Activate SIM
Removed Protected Broadcasts	Trigger Dangerous Operations and events	Trigger data sync, SMS received Airplane mode active, SIM is full
Non-Protected Content Providers	Data Pollution	Write to system logs, Add contacts Change instant messaging configurations
Non-Protected Content Providers	Data Leaks	Read emails, Read contacts Read blocked contact lists
Non-Protected Services	Trigger Dangerous Operations	Access Location, Bind to printing services Kill specific apps, Trigger backup
Non-Protected Activities	Change System wide Settings	Change Telephony settings, Access hidden activities
Non-Protected Receivers	Trigger Dangerous Operations	Send SMS messages, Trigger fake alerts Alter telephony settings , Issue SIM commands

way that can expose critical device drivers. At the framework/ app level, Harehunter [5] reveals the Hanging Attributes References (Hares) vulnerability caused by the under-regulated Android customization. The Hare vulnerability happens when an attribute is used on a device but the party defining it has been removed. A malicious app can then fill the gap to acquire critical capabilities, by simply disguising as the owner of the attribute. Previous works [13, 14, 25] have also highlighted security issues in the permission and components AC in preloaded apps. Gallo et al [13] analyzed five different devices and concluded that serious security issues such as poorer permission control grow sharply with the level of customization. Other prominent work [25] analyzes the pre-installed apps on 10 factory images and reports the presence of known problems such as over-privilege [11], permission re-delegation [12], etc. Our study is fundamentally different from the above work [25] which finds specific known vulnerabilities on a customized image through conducting a reachability analysis from an open entry point to privileged sinks. Instead, we leverage a differential analysis to point out inconsistencies in components’ protection, and consequently detect unintentionally exposed ones. Our analysis further gives insights about possible reasons behind the exposure.

Demystification of Android security configurations. The high flexibility of Android’s security architecture demands a complete understanding of configurable security parameters. Stowaway [11] and PScout [7] lead the way by mapping individual APIs to the required permission. Understanding these parameters provides the necessary domain knowledge in our feature selection. This understanding has inspired other researchers to detect vulnerabilities in apps. The prevalence of misconfigured content providers, activities and services is studied in [30, 8], respectively. These vulnerabilities are due to developers’ exposing critical components or misinterpreting Android’s security protection. Instead of focusing on analyzing an individual app to find if it is vulnerable, our approach learns from the configurations of the same app on other ROMs to deduct if it should be protected or not.

Android vulnerability analysis. Prior research has also uncovered security issues rooted in non-customized AOSP images. PileUp [26] brings to attention the problematic Android upgrading process. Two recent studies examine the crypto misuse in Android apps [9, 16]. Other works evaluate the security risks resulting from design flaws in the push-cloud messaging [18], in the multi-user architecture [24], in Android app uninstal-lation process [28] and in Android’s Clipboard and shar-ing mechanism [10]. Other researchers [20, 15] focused on uncovering vulnerabilities within specific Android apps in the web landscape. These vulnerabili-ties are complementary to the security issues detected in vendor customization, and jointly present a more complete picture of Android ecosystem’s security landscape. To analyze Android vulnerabilities, static and dynamic analysis techniques have been proposed to address the special characteristics of Android platform. CHEX [19], Epicc [21], and FlowDroid [6] apply static analysis to perform vulnerability analysis. Other works [23, 22, 17, 27] employ dynamic analysis to accurately understand app’s behaviors. Both techniques are bene-ficial to our research. Dynamic analysis can help us ex-ploit the likely risky inconsistencies, while static analysis can bring the control/data flow of framework/ app code as another security feature into our differential analysis. We will explore these ideas in future work.

10 Conclusion

In this paper, we make the first attempt to systematically detect security configuration changes introduced by An-droid customization. We list the security features applied at various Android layers and leverage differential analy-sis among a large set of custom ROMs to find out if they are consistent across all of them. By comparing security configura-tions of similar images (from the same vendor, running the same OS version, etc.), we can find critical security changes that might have been unintentionally introduced during the customization. Our analysis shows that indeed, customization parties change several config-

urations that can lead to severe vulnerabilities such as private data exposure and privilege escalation.

Abstract

Being a volunteer-run, distributed anonymity network, Tor is vulnerable to Sybil attacks. Little is known about real-world Sybils in the Tor network, and we lack practical tools and methods to expose Sybil attacks. In this work, we develop *sybilhunter*, a system for detecting Sybil relays based on their *appearance*, such as configuration; and *behavior*, such as uptime sequences. We used sybilhunter’s diverse analysis techniques to analyze nine years of archived Tor network data, providing us with new insights into the operation of real-world attackers. Our findings include diverse Sybils, ranging from botnets, to academic research, and relays that hijacked Bitcoin transactions. Our work shows that existing Sybil defenses do not apply to Tor, it delivers insights into real-world attacks, and provides practical tools to uncover and characterize Sybils, making the network safer for its users.

1 Introduction

In a Sybil attack, an attacker controls many virtual identities to obtain disproportionately large influence in a network. These attacks take many shapes, such as sockpuppets hijacking online discourse [34]; the manipulation of BitTorrent’s distributed hash table [35]; and, most relevant to our work, relays in the Tor network that seek to deanonymize users [8]. In addition to coining the term “Sybil,”¹ Douceur showed that practical Sybil defenses are challenging, arguing that Sybil attacks are always possible without a central authority [11]. In this work, we focus on Sybils in Tor—relays that are controlled by a single operator. But what harm can Sybils do?

The effectiveness of many attacks on Tor depends on how large a fraction of the network’s traffic—called the

consensus weight—an attacker can observe. As the attacker’s consensus weight grows, the following attacks become easier.

Exit traffic tampering: When leaving the Tor network, a Tor user’s traffic traverses exit relays, the last hop in a Tor circuit. Controlling exit relays, an attacker can eavesdrop on traffic to collect unencrypted credentials, break into TLS-protected connections, or inject malicious content [37, § 5.2].

Website fingerprinting: Tor’s encryption prevents guard relays (the first hop in a Tor circuit) from learning their user’s online activity. Ignoring the encrypted payload, an attacker can still take advantage of flow information such as packet lengths and timings to infer what websites Tor users are visiting [16].

Bridge address harvesting: Users behind censorship systems use private Tor relays—typically called bridges—as hidden stepping stones into the Tor network. It is important that censors cannot obtain all bridge addresses, which is why The Tor Project rate-limits bridge distribution. However, an attacker can harvest bridge addresses by running a middle relay and looking for incoming connections that do not originate from any of the publicly known guard relays [22, § 3.4].

End-to-end correlation: By running both entry guards and exit relays, an attacker can use timing analysis to link a Tor user’s identity to her activity, e.g., learn that *Alice* is visiting *Facebook*. For this attack to work, an attacker must run at least two Tor relays, or be able to eavesdrop on at least two networks [14].

Configuring a relay to forward more traffic allows an attacker to increase her consensus weight. However, the capacity of a single relay is limited by its link bandwidth and, because of the computational cost of cryptography, by CPU. Ultimately, increasing consensus weight

¹The term is a reference to a book in which the female protagonist, Sybil, suffers from dissociative identity disorder [29].

requires an adversary to add relays to the network; we call these additional relays *Sybils*.

In addition to the above attacks, an adversary needs Sybil relays to manipulate onion services, which are TCP servers whose IP address is hidden by Tor. In the current onion service protocol, six Sybil relays are sufficient to take offline an onion service because of a weakness in the design of the distributed hash table (DHT) that powers onion services [4, § V]. Finally, instead of being a direct means to an end, Sybil relays can be a *side effect* of another issue. In Section 5.1, we provide evidence for what appears to be botnets whose zombies are running Tor relays, perhaps because of a misguided attempt to help the Tor network grow.

Motivated by the lack of practical Sybil detection tools, we design and implement heuristics, leveraging our observations that Sybils (*i*) frequently go online and offline simultaneously, (*ii*) share similarities in their configuration, and (*iii*) may change their identity fingerprint—a relay’s fingerprint is the hash over its public key—frequently, to manipulate Tor’s DHT. Three of our four heuristics are automated and designed to run autonomously while one assists in manual analysis by ranking what relays in the network are the most similar to a given reference relay. Our evaluation suggests that our heuristics differ in their effectiveness; one method detected only a small number of incidents, but some of them no other method could detect. Other heuristics produced a large number of results, and seem well-suited to spot the “low hanging fruit.” We implemented these heuristics in a tool, *sybilhunter*, which we subsequently used to analyze 100 GiB worth of archived network data, consisting of millions of files, and dating back to 2007. Finally, we characterize the Sybil groups we discovered. To sum up, we make the following key contributions:

- We design and implement *sybilhunter*, a tool to analyze past and future Tor network data. While we designed it specifically for the use in Tor, our techniques are general in nature and can easily be applied to other distributed systems such as I2P [31].
- We characterize Sybil groups and publish our findings as datasets to stimulate future research.² We find that Sybils run MitM attacks, DoS attacks, and are used for research projects.

The rest of this paper is structured as follows. We begin by discussing related work in Section 2 and give some background on Tor in Section 3. Section 4 presents the design of our analysis tools, which is then followed by experimental results in Section 5. We discuss our results in Section 6 and conclude the paper in Section 7.

²The datasets are available online at <https://nymity.ch/sybilhunting/>.

2 Related work

In his seminal 2002 paper, Douceur showed that only a *central authority* that verifies new nodes as they join the distributed system is guaranteed to prevent Sybils [11]. This approach conflicts with Tor’s design philosophy that seeks to distribute trust and eliminate central points of control. In addition, a major factor contributing to Tor’s network growth is the low barrier of entry, allowing operators to set up relays both quickly and anonymously. An identity-verifying authority would raise that barrier, alienate privacy-conscious relay operators, and impede Tor’s growth. Barring a central authority, researchers have proposed techniques that leverage a resource that is difficult for an attacker to scale. Two categories of Sybil-resistant schemes turned out to be particularly popular, schemes that build on *social constraints* and schemes that build on *computational constraints*. For a broad overview of alternative Sybil defenses, refer to Levine et al. [19].

Social constraints rely on the assumption that it is difficult for an attacker to form trust relationships with honest users, e.g., befriend many strangers on online social networks. Past work leveraged this assumption in systems such as SybilGuard [39], SybilLimit [38], and SybilInfer [6]. Unfortunately, social graph-based defenses do not work in our setting because there is no existing trust relationship between relay operators.³ Note that we could create such a relationship by, e.g., linking relays to their operator’s social networking account, or by creating a “relay operator web of trust,” but again, we believe that such an effort would alienate relay operators and see limited adoption.

Orthogonal to social constraints, computational resource constraints guarantee that an attacker seeking to operate 100 Sybils needs 100 times the computational resources she would have needed for a single virtual identity. Both Borisov [5] and Li et al. [21] used computational puzzles for that purpose. Computational constraints work well in distributed systems where the cost of joining the network is low. For example, a lightweight client is sufficient to use BitTorrent, allowing even low-end consumer devices to participate. However, this is not the case in Tor because relay operations require constant use of bandwidth and CPU. Unlike in many other distributed systems, it is impossible to run 100 Tor relays while not spending the resources for 100 relays. Computational constraints are inherently tied to running a relay.

In summary, we believe that existing Sybil defenses are ill-suited for application in the Tor network; its distinctive features call for customized solutions that con-

³Relay operators can express in their configuration that their relays are run by the same operator, but this denotes an *intra*-person and not an *inter*-person trust relationship.

sider the nature of Tor relays. There has already been some progress towards that direction; namely, The Tor Project has incorporated a number of both implicit and explicit Sybil defenses that are in place as of June 2016. First, directory authorities—the “gatekeepers” of the Tor network—accept at most two relays per IP address to prevent low-resource Sybil attacks [3, 2]. Similarly, Tor’s path selection algorithm ensures that Tor clients never select two relays in the same /16 network [9]. Second, directory authorities automatically assign flags to relays, indicating their status and quality of service. The Tor Project has recently increased the minimal time until relays obtain the `Stable` flag (seven days) and the `HSDir` flag (96 hours). This change increases the cost of Sybil attacks and gives Tor developers more time to discover and block suspicious relays before they get in a position to run an attack. Finally, the operation of a Tor relay causes recurring costs—most notably bandwidth and electricity—which can further restrain an adversary.

3 Background

We now provide necessary background on the Tor network [10]. Tor consists of several thousand volunteer-run relays that are summarized in the *network consensus* that is voted on and published each hour by nine distributed *directory authorities*. The authorities assign a variety of flags to relays:

- Valid:** The relay is valid, i.e., not known to be broken.
- HSDir:** The relay is an onion service directory, i.e., it participates in the DHT that powers Tor onion services.
- Exit:** The relay is an exit relay.
- BadExit:** The relay is an exit relay, but is either misconfigured or malicious, and should therefore not be used by Tor clients.
- Stable:** Relays are stable if their mean time between failure is at least the median of all relays, or at least seven days.
- Guard:** Guard relays are the rarely-changing first hop for Tor clients.
- Running:** A relay is running if the directory authorities could connect to it in the last 45 minutes.

Tor relays are uniquely identified by their *fingerprint*, a Base32-encoded and truncated SHA-1 hash over their public key. Operators can further assign a *nickname* to their Tor relays, which is a string that identifies a relay (albeit not uniquely) and is easier to remember than its pseudo-random fingerprint. Exit relays have an *exit policy*—a list of IP addresses and ports that the relay allows connections to. Finally, operators that run more than one relay are encouraged to configure their relays to be part

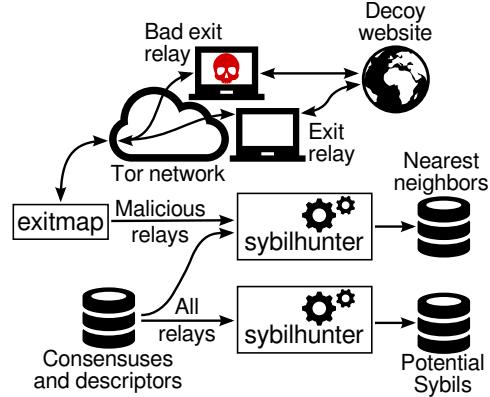

Figure 1: Sybilhunter’s architecture. Two datasets serve as input to sybilhunter; consensuses and server descriptors, and malicious relays gathered with exitmap [37, § 3.1].

of a *relay family*. Families are used to express that a set of relays is controlled by a single operator. Tor clients never use more than one family member in their path to prevent correlation attacks. In February 2016, there were approximately 400 relay families among all 7,000 relays.

4 Data and design

We define Sybils in the Tor network as two or more relays that are controlled by a single person or group of people. Sybils per se do not have to be malicious; a relay operator could simply have forgotten to configure her relays as a relay family. Such Sybils are no threat to the Tor network, which is why we refer to them as *benign Sybils*. What we are interested in is *malicious Sybils* whose purpose is to deanonymize or otherwise harm Tor users.

To uncover malicious Sybils, we draw on two datasets—one publicly available and one created by us. Our detection methods are implemented in a tool, sybilhunter, which takes as input our two datasets and then attempts to expose Sybil groups, as illustrated in Figure 1. Sybilhunter is implemented in Go and consists of 2,300 lines of code.

4.1 Datasets

Figure 1 shows how we use our two datasets. Archived consensuses and router descriptors (in short: descriptors) allow us to (i) restore past states of the Tor network, which sybilhunter mines for Sybil groups, and to (ii) find “partners in crime” of malicious exit relays that we discovered by running exitmap, a scanner for Tor exit relays that we discuss below.

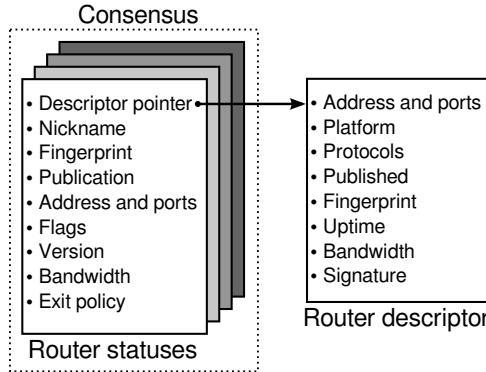

Figure 2: Our primary dataset contains nine years worth of consensuses and router descriptors.

4.1.1 Consensuses and router descriptors

The consensus and descriptor dataset is publicly available on CollecTor [32], an archiving service that is run by The Tor Project. Some of the archived data dates back to 2004, allowing us to restore arbitrary Tor network configurations from the last decade. Not all of CollecTor’s archived data is relevant to our hunt for Sybils, though, which is why we only analyze the following two:

Descriptors Tor relays and bridges periodically upload router descriptors, which capture their configuration, to directory authorities. Figure 2 shows an example in the box to the right. Relays upload their descriptors no later than every 18 hours, or sooner, depending on certain conditions. Note that some information in router descriptors is not verified by directory authorities. Therefore, relays can spoof information such as their operating system, Tor version, and uptime.

Consensuses Each hour, the nine directory authorities vote on their view of all Tor relays that are currently online. The vote produces the consensus, an authoritative list that comprises all running Tor relays, represented as a set of router statuses. Each router status in the consensus contains basic information about Tor relays such as their bandwidth, flags, and exit policy. It also contains a pointer to the relay’s descriptor, as shown in Figure 2. As of June 2016, consensuses contain approximately 7,000 router statuses, i.e., each hour, 7,000 router statuses are published, and archived, by CollecTor.

Table 1 gives an overview of the size of our consensus and descriptor archives. We found it challenging to repeatedly process these millions of files, amounting to more than 100 GiB of uncompressed data, so we implemented a custom parser in Go [36].

Dataset	# of files	Size	Time span
Consensuses	72,061	51 GiB	10/2007–01/2016
Descriptors	34,789,777	52 GiB	12/2005–01/2016

Table 1: An overview of our primary dataset; consensuses and server descriptors since 2007 and 2005, respectively.

4.1.2 Malicious exit relays

In addition to our publicly available and primary dataset, we collected malicious exit relays over 18 months. We call exit relays malicious if they modify forwarded traffic in bad faith, e.g., to run man-in-the-middle attacks. We add these relays to our dataset because they frequently *surface in groups*, as malicious Sybils, because an attacker runs the same attack on several, physically distinct exit relays. Winter et al.’s work [37, § 5.2] further showed that attackers make an effort to stay under the radar, which is why we cannot only rely on active probing to find such relays. We also seek to find potential “partners in crime” of each newly discovered malicious relay, which we discuss in Section 4.3.4.

We exposed malicious exit relays using Winter et al.’s exitmap tool [37, § 3.1]. Exitmap is a Python-based scanning framework for Tor exit relays. Exitmap modules perform a network task that can then be run over all exit relays. One use case is HTTPS man-in-the-middle detection: A module can fetch the certificate of a web server over all exit relays and then compare its fingerprint with the expected, valid fingerprint. Exposed attacks are sometimes difficult to attribute because an attack can take place upstream of the exit relay, e.g., at a malicious autonomous system. However, attribution is only a secondary concern. Our primary concern is protecting Tor users from harm, and we do not need to identify the culprit to do so.

In addition to using the original exitmap modules [37, § 3.1], we implemented modules that detect HTML and HTTP tampering by connecting to a decoy server under our control, and flagging an exit relay as malicious if the returned HTML or HTTP was modified, e.g., to inject data or redirect a user over a transparent HTTP proxy. Since we controlled the decoy server, we knew what our Tor client should get in response. Our modules ran periodically from August 2014 to January 2016, and discovered 251 malicious exit relays whose attacks are discussed in Appendix A. We reported all relays to The Tor Project, which subsequently blocked these relays.

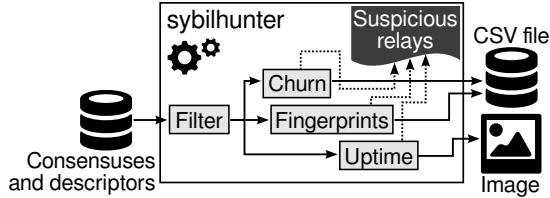

Figure 3: Sybilhunter’s internal architecture. After an optional filtering step, data is then passed on to one of three analysis modules that produce as output either CSV files or an image.

4.2 Threat model

Most of this paper is about applying sybilhunter to archived network data, but we can also apply it to newly incoming data. This puts us in an adversarial setting as attackers can tune their Sybils to evade our system. This is reflected in our adversarial assumptions. We assume that an adversary *does* run more than one Tor relay and exhibits redundancy in their relay configuration, or uptime sequence. An adversary further *can* know how sybilhunter’s modules work, run active or passive attacks, and make a limited effort to stay under the radar, by diversifying parts of their configuration. To detect Sybils, however, our heuristics require *some* redundancy.

4.3 Analysis techniques

Having discussed our datasets and threat model, we now turn to presenting techniques that can expose Sybils. Our techniques are based on the insight that Sybil relays frequently *behave or appear similarly*. Shared configuration parameters such as port numbers and nicknames cause similar appearance whereas Sybils behave similarly when they reboot simultaneously, or exhibit identical quirks when relaying traffic.

Sybilhunter can analyze (*i*) historical network data, dating back to 2007; (*ii*) online data, to detect new Sybils as they join the network; and (*iii*) find relays that might be associated with previously discovered, malicious relays. Figure 3 shows sybilhunter’s internal architecture. Tor network data first passes a filtering component that can be used to inspect a subset of the data, e.g., only relays with a given IP address or nickname. The data is then forwarded to one or more modules that implement an analysis technique. These modules work independently, but share a data structure to find suspicious relays that show up in more than one module. Depending on the analysis technique, sybilhunter’s output is either CSV files or images.

While developing sybilhunter, we had to make many design decisions that we tackled by drawing on the experience we gained by manually analyzing numerous Sybil

groups. We iteratively improved our code and augmented it with new features when we experienced operational shortcomings.

4.3.1 Network churn

The churn rate of a distributed system captures the rate of joining and leaving network participants. In the Tor network, these participants are relays. An unexpectedly high churn rate between two subsequent consensuses means that many relays joined or left, which can reveal Sybils and other network issues because many Sybil operators start and stop their Sybils at the same time, to ease administration—they behave similarly.

The Tor Project is maintaining a Python script [15] that determines the number of previously unobserved relay fingerprints in new consensus documents. If that number is greater than or equal to the static threshold 50, the script sends an e-mail alert. We reimplemented the script in sybilhunter and ran it over all archived consensus documents, dating back to 2007. The script raised 47 alerts in nine years, all of which seemed to be true positives, i.e., they should be of interest to The Tor Project. The script did not raise false positives, presumably because the median number of previously unseen fingerprints in a consensus is only six—significantly below the conservative threshold of 50. Yet, the threshold likely causes false negatives, but we cannot determine the false negative rate because we lack ground truth. In addition, The Tor Project’s script does not consider relays that left the network, does not distinguish between relays with different flags, and does not adapt its threshold as the network grows. We now present an alternative approach that is more flexible and robust.

We found that churn anomalies worthy of our attention range from *flat hills* (Figure 4) to *sudden spikes* (Figure 5). Flat hills can be a sign of an event that affected a large number of relays, over many hours or days. Such an event happened shortly after the Heartbleed bug, when The Tor Project asked relay operators to generate new keys. Relay operators acted gradually, most within two days. Sudden spikes can happen if an attacker adds many relays, all at once. These are mere examples, however; the shape of a time series cannot tell us anything about the nature of the underlying incident.

To quantify the churn rate α between two subsequent consensus documents, we adapt Godfrey et al.’s formula, which yields a churn value that captures both systems that joined and systems that left the network [13, § 2.1]. However, an unusually low number of systems that left could cancel out an unusually high number of new systems and vice versa—an undesired property for a technique that should spot abnormal changes. To address this issue, we split the formula in two parts, creating a

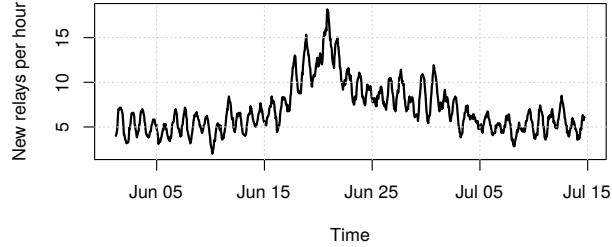

Figure 4: A flat hill of new relays in 2009. The time series was smoothed using a moving average with a window size of 12 hours.

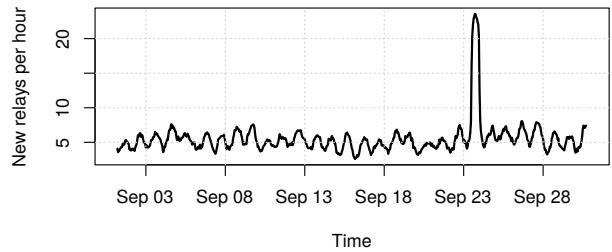

Figure 5: A sudden spike of new relays in 2010. The time series was smoothed using a moving average with a window size of 12 hours.

time series for new relays (α_n) and for relays that left (α_l). C_t is the network consensus at time t , and \ denotes the complement between two consensuses, i.e., the relays that are in the left operand, but not the right operand. We define α_n and α_l as

$$\alpha_n = \frac{|C_t \setminus C_{t-1}|}{|C_t|} \quad \text{and} \quad \alpha_l = \frac{|C_{t-1} \setminus C_t|}{|C_{t-1}|}. \quad (1)$$

Both α_n and α_l are bounded to the interval $[0, 1]$. A churn value of 0 indicates no change between two subsequent consensuses whereas a churn value of 1 indicates a complete turnover. Determining $\alpha_{n,l}$ for the sequence $C_t, C_{t-1}, \dots, C_{t-n}$, yields a time series of churn values that can readily be inspected for abnormal spikes. Figure 6 illustrates the maximum number of Sybils an attacker can add to the network given a threshold for α . The figure shows both the theoretical maximum and a more realistic estimate that accounts for noise, i.e., the median number of new relays in each consensus, which is 73.⁴ We found that many churn anomalies are caused by relays that share a flag, or a flag combination, e.g., HSDir (onion service directories) and Exit (exit relays). Therefore, sybilhunter can also generate per-flag churn time series that can uncover patterns that would be lost in a flag-agnostic time series.

⁴Note that this analysis is “memoryless” and includes relays that have been online before; unlike the analysis above that considered only previously unobserved relays, for which the median number was six.

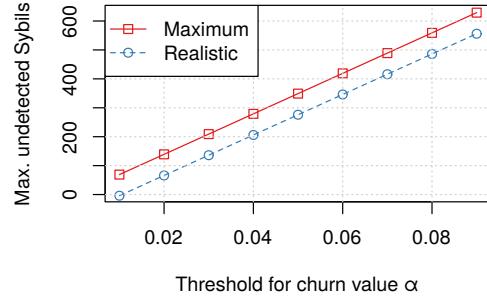

Figure 6: The number of new Sybils (y axis) that can remain undetected given a threshold for the churn value α (x axis). The diagram shows both the maximum and a more realistic estimate that accounts for the median number of new relays in consensuses.

Finally, to detect changes in the underlying time series trend—flat hills—we can smooth $\alpha_{n,l}$ using a simple moving average λ defined as

$$\lambda = \frac{1}{w} \cdot \sum_{i=0}^w \alpha_i. \quad (2)$$

As we increase the window size w , we can detect more subtle changes in the underlying churn trend. If λ or $\alpha_{n,l}$ exceed a manually defined threshold, an alert is raised. Section 5.3 elaborates on how we can select a threshold in practice.

4.3.2 Uptime matrix

For convenience, Sybil operators are likely to administer their relays simultaneously, i.e., update, configure, and reboot them all at the same time. This is reflected in their relays’ uptime. An operating system upgrade that requires a reboot of Sybil relays will induce a set of relays to go offline and return online in a synchronized manner. To isolate such events, we are visualizing the *uptime patterns* of Tor relays by grouping together relays whose uptime is highly correlated. The churn technique presented above is similar but it only provides an aggregate, high-level view on how Tor relays join and leave the network. Since the technique is aggregate, it is poorly suited for visualizing the uptime of specific relays; an abnormally high churn value attracts our attention but does not tell us what caused the anomaly. To fill this gap, we complement the churn analysis with an uptime matrix that we will now present.

This uptime matrix consists of the uptime patterns of all Tor relays, which we represent as binary sequences. Each hour, when a new consensus is published, we add a new data point—“online” or “offline”—to each Tor relay’s sequence. We visualize all sequences in a bitmap whose rows represent consensuses and whose columns

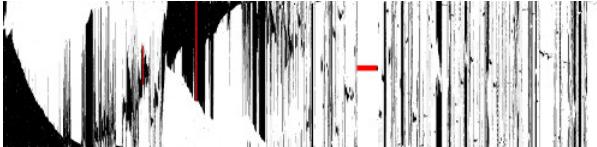

Figure 7: The uptime matrix for 3,000 Tor relays for all of November 2012. Rows represent consensuses and columns represent relays. Black pixels mean that a relay was online, and white means offline. Red blocks denote relays with identical uptime.

represent relays. Each pixel denotes the uptime status of a particular relay at a particular hour. Black pixels mean that the relay was online and white pixels mean that the relay was offline. This type of visualization was first proposed by Ensafi and subsequently implemented by Fifield [12].

Of particular importance is how the uptime sequences are sorted. If highly correlated sequences are not adjacent in the visualization, we might miss them. We sort sequences using single-linkage clustering, a type of hierarchical clustering algorithm that forms groups bottom-up, based on the minimum distance between group members. For our distance function, similar to Andersen et al. [1, § II.B], we use Pearson’s correlation coefficient because it tells us if two uptime sequences change together. The sample correlation coefficient r yields a value in the interval $[-1, 1]$. A coefficient of -1 denotes perfect anti-correlation (relay R_1 is only online when relay R_2 is offline) and 1 denotes perfect correlation (relay R_1 is only online when relay R_2 is online). We define our distance function as $d(r) = 1 - r$, so two perfectly correlated sequences have a distance of zero while two perfectly anti-correlated sequences have a distance of two. Once all sequences are sorted, we color five or more adjacent sequences in red if their uptime sequence is identical. Figure 7 shows an example of our visualization algorithm, the uptime matrix for a subset of all Tor relays in November 2012.

4.3.3 Fingerprint analysis

The information a Tor client needs to connect to an onion service is stored in a DHT that consists of a subset of all Tor relays, the onion service directories (HSDirs). As of June 2016, 47% of all Tor relays serve as HSDirs. A daily-changing set of six HSDirs hosts the contact information of any given onion service. Tor clients contact one of these six HSDirs to request information about the onion service they intend to connect to. A HSDir becomes responsible for an onion service if the difference between its relay fingerprint and the service’s descriptor ID is smaller than that of any other relay. The descrip-

tor ID is derived from the onion service’s public key, a time stamp, and additional information. All HSDirs are public, making it possible to determine at which position in the DHT an onion service will end up at any point in the future. Attackers can exploit the ability to predict the DHT position by repeatedly generating identity keys until their fingerprint is sufficiently close to the targeted onion service’s index, thus becoming its HSDir [4, § V.A].

We detect relays that change their fingerprint frequently by maintaining a lookup table that maps a relay’s IP address to a list of all fingerprints we have seen it use. We sort the lookup table by the relays that changed their fingerprints the most, and output the results. Note that reboots or newly assigned IP addresses are not an issue for this technique—as long as relays do not lose their long-term keys that are stored on their hard drive, their fingerprint stays the same.

4.3.4 Nearest-neighbor ranking

We frequently found ourselves in a situation where exitmap discovered a malicious exit relay and we were left wondering if there were similar, potentially associated relays. Looking for such relays involved tedious manual work, which we soon started to automate. We needed an algorithm for nearest-neighbor ranking that takes as input a “seed” relay and creates as output a list of all relays, ranked by their similarity to the seed relay. We define similarity as shared configuration parameters such as port numbers, IP addresses, exit policies, or bandwidth values. Our algorithm ranks relays by comparing these configuration parameters.

To quantify the similarity between two relays, we use the Levenshtein distance [18], a distance metric that takes as input two strings and determines the minimum number of modifications—insert, delete, and modify—that are necessary to turn string s_2 into s_1 . Our algorithm turns the router statuses and descriptors of two relays into strings and determines their Levenshtein distance. As an example, consider a simple representation consisting of the concatenation of nickname, IP address, and port. To turn string s_2 into s_1 , six operations are necessary; four modifications (green) and two deletions (red):

```
s1: Foo10.0.0.19001
s2: Bar10.0.0.2549001
```

Our algorithm determines the Levenshtein distance between a “seed” relay and all other relays in a consensus. It then ranks the calculated distances in ascending order. For a consensus consisting of 6,525 relays, our algorithm takes approximately 1.5 seconds to finish.⁵ Note

⁵We measured on an Intel Core i7-3520M CPU at 2.9 GHz, a consumer-grade CPU.

that we designed our ranking algorithm to assist in manual analysis. Unlike the other analysis techniques, it does not require a threshold.

5 Evaluation and results

Equipped with sybilhunter, we applied our techniques to nine years of archived Tor network data. We did not set any thresholds, to capture every single churn value, fingerprint, and uptime sequence, resulting in an unfiltered dataset of several megabytes of CSV files and uptime images. We then sorted this dataset in descending order by severity, and began manually analyzing the most significant incidents, e.g., the largest churn values. In Section 5.1, we begin by characterizing Sybil groups we discovered that way. Instead of providing an exhaustive list of all potential Sybils, we focus on our most salient findings—relay groups that were either clearly malicious or distinguished themselves otherwise.⁶ Afterwards, we explore the impact of sybilhunter’s thresholds in Sections 5.2 to 5.6.

Once we discovered a seemingly harmful Sybil group, we reported it to The Tor Project. To defend against Sybil attacks, directory authorities can either remove a relay from the consensus, or take away its *Valid* flag, which means that the relay is still in the consensus, but Tor clients will not consider it for their first or last hop in a circuit. The majority of directory authorities, i.e., five out of nine, must agree on either strategy. This mechanism is meant to distribute the power of removing relays into the hands of a diverse set of people in different jurisdictions.

5.1 Sybil characterization

Table 2 shows the most interesting Sybil groups we identified. The columns show (*i*) what we believe to be the purpose of the Sybils, (*ii*) when the Sybil group was at its peak size, (*iii*) the ID we gave the Sybils, (*iv*) the number of Sybil fingerprints at its peak, (*v*) the analysis techniques that could discover the Sybils, and (*vi*) a short description. The analysis techniques are abbreviated as “N” (Neighbor ranking), “F” (Fingerprint), “C” (Churn), “U” (Uptime), and “E” (exitmap). We now discuss the most insightful incidents in greater detail.

The “rewrite” Sybils These recurring Sybils hijacked Bitcoin transactions by rewriting Bitcoin addresses in relayed HTML. All relays had the *Exit* flag and replaced onion domains found in a web server’s HTTP response

⁶Our datasets and visualizations are available online, and can be inspected for an exhaustive set of potential Sybils. The URL is <https://nymity.ch/sybilhunting/>.

with an impersonation domain, presumably hosted by the attacker. Interestingly, the impersonation domains shared a prefix with the original. For example, the domain `sigaintevyh2rzvw.onion` was replaced with the impersonation domain `sigaintz7qjj3val.onion` whose first seven digits are identical to the original. The attacker could create shared prefixes by repeatedly generating key pairs until the hash over the public key resembled the desired prefix. Onion domains are generated by determining the SHA-1 hash over the public key, truncating it to its 80 most significant bits, and encoding it in Base32. Each Base32 digit of the 16-digit-domain represents five bits. Therefore, to get an n -digit prefix in the onion domain, 2^{5n-1} operations are required on average. For the seven-digit prefix above, this results in $2^{5 \cdot 7 - 1} = 2^{34}$ operations. The author of scallion [30], a tool for generating vanity onion domains, determined that an nVidia Quadro K2000M, a mid-range laptop GPU, is able to generate 90 million hashes per second. On this GPU, a partial collision for a seven-digit prefix can be found in $2^{34} \cdot \frac{1}{90,000,000} \simeq 190$ seconds, i.e., just over three minutes.

We inspected some of the phishing domains and found that the attackers further replaced the original Bitcoin addresses with addresses that are presumably controlled by the attackers, enabling them to hijack Bitcoin transactions. As a result, we believe that the attack was financially motivated.

The “redirect” Sybils These relays all had the *Exit* flag and tampered with HTTP redirects of exit traffic. To protect their users’ login credentials, some Bitcoin sites would redirect users from their HTTP site to the encrypted HTTPS version. This Sybil group tampered with the redirect and directed users to an impersonation site, resembling the original Bitcoin site, probably to steal credentials. We only observed this attack for Bitcoin sites, but cannot rule out that other sites were not attacked.

Interestingly, the Sybils’ descriptors and consensus entries had less in common than other Sybil groups. They used a small set of different ports, Tor versions, bandwidth values, and their nicknames did not exhibit an easily-recognizable pattern. In fact, the only reason why we know that these Sybils belong together is because their attack was identical.

We discovered three Sybil groups that implemented the redirect attack, each of them beginning to surface when the previous one got blocked. The initial group first showed up in May 2014, with only two relays, but slowly grew over time, until it was finally discovered in January 2015. We believe that these Sybils were run by the same attacker because their attack was identical.

It is possible that this Sybil group was run by the same

Purpose	Peak activity	Group ID	Number	Neighbor F Fingerprint Churn Uptime Exitmap	Description
MitM	Jan 2016	rewrite*	42	E	Replaced onion domains with impersonation site.
	Nov 2015	rewrite*	8	E	Replaced onion domains with impersonation site.
	Jun 2015	rewrite*	55	E	Replaced onion domains with impersonation site.
	Apr 2015	rewrite*	71	U,E	Replaced onion domains with impersonation site.
	Mar 2015	redirect†	24	E	Redirected users to impersonated site.
	Feb 2015	redirect†	17	E	Redirected users to impersonated site.
	Jan 2015	redirect†	26	E	Redirected users to impersonated site.
Botnet	Mar 2014	default	—	N	Likely a Windows-powered botnet. The group features wide geographical distribution, which is uncommon for typical Tor relays.
	Oct 2010	trotsky	649	N	The relays were likely part of a botnet. They appeared gradually, and were all running Windows.
Unknown	Jan 2016	cloudvps	61	C,U	Hosted by Dutch hoster XL Internet Services.
	Nov 2015	11BX1371	150	C,U	All relays were in two /24 networks and a single relay had the Exit flag.
	Jul 2015	DenkoNet	58	U	Hosted on Amazon AWS and only present in a single consensus. No relay had the Exit flag.
	Jul 2015	cloudvps	55	C,U	All relays only had the Running and Valid flag. As their name suggests, the relays were hosted by the Dutch hoster “CloudVPS.”
	Dec 2014	Anonpoke	284	C,U	The relays did not have the Exit flag and were removed from the network before they could get the HSDir flag.
	Dec 2014	FuslVZTOR	246	C,U	The relays showed up only hours after the LizardNSA incident.
	Dec 2014	LizardNSA	4,615	C,U	A group publicly claimed to be responsible for the attack [24]. All relays were hosted in the Google cloud and The Tor Project removed them within hours.
Research	May 2015	fingerprints	168	F	All twelve IP addresses, located in the same /24, changed their fingerprint regularly, presumably in an attempt to manipulate the distributed hash table.
	Mar 2014	FDCservers	264	C,U	Relays that were involved in an experimental onion service deanonymization attack [8].
	Feb 2013	AmazonEC2	1,424	F,C,U	We observed 1,424 relay fingerprints on 88 IP addresses. These Sybils were likely part of a research project [4, § V].
	Jun 2010	planetlab	595	C,U	According to a report from The Tor Project [20], a researcher started these relays to learn more about scalability effects.

Table 2: The most salient Sybil groups that sybilhunter and our exitmap modules discovered. We believe that groups marked with the symbols * and † were run by the same operator, respectively. Note that sybilhunter was unable to detect six Sybil groups in the category “MitM.”

attackers that controlled the “rewrite” group but we have no evidence to support that hypothesis. Interestingly, only our exitmap module was able to spot these Sybils. The relays joined the network gradually over time and had little in common in their configuration, which is why our heuristics failed. In fact, we cannot rule out that the

adversary was upstream of the exit relay, or gained control over these relays.

The “FDCservers” Sybils Attackers used these Sybils to deanonymize onion service users, as discussed by The Tor Project in a July 2014 blog post [8]. Sup-

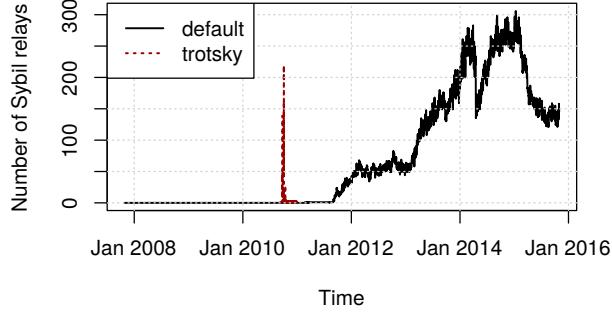

Figure 8: The number of “default” and “trotsky” Sybil members over time.

posedly, CMU/SEI-affiliated researchers were executing a traffic confirmation attack by sending sequences of RELAY_EARLY and RELAY cells as a signal down the circuit to the client, which the reference implementation never does [8, 7]. The attacking relays were both onion service directories and guards, allowing them to control both ends of the circuit for some Tor clients that were fetching onion service descriptors. Therefore, the relays could tell for a fraction of Tor users what onion service they were intending to visit. Most relays were running FreeBSD, used Tor in version 0.2.4.18-rc, had identical flags, mostly identical bandwidth values, and were located in 50.7.0.0/16 and 204.45.0.0/16. All of these shared configuration options made the relays easy to identify.

The relays were added to the network in batches, presumably starting in October 2013. On January 30, 2014, the attackers added 58 relays to the 63 existing ones, giving them control over 121 relays. On July 8, 2014, The Tor Project blocked all 123 IP addresses that were running at the time.

The “default” Sybils This group, named after the Sybils’ shared nickname “default,” has been around since September 2011 and consists of Windows-powered relays only. We extracted relays by filtering consensuses for the nickname “default,” onion routing port 443, and directory port 9030. The group features high IP address churn. For October 2015, we found “default” relays in 73 countries, with the top three countries being Germany (50%), Russia (8%), and Austria (7%). The majority of these relays had little uptime and exhibited a diurnal pattern, suggesting that they were powered off regularly—as it often is the case for desktop computers and laptops.

To get a better understanding of the number of “default” relays over time, we analyzed all consensuses, extracting the number of relays whose nickname was “default,” whose onion routing port was 443, and whose directory port was 9030. We did this for the first consensus

every day and plot the result in Figure 8. Note that we might overestimate the numbers as our filter could capture unrelated relays.

The above suggests that some of the “default” relays are running without the owner’s knowledge. While the relays do not fit the pattern of Sefnit (a.k.a. Mevade) [26] and Skynet [27]—two pieces of malware that use an onion service as command and control server—we believe that the “default” relays constitute a botnet.

The “trotsky” Sybils Similar to the “default” group, the “trotsky” relays appear to be part of a botnet. Most of the relays’ IP addresses were located in Eastern Europe, in particular in Slovenia, Croatia, and Bosnia and Herzegovina. The relays were all running on Windows, in version 0.2.1.26, and listening on port 443. Most of the relays were configured as exits, and The Tor Project assigned some of them the BadExit flag.

The first “trotsky” members appeared in September 2010. Over time, there were two relay peaks, reaching 139 (September 23) and 219 (October 3) relays, as illustrated in Figure 8. After that, only 1–3 relays remained in the consensus.

The “Amazon EC2” Sybils The relays all used randomly-generated nicknames, consisting of sixteen or seventeen letters and numbers; Tor in version 0.2.2.37; GNU/Linux; and IP addresses in Amazon’s EC2 net-block. Each of the 88 IP addresses changed its fingerprint 24 times, but not randomly: the fingerprints were chosen systematically, in a small range. For example, relay 54.242.248.129 had fingerprints with the prefixes 8D, 8E, 8F, and 90. The relays were online for 48 hours. After 24 hours, most of the relays obtained the HSDir flag. This behavior appears to be a clear attempt to manipulate Tor’s DHT.

We believe that this Sybil group was run by Biryukov, Pustogarov, and Weinmann as part of their Security and Privacy 2013 paper “Trawling for Tor Hidden Services” [4]—one of the few Sybil groups that were likely run by academic researchers.

The “Anonpoke” Sybils All relays shared the nickname “Anonpoke” and were online for four hours until they were rejected. All relays were hosted by a VPS provider in the U.S., Rackspace, with the curious exception of a single relay that was hosted in the UK, and running a different Tor version. The relays advertised the default bandwidth of 1 GiB/s on port 9001 and 9030. All relays were middle relays and running as directory mirror. All Sybils were configured to be an onion service directory, but did not manage to get the flag in time.

The “PlanetLab” Sybils A set of relays that used a variation of the strings “planet”, “plab”, “pl”, and “planetlab” as their nickname. The relays’ exit policy allowed ports 6660–6667, but they did not get the Exit flag. The Sybils were online for three days and then removed by The Tor Project, as mentioned in a blog post [20]. The blog post further says that the relays were run by a researcher to learn more about “cloud computing and scaling effects.”

The “LizardNSA” Sybils All relays were hosted in the Google Cloud and only online for ten hours, until the directory authorities started to reject them. The majority of machines were middle relays (96%), but the attackers also started some exit relays (4%). The Sybils were set up to be onion service directories, but the relays were taken offline before they could earn the HSDir flag. If all relays would have obtained the HSDir flag, they would have constituted almost 50% of all onion service directories; the median number of onion service directories on December 26 was 3,551.

Shortly after the attack began, somebody claimed responsibility on the tor-talk mailing list [24]. Judging by the supposed attacker’s demeanor, the attack was mere mischief.

The “FusIVZTOR” Sybils All machines were middle relays and hosted in the netblock 212.38.181.0/24, owned by a UK VPS provider. The directory authorities started rejecting the relays five hours after they joined the network. The relays advertized the default bandwidth of 1 GiB/s and used randomly determined ports. The Sybils were active in parallel to the “LizardNSA” attack, but there is no reason to believe that both incidents were related.

5.2 Alerts per method

Having investigated the different types of alerts our methods raised, we now provide intuition on how many of these alerts we would face in practice. To this end, we first determined conservative thresholds, chosen to yield a manageable number of alerts per week. For network churn, we set the threshold for α_n for relays with the Valid flag to 0.017. For the fingerprint method, we raised an alert if a relay changed its fingerprint at least ten times per month, and for uptime visualizations we raised an alert if at least five relays exhibited an identical uptime sequence. We used a variety of analysis windows to achieve representative results. For example, the Tor network’s churn rate slowly reduced over the years, which is why we only analyzed 2015 and 2016. Table 3 shows the results. For comparison, the table also shows our eximap modules, which did not require any thresholds.

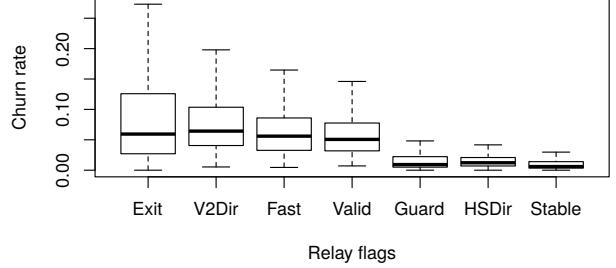

Figure 9: The churn distribution for seven relay flags. We removed values greater than the plot whiskers.

5.3 Churn rate analysis

We determined the churn rate between two subsequent consensuses for all 72,061 consensuses that were published between October 2007 and January 2016. Considering that (i) there are 162 gaps in the archived data, that (ii) we created time series for joining and leaving relays, and that (iii) we determined churn values for all twelve relay flags, we ended up with $(72,061 - 162) \cdot 2 \cdot 12 = 1,725,576$ churn values. Figure 9 shows a box plot for the churn distribution (joining and leaving churn values concatenated) for the seven most relevant relay flags. We removed values greater than the plot whiskers (which extend to values 1.5 times the interquartile range from the box) to better visualize the width of the distributions. Unsurprisingly, relays with the Guard, HSDir, and Stable flag experience the least churn, probably because relays are only awarded these flags if they are particularly stable. Exit relays have the most churn, which is surprising given that exit relays are particularly sensitive to operate. Interestingly, the median churn rate of the network has steadily decreased over the years, from 0.04 in 2008 to 0.02 in 2015.

Figure 10 illustrates churn rates for five days in August 2008, featuring the most significant anomaly in our data. On August 19, 822 relays left the network, resulting in a sudden spike, and a baseline shift. The spike was caused by the Tor network’s switch from consensus format version three to four. The changelog says that in version four, routers that do not have the Running flag are no longer listed in the consensus.

To alleviate the choice of a detection threshold, we plot the number of alerts (in log scale) in 2015 as the threshold increases. We calculate these numbers for three simple moving average window sizes. The result is shown in Figure 11. Depending on the window size, thresholds greater than 0.012 seem practical considering that 181 alerts per year average to approximately one alert in two days—a tolerable number of incidents to investigate. Unfortunately, we are unable to determine the false positive rate because we do not have ground truth.

Method	Analysis window	Threshold	Total alerts	Alerts per week
Fingerprint	10/2007–01/2016	10	551	1.3
Churn	01/2015–01/2016	0.017	110	1.9
Uptimes	01/2009–01/2016	5	3,052	8.3
Exitmap	08/2014–01/2016	—	251	3.2

Table 3: The number of alerts our methods raised. We used different analysis windows for representative results, and chose conservative thresholds to keep the number of alerts per week manageable.

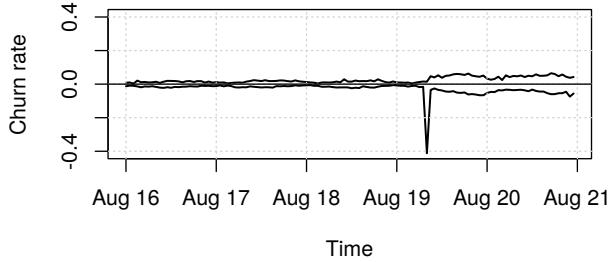

Figure 10: In August 2008, an upgrade in Tor’s consensus format caused the biggest anomaly in our dataset. The positive time series represents relays that joined and the negative one represents relays that left.

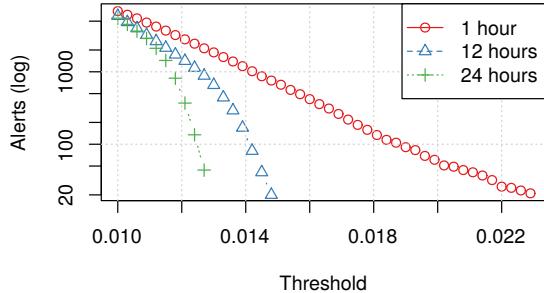

Figure 11: The number of alerts (in log scale) in 2015 as the detection threshold increases, for three smoothing window sizes.

5.4 Uptime analysis

We generated relay uptime visualizations for each month since 2007, resulting in 100 images. We now discuss a subset of these images, those containing particularly interesting patterns.

Figure 12 shows June 2010, featuring a clear “Sybil block” in the center. The Sybils belonged to a researcher who, as documented by The Tor Project [20], started several hundred Tor relays on PlanetLab for research on scalability (the “PlanetLab” Sybils discussed above). Our manual analysis could verify this. The relays were easy to identify because their nicknames suggested that they were hosted on PlanetLab, containing strings such as “planetlab,” “planet,” and “plab.” Note the small

Figure 12: In June 2010, a researcher started several hundred Tor relays on PlanetLab [20]. The image shows the uptime of 2,000 relays for all of June.

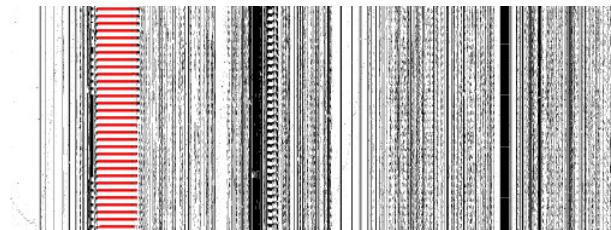

Figure 13: August 2012 featured a curious “step pattern,” caused by approximately 100 Sybils. The image shows the uptime of 2,000 relays for all of August.

height of the Sybil block, indicating that the relays were only online for a short time.

Figure 13 features a curious “step pattern” for approximately 100 relays, all of which were located in Russia and Germany. The relays appeared in December 2011, and started exhibiting the diurnal step pattern (nine hours uptime followed by fifteen hours downtime) in March 2012. All relays had similar nicknames, consisting of eight seemingly randomly-generated characters. In April 2013, the relays finally disappeared.

Figure 14 illustrates the largest Sybil group to date, comprising 4,615 Tor relays (the “LizardNSA” Sybils discussed above). An attacker set up these relays in the Google cloud in December 2014. Because of its magnitude, the attack was spotted almost instantly, and The Tor Project removed the offending relays only ten hours after they appeared.

Figure 14: In December 2014, an attacker started several thousand Tor relays in the Google cloud. The image shows the uptime of 4,000 relays for all of December.

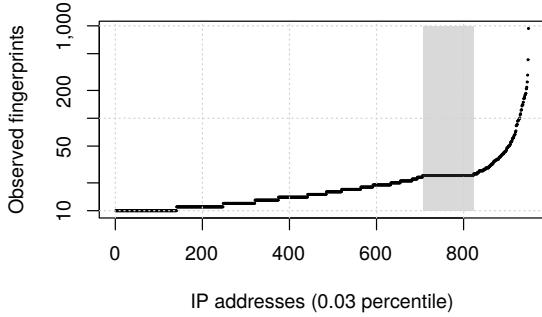

Figure 15: The number of observed fingerprints for the 1,000 relays that changed their fingerprints the most.

5.5 Fingerprint anomalies

We determined how often all Tor relays changed their fingerprint from 2007 to 2015. Figure 15 illustrates the number of fingerprints (y axis) we have observed for the 1,000 Tor relays (x axis) that changed their fingerprint the most. All these relays changed their fingerprint at least ten times. Twenty-one relays changed their fingerprint more than 100 times, and the relay at the very right end of the distribution changed its fingerprint 936 times. This relay’s nickname was “openwrt,” suggesting that it was a home router that was rebooted regularly, presumably losing its long-term keys in the process. The relay was running from August 2010 to December 2010.

Figure 15 further contains a peculiar plateau, shown in the shaded area between index 707 and 803. This plateau was caused by a group of Sybils, hosted in Amazon EC2, that changed their fingerprint exactly 24 times (the “Amazon EC2” Sybils discussed above). Upon inspection, we noticed that this was likely an experiment for a Security and Privacy 2013 paper on deanonymizing Tor onion services [4, § V].

We also found that many IP addresses in the netblock 199.254.238.0/24 frequently changed their fingerprint. We contacted the owner of the address block and were told that the block used to host VPN services. Apparently, several people started Tor relays and since the VPN service would not assign permanent IP addresses, the Tor relays would periodically change their address, causing the churn we observe.

5.6 Accuracy of nearest-neighbor ranking

Given a Sybil relay, how good is our nearest-neighbor ranking at finding the remaining Sybils? To answer this question, we now evaluate our algorithm’s accuracy, which we define as the fraction of neighbors it correctly labels as Sybils. For example, if eight out of ten Sybils are correctly labeled as neighbors, the accuracy is 0.8.

A sound evaluation requires ground truth, i.e., relays that are *known* to be Sybils. All we have, however, are relays that we *believe* to be Sybils. In addition, the number of Sybils we found is only a lower bound—we are unlikely to have detected all Sybil groups. Therefore, our evaluation is doomed to overestimate our algorithm’s accuracy because we are unable to test it on the Sybils we did not discover.

We evaluate our ranking algorithm on two datasets; the “bad exit” Sybil groups from Table 5, and relay families. We chose the bad exit Sybils because we observed them running identical, active attacks, which makes us confident that they are in fact Sybils. Recall that a relay family is a set of Tor relays that is controlled by a single operator, but configured to express this mutual relationship in the family members’ configuration file. Therefore, relay families are benign Sybils. As of January 2016, approximately 400 families populate the Tor network, ranging in size from only two to 25 relays.

We evaluate our algorithm by finding the nearest neighbors of a family member. Ideally, all neighbors are family members, but the use of relay families as ground truth is very likely to overestimate results because family operators frequently configure their relays identically on purpose. At the time of this writing, a popular relay family has the nicknames “AccessNow000” to “AccessNow009,” adjacent IP addresses, and identical contact information—perfect prerequisites for our algorithm. We expect the operators of *malicious* Sybils, however, to go out of their way to obscure the relationship between their relays.

To determine our algorithm’s accuracy, we used all relay families that were present in the first consensus that was published in October 2015. For each relay that had at least one mutual family relationship, we determined its $n - 1$ nearest neighbors where n is the family size. Basically, we evaluated how good our algorithm is at finding the relatives of a family member. We determined the accuracy—a value in $[0, 1]$ —for each family member. The result is shown in Figure 16(b), a distribution of accuracy values.

Next, we repeated the evaluation with the bad exit Sybil groups from Table 5. Again, we determined the $n - 1$ nearest neighbors of all bad exit relays, where n is the size of the Sybil group. The accuracy is the fraction of relays that our algorithm correctly classified as neigh-

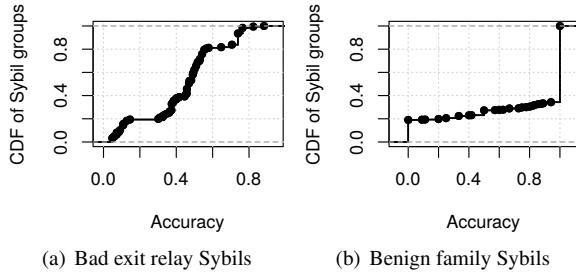

Figure 16: ECDF for our two evaluations, the bad exit Sybils in Fig. 16(a) and the benign family Sybils in Fig. 16(b).

Method	Analysis window	Run time
Churn	Two consensuses	~0.2s
Neighbor ranking	One consensus	~1.6s
Fingerprint	One month	~58.0s
Uptimes	One month	~145.0s

Table 4: The computational cost of our analysis techniques.

bor. The result is illustrated in Figure 16(a).

As expected, our algorithm is significantly more accurate for the family dataset—66% of rankings had perfect accuracy. The bad exit dataset, however, did worse. Not a single ranking had perfect accuracy and 59% of all rankings had an accuracy in the interval [0.3, 0.6]. Nevertheless, we find that our algorithm facilitates manual analysis given how quickly it can provide us with a list of the most similar relays. Besides, inaccurate results (i.e., similar neighbors that are not Sybils) are cheap as sybilhunter users would not spend much time on neighbors that bear little resemblance to the “seed” relay.

5.7 Computational cost

Fast techniques lend themselves to being run hourly, for every new consensus, while slower ones must be run less frequent. Table 4 gives an overview of the runtime of our methods.⁷ We stored our datasets on a solid state drive to eliminate I/O as performance bottleneck.

The table columns contain, from left to right, our analysis technique, the technique’s analysis window, and how long it takes to compute its output. Network churn calculation is very fast; it takes as input only two consensus files and can easily be run for every new network consensus. Nearest-neighbor ranking takes approximately 1.6 seconds for a single consensus counting 6,942 relays. Fingerprint and uptime analysis for one month worth of

⁷We determined all performance numbers on an Intel Core i7-3520M CPU at 2.9 GHz, a consumer-grade CPU.

consensuses takes approximately one and two minutes, respectively—easy to invoke daily, or even several times a day.

6 Discussion

Having used sybilhunter in practice for several months, we now elaborate on both our operational experience and the shortcomings we encountered.

6.1 Operational experience

Our practical work with sybilhunter taught us that analyzing Sybils frequently requires manual verification, e.g., (i) comparing an emerging Sybil group with a previously disclosed one, (ii) using exitmap to send decoy traffic over Sybils, or (iii) sorting and comparing information in relay descriptors. We found that the amount of manual work greatly depends on the Sybils under investigation. The MitM groups in Table 2 were straightforward to spot—in a matter of minutes—while the botnets required a few hours of effort. It is difficult to predict all analysis scenarios that might arise in the future, so we designed sybilhunter to be interoperable with Unix command line tools [28]. Sybilhunter’s CSV-formatted output can easily be piped into tools such as sed, awk, and grep. We found that compact text output was significantly easier to process, both for plotting and for manual analysis. Aside from Sybil detection, sybilhunter can serve as valuable tool to better understand the Tor network and monitor its reliability. Our techniques have disclosed network consensus issues and can illustrate the diversity of Tor relays, providing empirical data that can support future network design decisions.

A key issue in the arms race of eliminating harmful relays lies in *information asymmetry*. Our detection techniques and code are freely available while our adversaries operate behind closed doors, creating an uphill battle that is difficult to sustain given our limited resources. In practice, we can reduce this asymmetry and limit our adversaries’ knowledge by keeping secret sybilhunter’s thresholds and exitmap’s detection modules, so our adversary is left guessing what our tools seek to detect. This differentiation between an *open* analysis framework such as the one we discuss in this paper, and *secret* configuration parameters seems to be a sustainable trade-off. Note that we are not arguing in favor of the flawed practice of security by obscurity. Instead, we are proposing to add a layer of obscurity *on top* of existing defense layers.

We are working with The Tor Project on incorporating our techniques in Tor Metrics [33], a website containing network visualizations that are frequented by numerous volunteers. Many of these volunteers discover anomalies and report them to The Tor Project. By incorporating

our techniques, we hope to benefit from “crowd-sourced” Sybil detection.

6.2 Limitations

In Section 4.2, we argued that we are unable to expose all Sybil attacks, so our results represent a lower bound. An adversary unconstrained by time and money can add an unlimited number of Sybils to the network. Indeed, Table 2 contains six Sybil groups that sybilhunter was unable to detect. Fortunately, exitmap was able to expose these Sybils, which emphasizes the importance of diverse and complementary analysis techniques. Needless to say, sybilhunter works best when analyzing attacks that took place before we built sybilhunter. Adversaries that know of our methods can evade them at the cost of having to spend time and resources. To evade our churn and uptime heuristics, Sybils must be added and modified independently over time. Evasion of our fingerprint heuristic, e.g., to manipulate Tor’s DHT, requires more physical machines. Finally, manipulation of our neighbor ranking requires changes in configuration. This arms race is unlikely to end, barring fundamental changes in how Tor relays are operated.

Sybilhunter is unable to ascertain the purpose of a Sybil attack. While the purpose is frequently obvious, Table 2 contains several Sybil groups that we could not classify. In such cases, it is difficult for The Tor Project to make a call and decide if Sybils should be removed from the network. Keeping them runs the risk of exposing users to an unknown attack, but removing them deprives the network of bandwidth. Often, additional context is helpful in making a call. For example, Sybils that are (i) operated in “bulletproof” autonomous systems [17, § 2], (ii) show signs of not running the Tor reference implementation, or (iii) spoof information in their router descriptor all suggest malicious intent. In the end, Sybil groups have to be evaluated case by case, and the advantages and disadvantages of blocking them have to be considered.

Finally, there is significant room for improving our nearest neighbor ranking. For simplicity, our algorithm represents relays as strings, ignoring a wealth of nuances such as topological proximity of IP addresses, or predictable patterns in port numbers.

7 Conclusion

We presented sybilhunter, a novel system that uses diverse analysis techniques to expose Sybils in the Tor network. Equipped with this tool, we set out to analyze nine years of The Tor Project’s archived network data. We discovered numerous Sybil groups, twenty of which we present in this work. By analyzing the Sybil

groups sybilhunter discovered, we found that (i) Sybil relays are frequently configured very similarly, and join and leave the network simultaneously; (ii) attackers differ greatly in their technical sophistication; and (iii) our techniques are not only useful for spotting Sybils, but turn out to be a handy analytics tool to monitor and better understand the Tor network. Given the lack of a central identity-verifying authority, it is always possible for well-executed Sybil attacks to stay under our radar, but we found that a complementary set of techniques can go a long way towards finding malicious Sybils, making the Tor network more secure and trustworthy for its users.

All our code, data, visualizations, and an open access bibliography of our references are available online at <https://nymity.ch/sybilhunting/>.

Acknowledgments

We want to thank our shepherd, Tudor Dumitraş, for his guidance on improving our work. We also want to thank Georg Koppen, Prateek Mittal, Stefan Lindskog, the Tor developers, and the wider Tor community for helpful feedback. A Exposed malicious exit relays

Table 5 provides an overview of our second dataset, 251 bad exit relays that we discovered between August 2014 and January 2016. We believe that all single relays in the dataset were isolated incidents while sets of relays constituted Sybil groups. Sybil groups marked with the symbols *, †, and ‡ were run by the same attacker, respectively.

Discovery	# of relays	Attack description
Aug 2014	1	The relay injected JavaScript into returned HTML. The script embedded another script from the domain fluxx.crazytall.com—not clearly malicious, but suspicious.
	1	The relay injected JavaScript into returned HTML. The script embedded two other scripts, jquery.js from the official jQuery domain, and clr.js from adobe.flashdst.com. Again, this was not necessarily malicious, but suspicious.
Sep 2014	1	The exit relay routed traffic back into the Tor network, i.e., we observed traffic that was supposed to exit from relay <i>A</i> , but came from relay <i>B</i> . The system presented by Ling et al. behaves the same [23]; the authors proposed to run intrusion detection systems on Tor traffic by setting up an exit relay that runs an NIDS system, and routes the traffic back into the Tor network after having inspected the traffic.
Oct 2014	1	The relay injected JavaScript into returned HTML.
	1	The relay ran the MitM tool sslstrip [25], rewriting HTTPS links to unencrypted HTTP links in returned HTML.
	1	Same as above.
Jan 2015	23*	Blockchain.info’s web server redirects its users from HTTP to HTTPS. These relays tampered with blockchain.info’s redirect and returned unprotected HTTP instead—presumably to sniff login credentials.
	1	The relay used OpenDNS as DNS resolver and had the website category “proxy/anonymizer” blocked, resulting in several inaccessible websites, including torproject.org.
Feb 2015	1	The relay injected a script that attempted to load a resource from the now inaccessible torclick.net. Curiously, torclick.net’s front page said “We place your advertising materials on all websites online. Your ads will be seen only for anonymous network TOR [sic] users. Now it is about 3 million users. The number of users is always growing.”
	17†	Again, these relays tampered with HTTP redirects of Bitcoin websites. Interestingly, the attack became more sophisticated; these relays would begin to target only connections whose HTTP headers resembled Tor Browser.
Mar 2015	18*	Same as above.
	1	The relay injected JavaScript and an iframe into the returned HTML. The injected content was not clearly malicious, but suspicious.
Apr 2015	70‡	These exit relays transparently rewrote onion domains in returned HTML to an impersonation domain. The impersonation domain looked identical to the original, but had different Bitcoin addresses. We believe that this was attempt to trick Tor users into sending Bitcoin transactions to phishing addresses.
Jun 2015	55†	Same as above.
Aug 2015	4†	Same as above.
Sep 2015	1	The relay injected an iframe into returned HTML that would load content that made the user’s browser participate in some kind of mining activity.
Nov 2015	1	The relay ran the MitM tool sslstrip.
	8†	Same as the relays marked with a †.
Dec 2015	1‡	The relay ran the MitM tool sslstrip.
	1‡	Same as above.
Jan 2016	43†	Same as the relays marked with a †.

Table 5: An overview of our second dataset, 251 malicious exit relays that we discovered using exitmap. We believe that Sybil groups marked with an *, †, and ‡ were run by the same adversary.

***k*-fingerprinting: a Robust Scalable Website Fingerprinting Technique**

Abstract

Website fingerprinting enables an attacker to infer which web page a client is browsing through encrypted or anonymized network connections. We present a new website fingerprinting technique based on random decision forests and evaluate performance over standard web pages as well as Tor hidden services, on a larger scale than previous works. Our technique, *k*-fingerprinting, performs better than current state-of-the-art attacks even against website fingerprinting defenses, and we show that it is possible to launch a website fingerprinting attack in the face of a large amount of noisy data. We can correctly determine which of 30 monitored hidden services a client is visiting with 85% true positive rate (TPR), a false positive rate (FPR) as low as 0.02%, from a world size of 100,000 unmonitored web pages. We further show that error rates vary widely between web resources, and thus some patterns of use will be predictably more vulnerable to attack than others.

1 Introduction

Traditional encryption obscures only the content of communications and does not hide metadata such as the size and direction of traffic over time. Anonymous communication systems obscure both content and metadata, preventing a passive attacker from observing the source or destination of communication.

Anonymous communications tools, such as Tor [11], route traffic through relays to hide its ultimate destination. Tor is designed to be a low-latency system to support interactive activities such as instant messaging and web browsing, and does not significantly alter the shape of network traffic. This allows an attacker to exploit information leaked via the order, timing and volume of resources requested from a website. As a result, many works have shown that website fingerprinting attacks are possible even when a client is browsing with encryption or using an anonymity tool such as Tor [7, 16, 17, 21, 23, 27, 32, 36, 38, 39].

Website fingerprinting is commonly formulated as a classification problem. An attacker wishes to know whether a client browses one of n web pages. The attacker first collects many examples of traffic traces from each of the n web pages by performing web-requests through the protection mechanism under attack; features are extracted and a machine learning algorithm is trained to classify the website using those features. When a client browses a web page, the attacker passively collects the traffic, passes it in to their classifier and checks if the client visited one of the n web pages. In the literature this is referred to as the closed-world setting – a client is restricted to browse a limited number of web pages, monitored by the attacker. However, the closed-world model has been criticized for being unrealistic [17, 29] since a client is unlikely to only browse a limited set of web pages. The open-world setting attempts to model a more realistic setting where the attacker monitors a small number of web pages, but allows a client to additionally browse to a large world size of unmonitored web pages.

Our attack is based on random decision forests [6], an ensemble method using multiple decision trees. We extend the random forest technique to allow us to extract fingerprints to perform identification in an open-world.

The key contributions of this work are as follows:

- A new attack, *k*-fingerprinting, based on extracting a fingerprint for a web page via a novel variant of random forests. We show *k*-fingerprinting is more accurate and faster than other state-of-the-art website fingerprinting attacks [7, 28, 39] even under proposed website fingerprinting defenses.
- An analysis of the features used in this and prior work to determine which yield the most information about an encrypted or anonymized web page. We show that simple features such as counting the number of packets in a sequence leaks more information about the identity of a web page than complex features such as packet ordering or packet inter-arrival time features.
- An open-world setting that is an order of magnitude

larger than the previous open-world website fingerprinting work of 5,000 unmonitored web pages [39]¹, and nearly twice as large in terms of unique numbers websites than [28], reflecting a more realistic website fingerprinting attack over multiple browsing sessions. In total we tested k -fingerprinting on 101,130 unique websites².

- We show that a highly accurate attack can be launched by training a small fraction of the total data, greatly reducing the start-up cost an attacker would need to perform the attack.
- We observe that the error rate is uneven and so it may be advantageous to throw away some training information that could confuse a classifier. An attacker can learn the error rate of their attack from the training set, and use this information to select which web pages they wish to monitor in order to minimize their error rates.
- We confirm that browsing over Tor does not provide any additional protection against fingerprinting attacks over browsing using a standard web browser. Furthermore we show that k -fingerprinting is highly accurate on Tor hidden services, and that they can be distinguished from standard web pages.

2 Related Work

Website Fingerprinting. Website fingerprinting has been studied extensively. Early work by Wagner and Schneier [34], Cheng and Avnur [10] exposed the possibility that encrypted HTTP GET requests may leak information about the URL, conducting preliminary experiments on a small number of websites. They asked clients in a lab setting to browse a website for 5-10 minutes, pausing two seconds between page loading. With caching disabled they were able to correctly identify 88 pages out of 92 using simple packet features. Early website fingerprinting defenses were usually designed to safeguard against highly specific attacks. In 2009, Wright et al. [40] designed ‘traffic morphing’ that allowed a client to shape their traffic to look as if it was generated from a different website. They were able to show that this defense does well at defeating early website fingerprinting attacks that heavily relied on exploiting unique packet length features [21, 32].

¹[17] considers an open world size of $\sim 35K$ but only tried to separate monitored pages from unmonitored pages instead of further classifying the monitored pages to the correct website. The authors assume the adversary monitors four pages: google.com, facebook.com, wikipedia.org and twitter.com. They trained a classifier using 36 traces for each of the Alexa Top 100 web pages, including the web pages of the monitored pages. The four traces for each of the monitored sites plus one trace for each of the unmonitored sites up to $\sim 35K$ are used for testing.

²All code will be made available through code repositories under a liberal open source license and data will be deposited in open data repositories.

In a similar fashion, Tor pads all packets to a fixed-size cells of 512 bytes. Tor also implemented randomized ordering of HTTP pipelines [30] in response to the attack by Panchenko et al. [27] who used packet ordering features to train an SVM classifier. This attack on Tor achieved an accuracy of 55%, compared to a previous attack that did not use such fine grained features achieving 3% accuracy on the same data set using a Naive-Bayes classifier [16]. Other defenses such as the decoy defense [27] loads a camouflage website in parallel to a legitimate website, adding a layer of background noise. They were able to show using this defense attack accuracy of the SVM again dropped down to 3%.

Luo et al. [24] designed the HTTPOS fingerprinting defense at the application layer. HTTPOS acts as a proxy accepting HTTP requests and obfuscating them before allowing them to be sent. It modifies network features on the TCP and HTTP layer such as packet size, packet time and payload size, along with using HTTP pipelining to obfuscate the number of outgoing packets. They showed that HTTPOS was successful in defending against a number of classifiers [5, 9, 21, 32].

More recently Dyer et al. [12] created a defense, BuFLO, that combines many previous countermeasures, such as fixed packet sizes and constant rate traffic. Dyer et al. showed this defense improved upon other defenses at the expense of a high bandwidth overhead. Cai et al. [8] made modifications to the BuFLO defense based on rate adaptation again at the expense of a high bandwidth overhead. Following this Nithyanand et al. [25] proposed Glove, that groups website traffic into clusters that cannot be distinguished from any other website in the set. This provides information theoretic privacy guarantees and reduces the bandwidth overhead by intelligently grouping web traffic in to similar sets.

Cai et al. [7] modified the kernel in Panchenko et al.’s SVM to improve an attack on Tor, and was further improved in an open-world setting by Wang and Goldberg in 2013 [38], achieving a true positive rate (TPR) of over 0.95 and a false positive rate (FPR) of 0.002 when monitoring one web page. Wang et al. [39] conducted attacks on Tor using large open-world sets. Using a k -nearest neighbor classifier they achieved a TPR of 0.85 and FPR of 0.006 when monitoring 100 web pages out of 5100 web pages. More recently Wang and Goldberg [37] suggested a defense using a browser in half-duplex mode – meaning a client cannot send multiple requests to servers in parallel. In addition to this simple modification they add random padding and show they can even foil an attacker with perfect classification accuracy with a comparatively (to other defenses) small bandwidth overhead. Wang and Goldberg [36] then investigated the practical deployment of website fingerprinting attacks on Tor. By maintaining an up-to-date training set and splitting a full

packet sequence in to components comprising of different web page load traces they show that practical website fingerprinting attacks are possible. By considering a time gap of 1.5 seconds between web page loads, their splitting algorithm can successfully parse a single packet sequence in to multiple packet sequences with no loss in website fingerprinting accuracy. Gu et al. [15] studied website fingerprinting in multi-tab browsing setting. Using a Naive Bayes classifier on the 50 top ranked websites in Alexa, they show when tabs are opened with a delay of 2 seconds, they can classify the first tab with 75.9% accuracy, and the background tab with 40.5%. More recently, Kwon et al. [19] showed that website fingerprinting attacks can be applied to Tor hidden services, and due to the long lived structure of hidden services, attacks can be even more accurate than when compared to non-hidden pages. They correctly deanonymize 50 monitored hidden service servers with TPR of 88% and FPR of 7.8% in an open world setting. We further improve on this in our work, resulting in a more accurate attack on the same data set.

In concurrent work, Panchenko et al. [28] have experimented with large datasets. Using a mix of different sources they produced two datasets, one of 34,580 unique websites (118,884 unique web pages) and another of 65,409 unique websites (211,148 unique web pages). Using a variation of a sequence of cumulative summations of packet sizes in a traffic trace they show their attack, CUMUL, was of similar accuracy to k -NN [39] under normal browsing conditions. However, we show that due to their feature set dependency on order and packet counting, their attack suffers substantially under simple website fingerprinting defenses and is outperformed by our technique, k -fingerprinting.

Random Forests. Random forests are a classification technique consisting of an ensemble of decision trees, taking a consensus vote of how to classify a new object. They have been shown to perform well in classification, regression [6, 20] and anomaly detection [22]. Each tree in the forest is trained using labeled objects represented as feature vectors of a fixed size. Training includes some randomness to prevent over-fitting: the training set for each tree is sampled from the available training set with replacement. Due to the bootstrap sampling process there is no need for k -fold cross validation to measure k -fingerprinting performance, it is estimated via the unused training samples on each tree [6]. This is referred to as the *out-of-bag* score.

3 Attack Design

We consider an attacker that can passively collect a client’s encrypted or anonymized web traffic, and aims to infer which web resource is being requested. Dealing with an open-world, makes approaches based purely on

classifying previously seen websites inapplicable. Our technique, k -fingerprinting, aims to define a distance-based classifier. It automatically manages unbalanced sized classes and assigns meaningful distances between packet sequences, where close-by ‘fingerprints’ denote requests likely to be for the same resources.

3.1 k -fingerprints from random forests

In this work we use random forests to extract a fingerprint for each traffic instance³, instead of using directly the classification output of the forest. We define a distance metric between two traces based on the output of the forest: given a feature vector each tree in the forest associates a leaf identifier with it, forming a vector of leaf identifiers for the item, which we refer to as the *fingerprint*.

Once fingerprint vectors are extracted for two traces, we use the Hamming⁴ distance to calculate the distance between these fingerprints⁵. We classify a test instance as the label of the closest k training instances via the Hamming distance of fingerprints – assuming all labels agree. We evaluate the effect of varying k , the number of fingerprints used for comparison, in Sections 7, 8 and 9.

This leafs vector output represents a robust fingerprint: we expect similar traffic sequences are more likely to fall on the same leaves than dissimilar traffic sequences. Since the forest has been trained on a classification task, traces from the same websites are preferentially aggregated in the same leaf nodes, and those from different websites kept apart.

We can vary the number of training instances k a fingerprint should match, to allow an attacker to trade the true positive rate (TPR) for false positive rate (FPR). This is not possible using the direct classification of the random forest. By using a k closest fingerprint technique for classification, the attacker can choose how they wish to decide upon final classification⁶. For the closed-world setting we do not need the additional fingerprint layer for classification, we can simply use the classification output of the random forest since all classes are balanced and our attack does not have to differentiate between False Positives and False Negatives. For the closed-world setting we measure the mean accuracy of the random forest.

³We define a traffic instance as the network traffic generated via a web page load.

⁴We experimented with using the Hamming, Euclidean, Mahalanobis and Manhattan distance functions and found Hamming to provide the best results.

⁵For example, given the Hamming distance function $d : V \times V \rightarrow \mathbb{R}$, where V is the space of leaf symbols, we expect given two packet sequences generated from loading *google.com*, with fingerprints vectors f_1, f_2 and a packet sequence generated from loading *facebook.com* with fingerprint f_3 , that $d(f_1, f_2) < d(f_1, f_3)$ and $d(f_1, f_2) < d(f_2, f_3)$.

⁶We chose to classify a traffic instance as a monitored page if all k fingerprints agree on the label, but an attacker could choose some other metric such as majority label out of the k fingerprints.

3.2 The k -fingerprinting attack

Our k -fingerprinting attack proceeds in two phases: The attacker chooses which web pages they wish to monitor and captures network traffic generated via loading the monitored web pages and a large number of unmonitored web pages. These target traces for monitored websites, along with some traces for unmonitored websites, are used to train a random forest for classification. Given a packet sequence representing each training instance of a monitored web page, it is converted to a fixed length fingerprint as described in Section 3.1 and stored.

The attacker then passively collects instances of web page loads from a client’s browsing session. A fingerprint is extracted from the newly collected packet sequence. The attacker then computes the Hamming distance of this new fingerprint against the corpus of fingerprints collected during training and is classified as a monitored page if and only if all k fingerprints agree on classification, as described in Section 3.1, otherwise it is classified as an unmonitored page.

We define the following performance measures for the attack:

- **True Positive Rate (TPR).** The probability that a monitored page is classified as the correct monitored page.
- **False Positive Rate (FPR).** The probability that an unmonitored page is incorrectly classified as a monitored page.
- **Bayesian Detection Rate (BDR).** The probability that a page corresponds to the correct monitored page given that the classifier recognized it as that monitored page. Assuming a uniform distribution of pages BDR can be found from TPR and FPR using the formula

$$\frac{TPR \cdot Pr(M)}{(TPR \cdot Pr(M) + FPR \cdot Pr(U))}$$

where

$$Pr(M) = \frac{|\text{Monitored}|}{|\text{Total Pages}|}, \quad Pr(U) = 1 - Pr(M).$$

Ultimately BDR indicates the practical feasibility of the attack as it measures the main concern of the attacker, the probability that the classifier made a correct prediction.

4 Data gathering

We collect two data sets: one via Tor⁷ DS_{Tor} , and another via a standard web browser, DS_{Norm} . DS_{Norm} consists of 30 instances from each of 55 monitored web pages, along with 7,000 unmonitored web pages chosen from Alexa’s top 20,000 web sites [1]. We collected DS_{Norm} using a number of Amazon EC2

⁷The most recent version at the time of collection was used, Tor Browser 5.0.6.

instances⁸, Selenium⁹ and the headless browser PhantomJS¹⁰. We used `tcpdump`¹¹ to collect network traces for 20 seconds with 2 seconds between each web page load. Monitored pages were collected in batches of 30 and unmonitored web pages were collected successively. Page loading was performed with no caches and time gaps between multiple loads of the same web page, as recommended by Wang and Goldberg [38]. We chose to monitor web pages from Alexa’s top 100 web sites [1] to provide a comparison with the real world censored web pages used in the Wang et al. [39] data set¹². DS_{Tor} was collected in a similar manner to DS_{Norm} but was collected via the Tor browser. DS_{Tor} consists of two subsets of monitored web pages: (i) 100 instances from each of the 55 top Alexa monitored web pages and (ii) 80 instances from each of 30 popular Tor hidden services. A Tor hidden service is a website that is hosted behind a Tor client’s *Onion Proxy*, which serves as the interface between application and network. Tor hidden services allow both a client accessing the website and the server hosting the website to remain anonymous to one another and any external observers. We chose hidden services to fingerprint based on popularity as listed by the `.onion` search engine Ahmia¹³. The unmonitored set is comprised of the top 100,000 Alexa web pages, excluding the top 55. We chose to fingerprint web pages as listed by Alexa as these constitute the most popular web pages in the world over extended periods of time, and hence provide a more realistic dataset than choosing pages at random and/or using transiently popular website links as included in Panchenko et al.’s recent work [28]. By including website visits to trending topics we argue that this diminishes the ability to properly measure how effective a website fingerprinting attack will perform in general.

For comparison to previous work, we evaluated our attack on one of the previous largest website fingerprinting data sets [39], which collected 90 instances from each of 100 monitored sites, along with 5000 unmonitored web pages. The Wang et al. monitored web pages are various real-world censored websites from UK, Saudi Arabia and China providing a realistic set of web pages an attacker may wish to monitor. The unmonitored web pages are chosen at random from Alexa’s top 10,000 websites – with no intersection between monitored and unmonitored web pages.

¹¹<http://www.tcpdump.org/>

¹²We used TCP/IP packets for final classification over abstracting to the Tor cell layer [38], preliminary experiments showed no consistent improvements from using one data layer for classification over the other.

¹³<http://www.ahmia.fi/>

This allows us to validate k -fingerprinting on two different data sets while allowing for direct comparison against the state-of-the-art k -Nearest Neighbor attack [39]. We can also infer how well the attack works on censored web pages which may not have small landing pages or be set up for caching like websites in the top Alexa list. Testing k -fingerprinting on both real-world censored websites and top alexa websites indicates how the attack performs across a wide range of websites.

For the sake of comparison, according to a study by research firm Nielsen [3] the number of unique websites visited per month by an average client in 2010 was 89. Another study [17, 26] collected web site statistics from 80 volunteers in a virtual office environment. Traffic was collected from each volunteer for a total of 40 hours. The mean unique number of websites visited per volunteer was 484, this is substantially smaller than the world sizes we consider in our experiments.

5 Feature selection

Our first contribution is a systematic analysis of feature importance. Despite some preliminary work by Panchenko et al. [27], there is a notable absence of feature analysis in the website fingerprinting literature. Instead features are picked based on heuristic arguments. All feature importance experiments were performed with the Wang et al. data set [39] so as to allow direct comparison with their attack results.

We train a random forest classifier in the closed-world setting using a feature vector comprised of features in the literature, and labels corresponding to the monitored sites. We use the gini coefficient as the purity criterion for splitting branches and estimate feature importance using the standard methodology described by Breiman [2, 6, 13]. Each time a decision tree branches on a feature the weighted sum of the gini impurity index for the two descendant nodes is higher than the purity of the parent node. We add up the gini decrease for each individual feature over the entire forest to get a consistent measure of feature importance.

Figure 1 illustrates the effect of using a subset of features for random forest classification. We first train a random forest classifier to establish feature importance; and then train new random forests with only subsets of the most informative features in batches of five. As we increase the number of features we observe a monotonic increase in accuracy; however there are diminishing returns as we can achieve nearly the same accuracy after using the 30 most important features. We chose to use 150 features in all following experiments since the difference in training time when using fewer features was negligible.

Figure 2 identifies the top-20 ranked features and illustrates their variability across 100 repeated experiments.

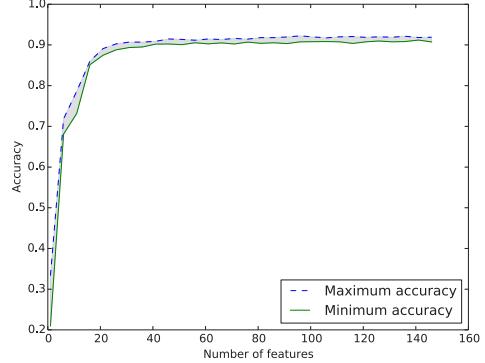

Figure 1: Accuracy of k -fingerprinting in a closed-world setting as the number of features is varied.

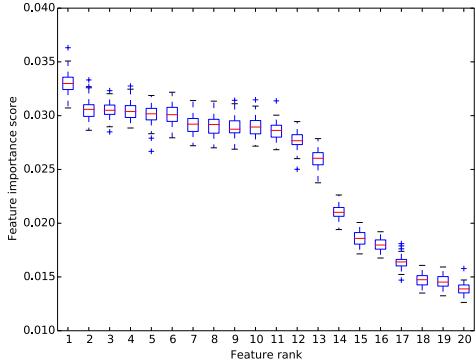

As seen in Figure 1 there is a reduction in gradient when combining the top 15 features compared to using the top 10 features. Figure 2 shows that the top 13 features are comparatively much more important than the rest of the top 20 features, hence there is only a slight increase in accuracy when using the top 15 features compared to using the top 10. After the drop between the rank 13 and rank 14 features, feature importance falls steadily until feature rank 40, after which the reduction in feature importance is less prominent¹⁴. Note that there is some interchangeability in rank between features, we assign ranks based on the average rank of a feature over the 100 experiments.

Feature Importance

From each packet sequence we extract the following features:

- **Number of packets statistics.** The total number of packets, along with the number of incoming and outgoing packets [12, 27, 39]. The number of incoming packets during transmission is the most important feature, and together with the number of outgoing packets during transmission are always two of the five most important features. The total number of packets in transmission has rank 10.
- **Incoming & outgoing packets as fraction of total packets.** The number of incoming and outgoing packets as a fraction of the total number of packets [27]. Always two of the five most important features.
- **Packet ordering statistics.** For each successive incoming and outgoing packet, the total number of packets seen before it in the sequence [7, 27, 39]. The standard deviation of the outgoing packet ordering list has rank 4, the average of the outgoing packet ordering list has rank 7. The standard deviation of the incoming packet ordering list has rank 12 and the average of the

¹⁴The total feature importance table is shown in Appendix A.

Nº	Feature Description
1.	Number of incoming packets.
2.	Number of outgoing packets as a fraction of the total number of packets.
3.	Number of incoming packets as a fraction of the total number of packets.
4.	Standard deviation of the outgoing packet ordering list.
5.	Number of outgoing packets.
6.	Sum of all items in the alternative concentration feature list.
7.	Average of the outgoing packet ordering list.
8.	Sum of incoming, outgoing and total number of packets.
9.	Sum of alternative number packets per second.
10.	Total number of packets.
11-18.	Packet concentration and ordering features list.
19.	The total number of incoming packets stats in first 30 packets.
20.	The total number of outgoing packets stats in first 30 packets.

Figure 2: The 20 most important features.

incoming packet ordering list has rank 13.

- **Concentration of outgoing packets.** The packet sequence split into non-overlapping chunks of 20 packets. Count the number of outgoing packets in each of the chunks. Along with the entire chunk sequence, we extract the standard deviation (rank 16), mean (rank 11), median (rank 64) and max (rank 65) of the sequence of chunks. This provides a snapshot of where outgoing packets are concentrated [39]. The features that make up the concentration list are between the 15th and 30th most important features, but also make up the bulk of the 75 least important features.
- **Concentration of incoming & outgoing packets in first & last 30 packets.** The number of incoming and outgoing packets in the first and last 30 packets [39]. The number of incoming and outgoing packets in the first thirty packets has rank 19 and 20, respectively. The number of incoming and outgoing packets in the last thirty packets has rank 50 and 55, respectively.
- **Number of packets per second.** The number of packets per second, along with the mean (rank 44), standard deviation (rank 38), min (rank 117), max (42), median (rank 50).
- **Alternative concentration features.** This subset of features is based on the concentration of outgoing

packets feature list. The outgoing packets feature list split into 20 evenly sized subsets and sum each subset. This creates a new list of features. Similarly to the concentration feature list, the alternative concentration feature list are regularly in the top 20 most important features and bottom 50 features. Note though concentration features are never seen in the top 15 most important features whereas alternative concentration features are, – at rank 14 and 15, – so information is gained by summing the concentration subsets.

- **Packet inter-arrival time statistics.** For the total, incoming and outgoing packet streams extract the lists of inter-arrival times between packets. For each list extract the max, mean, standard deviation, and third quartile [5]. These features have rank between 40 and 70.

- **Transmission time statistics.** For the total, incoming and outgoing packet sequences we extract the first, second, third quartile and total transmission time [39]. These features have rank between 30 and 50. The total transmission time for incoming and outgoing packet streams are the most important out of this subset of features.

- **Alternative number of packets per second features.** For the number of packets per second feature list we create 20 even sized subsets and sum each subset. The sum of all subsets is the 9th most important feature. The features produced by each subset are in the bottom 50 features - with rank 101 and below. The important features in this subset are the first few features with rank between 66 and 78, that are calculated from the first few seconds of a packet sequence.

We conclude that the total number of incoming packets is the most informative feature. This is expected as different web pages have different resource sizes, that are poorly hidden by encryption or anonymization. The number of incoming and outgoing packets as a fraction of the total number of packets are also informative for the same reason.

The least important features are from the padded concentration of outgoing packets list, since the original concentration of outgoing packets lists were of non-uniform size and so have been padded with zeros to give uniform length. Clearly, if most packet sequences have been padded with the same value this will provide a poor criterion for splitting, hence being a feature of low importance. Packet concentration statistics, while making up the bulk of “useless features” also regularly make up a few of the top 30 most important features, they are the first few items that are unlikely to be zero. In other words, the first few values in the packet concentration list do split the data well.

Packet ordering features have rank 4, 7, 12 and 13, indicating these features are a good criterion for classifi-

cation. Packet ordering features exploit the information leaked via the way in which browsers request resources and the end server orders the resources to be sent. This supports conclusions in [7, 39] about the importance of packet ordering features.

We also found that the number of incoming and outgoing packets in the first thirty packets, with rank 19 and 20, were more important than the number of incoming and outgoing packets in the last thirty packets, with rank 50 and 55. In the alternative number packets per second feature list the earlier features were a better criterion for splitting than the later features in the list. This supports claims by Wang et al. [39] that the beginning of a packet sequence leaks more information than the end of a packet sequence. In contrast to Bissias et al. [5] we found packet inter-arrival time statistics, with rank between 40 and 70, only slightly increase the attack accuracy, despite being a key feature in their work.

6 Attack on hardened defenses

For direct comparison we tested our random forest classifier in a closed-world setting on various defenses against the k -NN attack and the more recent CUMUL [28] attack using the Wang et al. data set [39]. Note that most of these defenses require large bandwidth overheads that may render them unusable for the average client. We test against the following defenses:

- **BuFLO [12].** This defense sends packets at a constant size during fixed time intervals. This potentially extends the length of transmission and requires dummy packets to fill in gaps.
- **Decoy pages [27].** This defense loads a decoy page whenever another page is loaded. This provides background noise that degrades the accuracy of an attack. This is essentially a defense that employs multi-tab browsing.
- **Traffic morphing [40].** Traffic morphing shapes a client’s traffic to look like another set of web pages. A client chooses the source web pages that they would like to defend, as well as a set of target web pages that they would like to make the source processes look like.
- **Tamaraw [35].** Tamaraw operates similarly to BuFLO but fixes packet sizes depending on their direction. Outgoing traffic is fixed at a higher packet interval, this reduces overhead as outgoing traffic is less frequent.
- **Adaptive Padding (AP) [18, 31].** AP protects anonymity by introducing traffic in to statistically unlikely delays between packets in a flow. This limits the amount of extra bandwidth required and does not incur any latency costs. AP uses previously computed histograms of inter-arrival packet times from website loads to determine when a dummy packet should be in-

Table 1: Attack comparison under various website fingerprinting defenses.

Defenses	This work	k -NN [39]	CUMUL [28]	Bandwidth overhead (%)
No defense	0.91 ± 0.01	0.91 ± 0.03	0.91 ± 0.04	0
Morphing [40]	0.90 ± 0.03	0.82 ± 0.06	0.75 ± 0.07	50 ± 10
Decoy pages [27]	0.37 ± 0.01	0.30 ± 0.06	0.21 ± 0.02	130 ± 20
Adaptive Padding [31]	0.30 ± 0.04	0.19 ± 0.03	0.16 ± 0.03	54
BuFLO [12]	0.21 ± 0.02	0.10 ± 0.03	0.08 ± 0.03	190 ± 20
Tamaraw [35]	0.10 ± 0.01	0.09 ± 0.02	0.08 ± 0.03	96 ± 9

jected¹⁵. This is currently the favored option if padding were to be implemented in Tor [4].

Table 1 shows the performance of k -fingerprinting against k -NN and CUMUL under various website fingerprinting defenses in a closed-world setting. Under every defense k -fingerprinting is comparable or achieves better results than the k -NN attack and performs significantly better than CUMUL. Note that k -fingerprinting does equally well when traffic morphing is applied compared to no defense. As Lu et al. [23] note, traffic morphing is only effective when the attacker restricts attention to the same features targeted by the morphing process. Our results confirm that attacks can succeed even when traffic morphing is employed. k -fingerprinting also performs nearly 10% better than k -NN when decoy pages are used, which is in effect a marker for how well the attack performs on multi-tab browsing. Due to the dependency of packet length and sequence length features, CUMUL performs substantially worse than the other two attacks under website fingerprinting defenses. Though CUMUL uses a similar number of features and is of similar computational efficiency to k -fingerprinting, simple defenses remove the feature vector patterns between similar web pages used in CUMUL, rendering the attack ineffectual. More generally, any attack that uses a restricted set of features will suffer greatly from a defense that targets those features. k -fingerprinting performs well under defenses due to its feature set that captures traffic information not used in CUMUL such as packet timings and burst patterns. The k -NN attack performs slightly better than CUMUL but requires an order of magnitude more features than both CUMUL and k -fingerprinting. Our attack is both more efficient and more accurate than CUMUL and k -NN under defenses.

7 k -fingerprinting the Wang et al. data set

We first evaluate k -fingerprinting on the Wang et al. data set [39]. This data set was collected over Tor, and thus implements padding of packets to fixed-size cells (512-bytes) and randomization of request orders [30]. Thus

¹⁵As Juarez et al. [18] note, the distribution of histogram bins is dependent on the individual client bandwidth capacity. Optimizing histograms for a large number of clients is an open problem. Here we implement a naive version of AP with one master histogram for all clients.

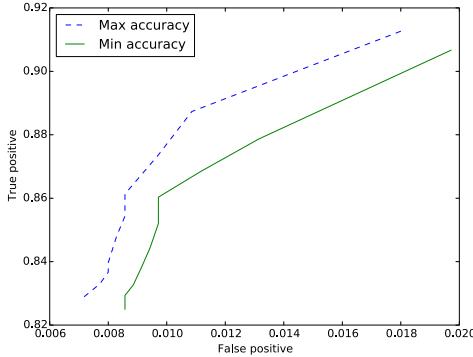

Figure 3: Attack results for 1500 unmonitored training pages while varying the number of fingerprints used for comparison, k , over 10 experiments.

Table 2: k -fingerprinting results for $k=3$ while varying the number of unmonitored training pages.

Training pages	TPR	FPR	BDR
0	0.90 ± 0.02	0.750 ± 0.010	0.419
1500	0.88 ± 0.02	0.013 ± 0.007	0.983
2500	0.88 ± 0.01	0.007 ± 0.001	0.993
3500	0.88 ± 0.01	0.005 ± 0.001	0.997
4500	0.87 ± 0.02	0.009 ± 0.001	0.998

the only available information to k -fingerprinting are timing and volume features. We train on 60 out of the 90 instances for each of the 100 monitored web pages; we vary the number of pages on which we train from the 5000 unmonitored web pages. For the attack evaluation we use fingerprints of length 200 and 150 features. Final classification is as described in Section 3.2, if all k fingerprints agree on classification a test instance is classified as a monitored web page, otherwise it is classified as an unmonitored web page.

The scenario for the attack is as follows: an attacker monitors 100 web pages; they wish to know whether a client is visiting one of those pages, and establish which one. The client can browse to any of these web pages or to 5000 unmonitored web pages, which the attacker classifies in bulk as an unmonitored page.

Using the k -fingerprinting method for classifying a web page we measure a TPR of 0.88 ± 0.01 and a FPR of 0.005 ± 0.001 when training on 3500 unmonitored web pages and k , the number of training instances used for classification, set at $k=3$. k -fingerprinting achieves better accuracy than the state-of-the-art k -NN attack that has a TPR of 0.85 ± 0.04 and a FPR of 0.006 ± 0.004 . Given a monitored web page k -fingerprinting will misclassify this page 12% of the time, while k -NN will misclassify with 15% probability.

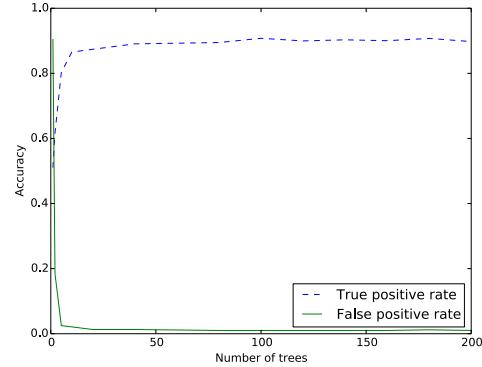

Figure 4: Accuracy of k -fingerprinting as we vary the number of trees in the forest.

Best results are achieved when training on 3500 unmonitored web pages. Table 2 reports TPR and FPR when using different numbers of unmonitored web pages for training with $k=3$. As we train more unmonitored web pages we decrease our FPR with almost no reduction in TPR. After training 3500 unmonitored pages there is no decrease in FPR and so no benefit in training more unmonitored web pages. This is confirmed by the marginal increase in BDR after training on at least some of the unmonitored set. Furthermore without training on any of the unmonitored web pages, despite the high FPR the classifier has more than 40% probability of being correct when classifying a web page as monitored.

Figure 3 illustrates how classification accuracy changes as, k , the number of fingerprints used for classification changes. For a low k the attack achieves a FPR of around 1%, as we increase the value of k we reduce the number of misclassifications since it is less likely that all k fingerprints will belong to the same label, but we also reduce the TPR. Altering the number of fingerprints used for classification allows an attacker to tune the classifier to either a low FPR or high TPR depending on the desired application of the attack.

We find that altering the number of fingerprints used for classification, k , affects the TPR and FPR more than the number of unmonitored training pages. This suggests that while it is advantageous to have a large world size of unmonitored pages, increasing the number of unmonitored training pages does not increase accuracy of the classifier dramatically. This supports Wang et al.’s [39] claims to the same effect. In practice an attacker will need to train on at least some unmonitored pages to increase the BDR, though this does not need to be a substantial amount; training 1500 unmonitored web pages leads to a 98.3% chance the classifier is correct when claiming to have recognized a monitored web page.

Fingerprint length. Changing the length of the fingerprint vector will affect k -fingerprinting accuracy. For a

Table 3: Attack results on top Alexa sites for $k=2$ while varying the number of unmonitored training pages.

Training pages	TPR	FPR	BDR
2000	0.93 ± 0.03	0.032 ± 0.010	0.33
4000	0.93 ± 0.01	0.018 ± 0.007	0.47
8000	0.92 ± 0.01	0.008 ± 0.002	0.67
16000	0.91 ± 0.02	0.003 ± 0.001	0.86

small fingerprint length there may not be enough diversity to provide an accurate measure of distance over all packet sequences. Figure 4 shows the resulting TPR and FPR as we change the length of fingerprints in the Wang et al. [39] data set. We set $k=1$ and train on 4000 unmonitored web pages. Using only a fingerprint of length one results in a TPR of 0.51 and FPR of 0.904. Clearly using a fingerprint of length one results in a high FPR since there is a small universe of leaf symbols from which to create the fingerprint. A fingerprint of length 20 results in a TPR of 0.87 and FPR of 0.013. After this there are diminishing returns for increasing the length of the fingerprint vector.

8 Attack evaluation on DS_{Tor}

We now evaluate k -fingerprinting on DS_{Tor} . First we evaluate the attack given a monitored set of the top 55 Alexa web pages, with 100 instances for each web page. Then we evaluate the attack given a monitored set of 30 Tor hidden services, with 80 instances for each hidden service. The unmonitored set remains the same for both evaluations, the top 100,000 Alexa web pages with one instance for each web page.

8.1 Alexa web pages monitored set

Table 3 shows the accuracy of k -fingerprinting as the number of unmonitored training pages is varied. For the monitored web pages, 70 instances per web page were trained upon and testing was done on the remaining 30 instances of each web page. As expected, the FPR decreases as the number of unmonitored training samples grows. Similar to Section 7 there is only a marginal decrease in TPR while we see a large reduction in the FPR as the number of training samples grows. Meaning an attacker will not have to compromise on TPR to decrease the FPR; when scaling the number of unmonitored training samples from 2% to 16% of the entire set the TPR decreases from 93% to 91% while the FPR decreases from 3.2% to 0.3%. There is a more pronounced shift in BDR with the increase of unmonitored training pages, however an attacker needs to train on less than 10% of the entire dataset to have nearly 70% confidence that classifier was correct when it claims to have detected a monitored page.

Clearly the attack will improve as the number of train-

Table 4: Attack results on Tor hidden services for $k=2$ while varying the number of unmonitored training pages.

Training pages	TPR	FPR	BDR
2000	0.82 ± 0.03	0.0020 ± 0.0015	0.72
4000	0.82 ± 0.04	0.0007 ± 0.0006	0.88
8000	0.82 ± 0.02	0.0002 ± 0.0001	0.96
16000	0.81 ± 0.02	0.0002 ± 0.0002	0.97

ing samples grows, but in reality an attacker may have limited resources and training on a significant fraction of 100,000 web pages may be unfeasible. Figure 5 shows the TPR and FPR of k -fingerprinting as the number of unmonitored web pages used for testing grows while the number of unmonitored web pages used for training is kept at 2000, for different values of k . We may think of this as the evaluation of success of k -fingerprinting as a client browses to more and more web pages over multiple browsing sessions. Clearly for a small k , both TPR and FPR will be comparatively high. Given that, with $k=5$ only 2.5% of unmonitored web pages are falsely identified as monitored web pages, out of 98,000 unmonitored web pages.

8.2 Hidden services monitored set

Table 4 shows the accuracy of k -fingerprinting as the number of unmonitored training pages is varied. For the monitored set, 60 instances per hidden service were trained upon and testing was done on the remaining 20 instances of each hidden service. Again we observe a marginal loss of TPR and a large reduction in FPR as the number of training samples grows. When scaling the number of unmonitored training samples from 2% to 16% of the entire set the TPR decreases from 82% to 81% while the FPR decreases by an order of magnitude from 0.2% to 0.02%. As a result, when training on 16% of the unmonitored set only 16 unmonitored web pages out of 84,000 were misclassified as a Tor hidden service. In comparison to the Alexa web pages monitored set the TPR is around 10% lower, while the FPR is also greatly reduced. This is evidence that Tor hidden services are easy to distinguish from standard web pages loaded over Tor. There is also a higher but more gradual increase in BDR compared to standard web pages. An attacker need only train on as little as 2% of unmonitored pages to have over 70% confidence that classification of a monitored page was correct, with this rising to 97% when training on 16% of the unmonitored dataset.

Similarly to Figure 5, Figure 6 shows the TPR and FPR of k -fingerprinting as the number of unmonitored web pages used for testing grows while the number of unmonitored web pages used for training is kept at 2000, for different values of k . Both the TPR and FPR is lower

than in Figure 5. For example using $k=5$, the FPR is 0.2% which equates to only 196 out of 98,000 unmonitored pages being falsely classified as monitored pages.

From Figure 7 we observe that the BDR of both standard web pages and hidden services monitored sets depends heavily on not only the world size but the number of fingerprints used for classification. With $k=10$, when a web page is classified as a monitored hidden service page, there is over an 80% chance that the classifier was correct, despite the unmonitored world size (98,000) being over 160 times larger than the monitored world size (600). The high BDR regardless of the disparity in world sizes makes it clear that our attack is highly effective under realistic large world size conditions.

It is clear that an attacker need only train on a small fraction of data to launch a powerful fingerprinting attack. It is also clear that Tor hidden services are easily distinguished from standard web pages, rendering them vulnerable to website fingerprinting attacks. We attribute the lower FPR of Tor hidden services when compared to a monitored training set of standard web page traffic to this distinguishability. A standard web page over Tor is more likely to be confused with another standard web page than a Tor hidden service.

Comparison with Kwon et al. [19] hidden services results. For comparison we ran k -fingerprinting on the data set used in the Kwon et al. study on fingerprinting hidden services. This data set simulated a client connecting to a hidden service. The data set consists of 50 instances for each of 50 monitored hidden services and an unmonitored set of 950 hidden services. When training on 100 of the unmonitored pages they report attack accuracy of 0.9 TPR and 0.4 FPR. k -fingerprinting achieved a similar true positive rate but the FPR is reduced to 0.22. This FPR reduction in comparison with Kwon et al. continued regardless of the amount of data used for training.

9 Attack evaluation on DS_{Norm}

Besides testing on DS_{Tor} , Wang et al. [39] data set and the Kwon et al. [19] data set we tested the efficacy of k -fingerprinting on DS_{Norm} . This allows us to establish how accurate k -fingerprinting is over a standard encrypted web browsing session or through a VPN.

9.1 Attack on encrypted browsing sessions

An encrypted browsing session does not pad packets to a fixed size so the attacker may extract the following features in addition to time features:

- **Size transmitted.** For each packet sequence we extract the total size of packets transmitted, in addition, we extract the total size of incoming packets and the total size of outgoing packets.
- **Size transmitted statistics.** For each packet sequence we extract the average, variance, standard deviation

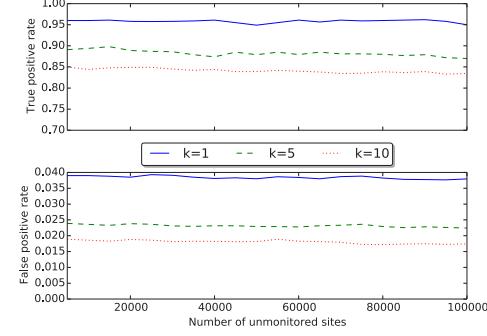

Figure 5: Attack accuracy on DS_{Tor} with Alexa monitored set.

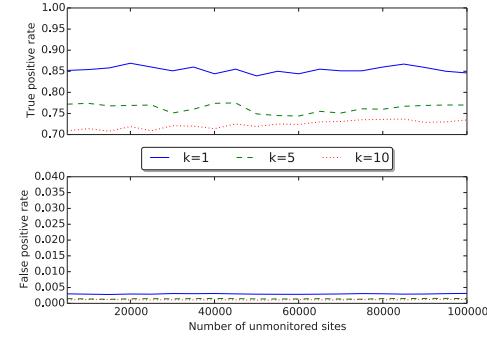

Figure 6: Attack accuracy on DS_{Tor} with Tor hidden services monitored set.

and maximum packet size of the total sequence, the incoming sequence and the outgoing sequence.

Apart from this modification in available features, the attack setting is similar: An attacker monitors a client browsing online and attempts to infer which web pages they are visiting. The only difference is that browsing with the Transport Layer Security (TLS) protocol, or Secure Sockets Layer (SSL) protocol, versions 2.0 and 3.0, exposes the destination IP address and port. The attack is now trying to infer which web page the client is visiting from the known website¹⁶.

The attacker monitors 55 web pages; they wish to know if the client has visited one of these pages. The client can browse to any of these web pages or to 7000 other web pages, which the attacker does not care to classify other than as unmonitored. We train on 20 out of the 30 instances for each monitored page and vary the number of unmonitored pages on which we train.

Despite more packet sequence information to exploit, the larger cardinality of world size gives rise to more

¹⁶Note that the data sets are composed of traffic instances from some websites without SSL and TLS, as well as websites using the protocols. We expect our experiment conditions are much larger than the number possible web pages an attacker may wish to fingerprinting from a standard website.

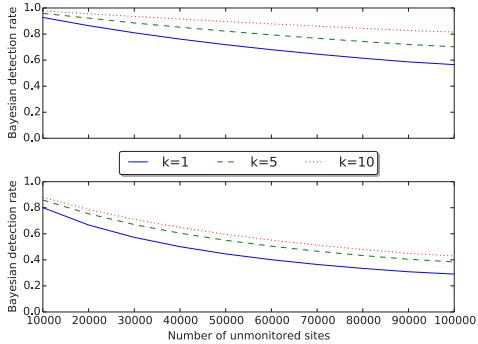

Figure 7: BDR for hidden services monitored set (above) and Alexa monitored set (below).

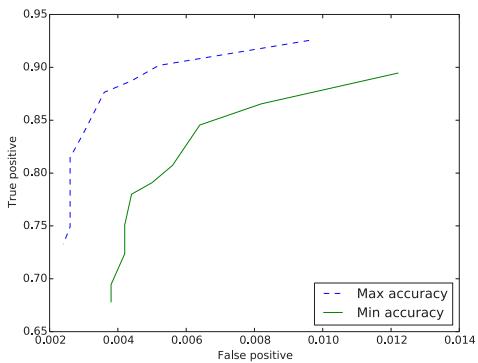

Figure 8: Attack results for 2000 unmonitored training pages while varying the number of fingerprints used for comparison, k , over 10 experiments.

opportunities for incorrect classifications. The attack achieves a TPR of 0.87 and a FPR of 0.004. We achieved best results when training on 4000 unmonitored web pages. Table 5 reports results for training on different numbers of unmonitored web pages, with $k = 2$. Figure 8 shows our results when modifying the number of fingerprints used (k) and training on 2000 unmonitored pages. We find that altering the number of unmonitored training pages decreases the FPR while only slightly decreasing the TPR. This mirrors our experimental findings from DS_{Tor} and the Wang et al. data set.

9.2 Attack without packet size features

DS_{Norm} was not collected via Tor and so also contains packet size information. We remove this to allow for comparison with DS_{Tor} and the Wang et al. data set which was collected over Tor. This also gives us a baseline for how much more powerful k -fingerprinting is when we have additional packet size features available. We achieved a TPR of 0.81 and FPR of 0.005 when training on 5000 unmonitored web pages. Table 6 shows our results at other sizes of training samples, with $k=2$.

Table 5: Attack results with packet size features for a varying number of unmonitored training pages.

Training pages	TPR	FPR	BDR
0	0.95 ± 0.01	0.850 ± 0.010	0.081
2000	0.90 ± 0.01	0.010 ± 0.004	0.908
4000	0.87 ± 0.02	0.004 ± 0.001	0.976
6000	0.86 ± 0.01	0.005 ± 0.002	0.990

Table 6: Attack results without packet size features for a varying number of unmonitored training pages.

Training pages	TPR	FPR	BDR
0	0.90 ± 0.01	0.790 ± 0.020	0.082
2000	0.83 ± 0.01	0.009 ± 0.001	0.910
4000	0.81 ± 0.02	0.006 ± 0.001	0.961
6000	0.80 ± 0.02	0.005 ± 0.001	0.989

Removing packet size features reduces the TPR by over 0.05 and increases the FPR by 0.001. Clearly packet size features improve our classifier in terms of correct identifications but do not decrease the number of unmonitored test instances that were incorrectly classified as a monitored page. Despite the difference in FPR when including packet size information, the BDR is similar, suggesting that BDR is dominated by the amount of information that can be trained upon.

Closed-World. In the closed-world setting in which the client can only browse within the 55 monitored web pages k -fingerprinting is 0.91, compared to 0.96 when packet size features are available. In the closed-world setting attack accuracy improves by 5% when we include packet size features.

10 Fine grained open-world false positives on Alexa monitored set of DS_{Tor}

We observe that the classification error is not uniform across all web pages¹⁷. Some pages are misclassified many times, and confused with many others, while others are never misclassified. An attacker can leverage this information to estimate the misclassification rate of each of the web page classes instead of using the global average misclassification rate. A naive approach to this problem would be to first find which fingerprints contribute to the many misclassifications and remove them. Our analysis shows that the naive approach of removing “bad” fingerprints that contribute to many misclassifications will ultimately lead to a higher misclassification rate. Figure 9 shows the 50 fingerprints that cause the most misclassifications, and also shows for those same fingerprints the number of correct classifications they contribute towards.

¹⁷See additional evidence in Appendix B.

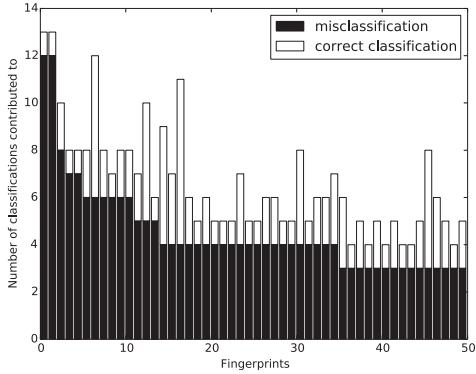

Figure 9: The fingerprints that lead to the most misclassifications and the correct classifications they contribute towards. Training on 2% of unmonitored pages with $k=3$.

As we can see nearly all “bad” fingerprints actually contribute to many correct classifications. One may think it may still be beneficial to remove these fingerprints as the cumulative sum of misclassifications outweigh the number of correct classifications. This removal will then promote fingerprints that are further away in terms of Hamming distance from the fingerprinting that is being tested, which will lead to a greater number of misclassifications.

Instead an attacker can use their training set of web pages to estimate the TPR and FPR of each web page class, by splitting the training set in to a smaller training set and validation set. Since both sets are from the original training set the attacker has access to the true labels. The attacker then computes the TPR and FPR rates of each monitored class, this is used as an estimation for TPR and FPR when training on the entire training set and testing on new traffic instances. More specifically we split, for the monitored training set of 70 instance for each of the Alexa top 55 web pages, into smaller training sets of 40 instances and validation sets of 30 instances. This is used as a misclassification estimator for the full monitored training set against the monitored test set of 30 instances per class. Similarly we split the unmonitored training in half, one set as a smaller training set and the other as a validation set.

Figure 10 shows the TPR and FPR estimation accuracy for 2000 unmonitored training pages. Monitored classes are first ordered from best to worst in terms of their classification accuracy. Even with a small unmonitored training set of 2000 web pages, which is then split in to a training set of 1000 web pages and a validation set of 1000 web pages, an attacker can accurately estimate the FPR of the attack if some of the monitored classes were removed. For example, using only the best 20 monitored classes (in terms of TPR), an attacker would estimate that using those 20 classes as a monitored set, the

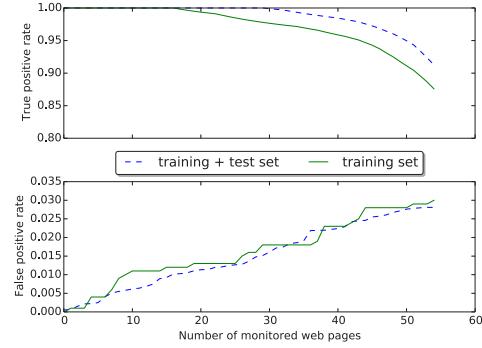

Figure 10: Rates for training on 1000 unmonitored pages, testing on 1000, and comparison when training on the full 2000 unmonitored pages and testing on the remaining 98000 unmonitored pages in DS_{Tor} , $k=3$.

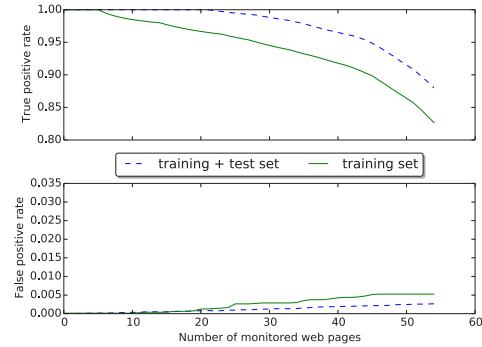

Figure 11: Rates for training on 8000 unmonitored pages, testing on 8000, and comparison when training on the full 16000 unmonitored pages and testing on the remaining 84000 unmonitored pages in DS_{Tor} , $k=3$.

FPR would be 0.012. Using the entire data set we see that the true FPR of these 20 classes is 0.010; the attacker has nearly precisely estimated the utility of removing a large fraction of the original monitored set.

There is a small difference between estimated and the actual FPR in both Figures 10 and 11. There is little benefit in training more unmonitored data if the attacker wants to accurately estimate the FPR; Figure 10 has a similar gap between the estimated FPR and true FPR when compared to Figure 11. It is evident even with a small training set, an attacker can identify web pages that are likely to be misclassified and then accurately calculate the utility of removing these web pages from their monitored set. Due to the overwhelmingly large world size of unmonitored web pages the BDR of Figure 10 does not grow dramatically with the removal of web pages that are likely to be misclassified; using the entire monitored set the BDR is 0.33, removing half of the monitored web pages the BDR is 0.35.

11 Attack Summary & Discussion

Attack Summary. Best attack results on data sets were achieved when training on approximately two thirds of the unmonitored web pages. Despite this, results from DS_{Tor} show that an attacker can achieve a very small false positive rate while only training on 2% of the unmonitored data. Training on 2% of 100,000 unmonitored web pages greatly reduces the attack set up costs while only marginally reducing the accuracy compared to training on more data, providing a realistic setting under which an attack could be launched. Results on all data sets also suggest that altering k , the number of fingerprints used for classification, has a greater influence on accuracy than the number of training samples¹⁸.

k -fingerprinting is robust; our technique achieves the same accuracy regardless of the type of monitored set or the manner in which it was collected (through Tor or standard web browsers). The monitored set in the Wang et al. [39] data set consists of real world censored websites, the Kwon et al. [19] monitored set consist of Tor hidden services and the $DS_{Tor/Norm}$ monitored sets were taken from Tor hidden services and top Alexa websites. We do see a reduction in FPR when the target monitored set are Tor hidden services due to the distinguishability between the hidden services and unmonitored standard web pages.

We also highlight the non-uniformity of classification performance: when a monitored web page is misclassified, it is usually misclassified on multiple tests. We show that an attacker can use their training set to estimate the error rate of k -fingerprinting per web page, and select targets with low misclassification rates.

Computational Efficiency. k -fingerprinting is more accurate and uses fewer features than state-of-the-art attacks. Furthermore k -fingerprinting is faster than current state-of-the-art website fingerprinting attacks. On the Wang et al. data set training time for 6,000 monitored and 2,500 unmonitored training pages is 30.738 CPU seconds on an 1.4 GHz Intel Core i5z. The k -NN attack [39] has training time per round of 0.064 CPU seconds for 2500 unmonitored training pages. For 6,000 rounds training time is 384.0 CPU seconds on an AMD Opteron 2.2 GHz cores. This can be compared to around 500 CPU hours using the attack described by Cai et al. [7]. Testing time per instance for k -fingerprinting is around 0.1 CPU seconds, compared to 0.1 CPU seconds to classify one instance for k -NN and 450 CPU seconds for the attack described by Cai et al. [7].

Discussion. Website fingerprinting research has been criticized for not being applicable to real-world scenarios

[17, 29]. We have shown that a website fingerprinting attack can scale to the number of traffic instance an attacker may sample over long period of time with a high BDR and low FPR. However, we did not consider the cases where background traffic may be present, for example from multitab browsing, or the effect that short-lived websites will have on our attack. Gu et al. [15] show in their work that a simple Naive-Bayes attack achieves highly accurate results even when a client browses in multiple tabs. Wang and Goldberg [36] also show that website fingerprinting is effective in practical scenarios. With no prior attack set-up to tailor to a multi-tab browsing session our attack was able to classify nearly 40% of monitored pages correctly when the decoy defense was employed.

Website content rapidly changes which will negatively affect the accuracy of a website fingerprinting attack [17]. As the content of a website changes so will the generated packet sequences, if an attacker cannot train on this new data then an attack will suffer. However we note that an attack will suffer from the ephemeral nature of websites at different rates depending on the type of website being monitored. For example, an attack monitoring a news or social media site can expect a faster degradation in performance compared to an attack monitoring a landing page of a top 10 Alexa site [1]. Also note Tor does not cache by default, so if in the realistic scenario where an attacker wanted to monitor www.socialmediawebsite.com a client would be forced to navigate to the social media website landing page, which is likely to host content that is long lived and not subject to change. The problem of content change is weakened when fingerprinting Tor hidden services. As show by Kwon et al. [19] hidden pages show minimal changes in comparison to non-hidden pages, resulting in devastatingly accurate attacks on hidden services that can persist.

12 Conclusion

We establish that website fingerprinting attacks are a serious threat to online privacy. Clients of both Tor and standard web browsers are at risk from website fingerprinting attacks regardless of whether they browse to hidden services or standard websites. k -fingerprinting improves on state-of-the-art attacks in terms of both speed and accuracy: current website fingerprinting defenses either do not defend against k -fingerprinting or incur very high bandwidth overheads. Our world size is an order of magnitude larger than previous website fingerprinting studies, and twice as large in terms of unique website than Panchenko et al.’s recent work [28]. We have validated our attack on four separate datasets showing that it is robust and not prone to overfit one dataset, and so is applicable to real world browsing environments at scale. k -fingerprinting is highly accurate even when an attacker

¹⁸Figure 17 illustrates that compared to training on a small number of monitored instances increasing the size of the monitored training set only incrementally increases accuracy.

trains on a small fraction of the total data. Untrustworthy data within that small fraction can then be filtered and removed before the attack is launched to later yield better results, showing that long term website fingerprinting attacks on a targeted client is a realistic threat.

A Total feature importance.

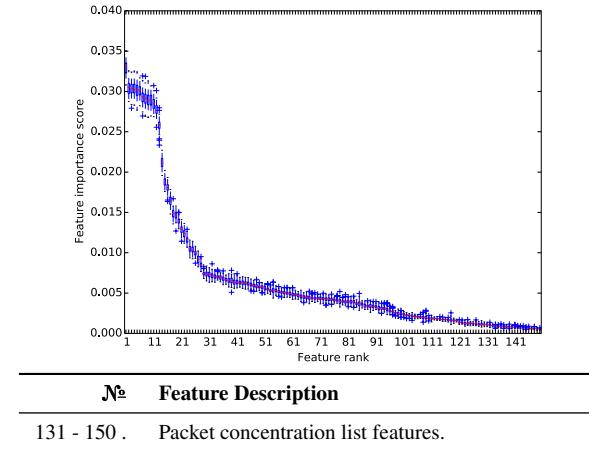

Figure 12: Feature importance score for all 150 features in order. The table gives the description for the 20 least important features.

B Closed World Error Rates

Figure 13 shows the confusion matrix in our closed-world setting, that is, it shows the 49 misclassifications (out of 550). We see that some persistent misclassification patterns of web pages appear, for example web page 54 is classified correctly four times but is misclassified as web page 0 six times. The misclassification rate in Figure 13 is 0.09 but this is the average error rate across all web pages.

Figure 13 shows that the classification error is not uniform across all web pages. Some pages are misclassified many times, and confused with many others, while others are never misclassified. An attacker can leverage this information to estimate the misclassification rate of each web page instead of using the global average misclassification rate.

As in Section 10, an attacker can use their training set of web pages to estimate the misclassification rate of each web page, by splitting the training set in to a smaller training set and validation set. Since both sets are from the original training set the attacker has access to the true labels. The attacker then computes the misclassification rate of each web page, which they can use as an estimation for the misclassification rate when training on the entire training set and testing on new traffic instances.

Figures 14 and 15 show the global misclassification rate for a varying number of monitored pages. Monitored pages are first ordered in terms of the misclassification rate they have, ordered from smallest to largest. From Figure 14, using the Wang et al. data set, we see that if the attacker considers only the top 50% on web pages in terms of per page misclassification rate, the true

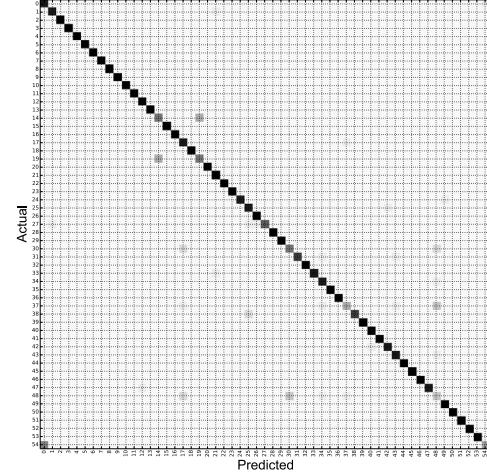

Figure 13: Confusion matrix for closed-world attack on Tor using DS_{Norm} . F1 score = 0.913, Accuracy: 0.915, 550 items.

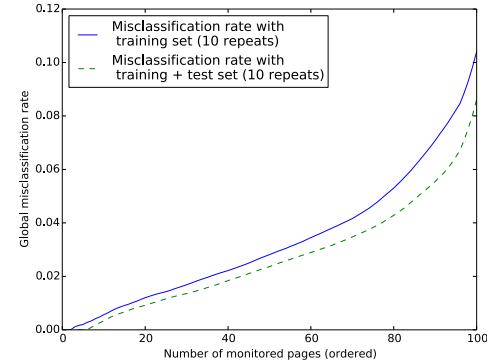

Figure 14: The global misclassification rate when considering different numbers of monitored pages from the Wang et al. data set. The monitored pages are ordered in terms of smallest misclassification rate to largest.

global misclassification rate and global misclassification rate estimated by the attacker drop by over 70%. Similarly from Figure 15, using DS_{Norm} , if the attacker considers only the top 50% on web pages in terms of per page misclassification rate, the true global misclassification rate and global misclassification rate estimated by the attacker drop by over 80%. This allows an attacker to train on monitored pages and then cull the pages that have too high an error rate, allowing for more confidence in the classification of the rest of the monitored pages.

The gap between the attacker's estimate and the misclassification rate of the test set is largely due to the size of the data set. Figure 14 has a smaller error of estimate than Figure 15 because the Wang et al. data set has 60 instances per monitored page, in comparison DS_{Norm} has 20 instances per monitored page. In practice, an attacker

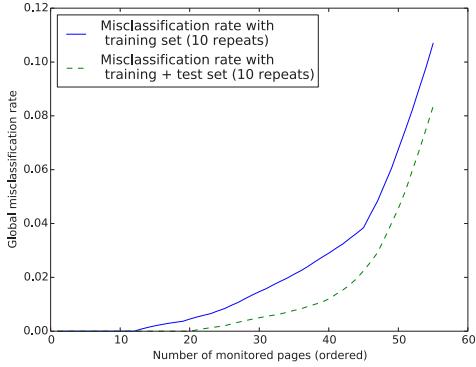

Figure 15: The global misclassification rate when considering different numbers of monitored pages from DS_{Norm} . The monitored pages are ordered in terms of smallest misclassification rate to largest.

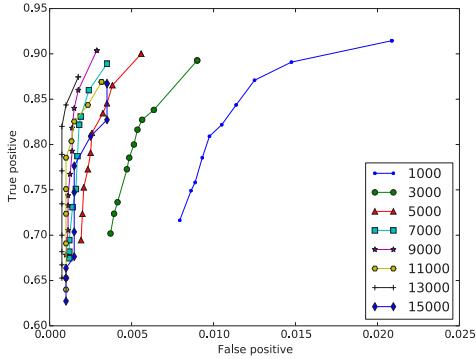

Figure 16: Attack accuracy for 17,000 unmonitored web pages. Each line represents a different number of unmonitored web pages that were trained, while varying k , the number of fingerprints used for classification.

cannot expect perfect alignment; they are generated from two different sets of data, the training and training + test set. Nevertheless the attacker can expect this difference to decrease with the collection of more training instances.

C Attack on larger world size of DS_{Norm}

We run k -fingerprinting on DS_{Norm} with the same number of monitored sites but increase the number of unmonitored sites to 17,000. We evaluate when we have both time and size features available.

Figure 16 shows the results of k -fingerprinting while varying the number of fingerprints (k) used for classification, from between 1 and 10, for various experiments trained with different numbers of unmonitored pages. We see that the attack results are comparable to the attack on 7000 unmonitored pages, meaning there is no degradation in attack accuracy when we increase the world

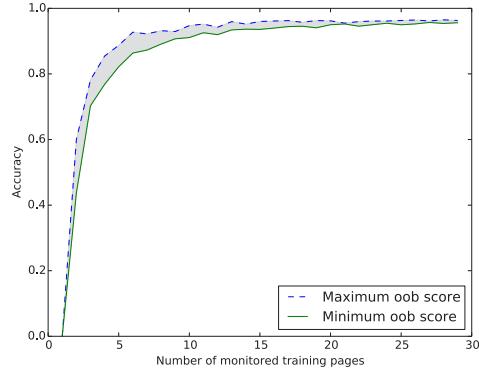

Figure 17: Attack out-of-bag score while varying the number of monitored training pages.

size by 10,000 web pages. Training on approximately 30% of the 7000 unmonitored web pages k -fingerprinting gives a TPR of over 0.90 and a FPR of 0.01 for $k=1$. Training on approximately 30% of the 17,000 unmonitored web pages k -fingerprinting gives a TPR of 0.90 and a FPR of 0.006 for $k=1$.

The fraction of unmonitored pages that were incorrectly classified as a monitored page decreased as we increased our world size. In other words, out of 12,000 unmonitored pages only 72 were classified as a monitored page, with this Figure dropping to 24 if we use $k=10$ for classification. This provides a strong indication that k -fingerprinting can scale to a real-world attack in which a client is free to browse the entire internet, with no decrease in attack accuracy.

Number of monitored training pages in closed-world. Figure 17 shows the *out-of-bag* score as we change the number of *monitored* pages we train. We found that training on any more than a third of the data gives roughly the same accuracy.

Protecting Privacy of BLE Device Users

Kassem Fawaz* Kyu-Han Kim† Kang G. Shin*

Abstract

Bluetooth Low Energy (BLE) has emerged as an attractive technology to enable Internet of Things (IoTs) to interact with others in their vicinity. Our study of the behavior of more than 200 types of BLE-equipped devices has led to a surprising discovery: the BLE protocol, despite its privacy provisions, fails to address the most basic threat of all—hiding the device’s presence from curious adversaries. Revealing the device’s existence is the stepping stone toward more serious threats that include user profiling/fingerprinting, behavior tracking, inference of sensitive information, and exploitation of known vulnerabilities on the device. With thousands of manufacturers and developers around the world, it is very challenging, if not impossible, to envision the viability of any privacy or security solution that requires changes to the devices or the BLE protocol.

In this paper, we propose a new device-agnostic system, called BLE-Guardian, that protects the privacy of the users/environments equipped with BLE devices/IoTs. It enables the users and administrators to control those who discover, scan and connect to their devices. We have implemented BLE-Guardian using Ubertooth One, an off-the-shelf open Bluetooth development platform, facilitating its broad deployment. Our evaluation with real devices shows that BLE-Guardian effectively protects the users’ privacy while incurring little overhead on the communicating BLE-devices.

1 Introduction

Bluetooth Low Energy (BLE) [4] has emerged as the *de facto* communication protocol in the new computing paradigm of the Internet of Things (IoTs) [8, 9, 15, 23, 24, 39]. In 2013, over 1.2 billion BLE products were shipped [9], with this number expected to hit 2.7 billion in 2020 [3]. BLE-equipped products are embedded and used in every aspect of our lives; they sense nearby

objects, track our fitness, control smart appliances and toys provide physical security, etc. The BLE protocol owes this proliferation to its low energy and small processing footprint as well as its support by most end-user devices [20], such as PCs, gateways, smartphones, and tablets.

A BLE-equipped device advertises its presence to let interested nearby devices initiate connections and glean relevant information. These advertisements, however, are a double-edged sword. An unauthorized, potentially malicious, party can use these advertisements to learn more about the BLE-equipped devices of a certain user or in a specific environment [22], generally referred to in literature as the *inventory attack* [42]. Revealing the device’s presence is the stepping stone toward more serious privacy and security attacks with grave consequences in the case of medical devices for example, especially for high-value targets [31].

The BLE specification contains some privacy provisions to minimize the effects of inventory attacks and ensuing threats, namely *address randomization* and *whitelisting*. A BLE device is supposed to randomize its address to prevent others from tracking it over time. Moreover, only devices with a pre-existing trust relationship (whitelisted devices) are supposed to access the BLE-equipped device.

In this paper, we first analyze how existing BLE’s privacy measures fare in the real-world deployments through our own data-collection campaign. To the best of our knowledge, this is the first study that systematically analyzes threats to the BLE-equipped devices in the wild. We recruited participants from our institution and the PhoneLab testbed [27] to collect the BLE advertisements in their vicinity. We have collected and analyzed the advertisements from 214 different types of BLE-equipped devices. Analyzing our dataset has led to a surprising discovery: BLE advertisements, due to poor design and/or implementation, leak an alarming amount of information that allows the tracking, profiling, and

fingerprinting of the users. Furthermore, some devices allow external connections without an existing trust relationship. Unauthorized entities can access unsecured data on the BLE-equipped devices that might leak sensitive information and potentially inflict physical harm to the bearer.

Almost all of the existing approaches addressing some of the above threats rely on mechanisms that necessarily include changes to the protocol itself or to the way the BLE-equipped devices function [21, 40]. Changing the operation of such devices, post-production, requires their patching by securely pushing a firmware update. With thousands of manufacturers and developers around the world, it is very challenging, sometimes impossible, to guarantee firmware patches to the millions of already deployed devices [11]. Even a security-aware user might lack the ability to update the firmware of a BLE-equipped device. Patch management is, therefore, the leading security challenge in the emerging IoTs [10, 19] (including BLE-equipped devices) for many reasons:

- Manufacturers might lack the ability to apply OTA updates [1] for some deployed BLE-equipped devices because they (such as a BLE-equipped pregnancy test) are neither programmable nor equipped with an Internet connection.
- Customers might neither receive news about the update nor be able to apply an update even if available. For example, a month after the 2013 “Foscam” webcams hacking incident, 40,000 of 46,000 vulnerable cameras were not updated although a firmware update was available [17].
- Companies do not have enough financial incentives or resources to maintain the devices post deployment [34]. For example, Samsung discontinued two lines of smart refrigerators after 2012 so that customers can’t receive updates for their purchased refrigerators [6].

There is, therefore, a need for a new class of practical approaches to mitigate the privacy threats to BLE-equipped devices. In this paper, we seek to answer the following related question: *can we effectively fend off the threats to BLE-equipped devices: (1) in a device-agnostic manner, (2) using COTS (Commercial-Off-The-Shelf) hardware only, and (3) with as little user intervention as possible?*

We present BLE-Guardian as an answer to the above question. It is a practical system that protects the user’s BLE-equipped devices so that *only* user-authorized entities can discover, scan, or connect to them. BLE-Guardian relies on an external and off-the-shelf Bluetooth radio as well as an accompanying application. Therefore, a user can easily install (and control) BLE-Guardian to any BLE gateway, be it a smartphone,

tablet, PC, Raspberry PI, Artik-10, etc. The external radio achieves the physical protection, while the application, running on the gateway, enables the user to interact with BLE-Guardian.

BLE-Guardian provides privacy and security protection by targeting the root of the threats, namely the advertisements. In particular, BLE-Guardian opportunistically invokes reactive jamming to determine the entities that can observe the device existence through the advertisements (*device hiding module*), and those that can issue connection requests in response to advertisements (*access control module*). In a typical BLE environment, however, achieving BLE-Guardian’s objective is rather challenging. Many BLE-equipped devices, including the ones to be protected, advertise on the same channel; while at the same time other devices, in response to advertisements, issue scan and connection requests. The timing is of an essence for BLE-Guardian; it invokes jamming at the right time for the right duration. Therefore, BLE-Guardian does not inadvertently harm other devices, preserves the ability of authorized entities to connect the BLE-equipped device, and always hides the BLE-equipped device when needed.

More than one device might be authorized to connect to the BLE-equipped device. BLE-Guardian differentiates the scan and connection requests originating from authorized devices versus those that are fraudulent. This is particularly challenging as the BLE advertisement channel lacks any authentication mechanism for the advertisements and connections. BLE-Guardian utilizes Bluetooth classic as an out-of-band (OOB) channel to authorize a device after obtaining the user’s permission. It uses the OOB channel to instruct the connecting device to issue ordinary connection requests with (varying) special parameters that other unauthorized devices can’t predict. It also alerts the user when unauthorized parties attempt connection to the user’s BLE devices.

BLE-Guardian achieves its objectives with minimum requirements from the external radio. Effectively, BLE-Guardian operates with a radio that offers only the basic capabilities of reception and transmission on the BLE channels. As a result, BLE-Guardian avoids employing sophisticated and customized (thus impractical) radios and signal processing approaches.

We implement BLE-Guardian using the commercially available Ubertooth One¹ USB dongle so that BLE-Guardian can be easily installed on any BLE gateway. We also implement accompanying apps for different BLE gateways, such as Android and Raspberry PI. We evaluate BLE-Guardian using several BLE devices for different real-world scenarios, where we assess its effectiveness in combating privacy threats, its low over-

¹<https://greatscottgadgets.com/ubertoothone/>

head on the channel and devices, and little disruption to the operation of legitimate BLE devices. In particular, BLE-Guardian is able to protect up to 10 class-2 target BLE-equipped devices within a 5m range with less than 16% energy overhead on the gateway.

The rest paper is organized as follows. Section 2 discusses the related work. Section 3 provides the necessary BLE background. Section 4 states the privacy threats arising from BLE advertisements through our data-collection campaign. Section 5 details the design of BLE-Guardian. Section 6 presents the implementation of BLE-Guardian and evaluates its effectiveness. Finally, the paper concludes with Section 7.

2 Related Work

There have been limited efforts related to BLE devices that target the security and privacy threats resulting from the devices revealing their presence. The only exception is the work by Wang [40], where a privacy enhancement is proposed for BLE advertisements to ensure confidentiality and prevent replay attacks as well as tracking. This enhancement is based on providing an additional 3-way handshake between the peripheral and the gateway. Unarguably, this enhancement changes both the protocol and the peripheral which is highly impractical as we argued before.

Another related field of research includes wearable and body-area networks. The work by Leonard [21] uses a honeypot to lure in adversaries that attempt to attack the user’s wearable devices. The honeypot uses a set of helper nodes to expose fake services with known weaknesses so that the attacker connects to them. This work, however, doesn’t handle the privacy threat arising from BLE advertisements. A determined attacker will be able to distinguish fake traffic from legitimate one based on RF signatures from the devices and issue connections to the user’s real devices.

Other relevant work includes approaches to protecting medical devices. Mare *et al.* [25] propose a mechanism that protects health sensors when communicating with a gateway. The proposed system, albeit relevant, doesn’t apply for the BLE ecosystem. It also mandates changing the medical devices. Gollakota *et al.* [12] propose an external device, called *Shield*, that the user wears to control access to his/her embedded medical device. *Shield* implements friendly jamming so that only an authorized programmer can communicate with the medical device.

BLE-Guardian takes an entirely different approach by targeting the control plane of the BLE protocol instead of the data plane. BLE-Guardian does not need to continually protect an ongoing authorized connection and more importantly need not invoke jamming signal cancellation that requires accurate estimation of chan-

nel condition in a dynamic mobile indoor environment as well as a full duplex radio. BLE-Guardian constitutes a reference design that can function with any radio that has reception and transmission capabilities on the 2.4 GHz band. BLE-Guardian, also, considers far less restrictive scenarios than *Shield*. It does not have to be within centimeters of the device-to-be-protected as the case with *Shield*. Moreover, BLE-Guardian’s practical design allows scaling up protection for multiple devices (multiple connectors and protected devices) simultaneously, which is not the case for *Shield* that considers a two-device scenario only [36].

Finally, researchers have explored ways to reduce information leaks from sensors in a smart home environment [30, 37]. Srinivasan *et al.* [37], Park *et al.* [30], and Schurgot *et al.* [35] propose a set of privacy enhancements that include perturbing the timing of broadcasted sensory data along with padding the real sensory data with fake data to confuse the adversary. These protocols fail to address the threats resulting from BLE advertisements and have the shortcoming of requiring changes to the sensors as well.

3 BLE Primer

The BLE (Bluetooth 4.0 and newer) protocol has been developed by the Bluetooth SIG to support low power devices such as sensors, fitness trackers, health monitors, etc. Currently, more than 75,000 devices in the market support this protocol along with most of more capable devices such as smartphones, tablet, PCs, and recently access points [2].

3.1 BLE States

A BLE device assumes either a central or peripheral role. A peripheral device is typically the one with lower capabilities and with the information to advertise. The central device, typically an AP, PC, or smartphone, scans for advertisements and initiates connections.

The BLE specification places a higher burden on the central device. It is responsible for initiating the connection and thus has to keep scanning until it receives an advertisement. Conversely, the peripheral (prior to its connection) sleeps for most of the time and only wakes up to advertise, which helps save its limited energy.

3.2 Advertisements

BLE advertisements are instrumental to the operation of the protocol, and constitute the only means by which a device can be discovered. The specification defines 4 advertisement message types as shown in Table 1, and 3

Table 1: The four types of BLE advertisements.

Type	Advertising Interval
ADV_IND	20ms – 10.24s
ADV_DIRECT_IND	3.75ms
ADV_NONCONN_IND	100ms – 10.24s
ADV_SCAN_IND	100ms – 10.24s

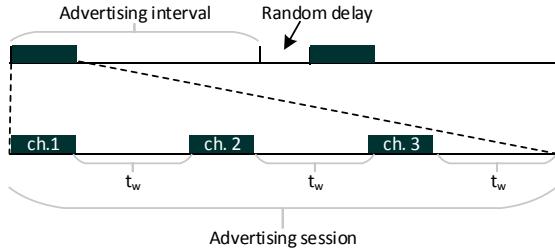

Figure 1: The advertisement pattern in BLE.

advertisement channels: 37 (2402MHz), 38 (2426MHz), and 39 (2480MHz).

ADV_DIRECT_IND (introduced in Bluetooth 4.2) is a special advertisement; it enables fast reconnection between the central and the peripheral devices. The peripheral, when turned on, will broadcast advertisements at a fast rate (once every 3.75ms, for 1.28 seconds) that are directed to the client (with a pre-existing trust relationship) before assuming the central role. The advertisement message only contains the message type, source, and destination addresses.

The other three advertisements are similar to each other in that they are periodic. The advertisement interval determines the frequency with which each device advertises. This interval has to be chosen, at configuration time, between 20ms and 10.24 seconds (at increments of 0.625ms) for the ADV_IND advertisement and between 300ms and 10.24 seconds for the other two advertisements. To prevent advertisements of different devices from colliding with each other, each device waits for a random amount of time between 0 and 10ms (in addition to the advertisement interval) before it advertises (Fig. 1).

The advertisement session constitutes the period when the device is actually advertising. During each advertisement session, the device advertises on the three advertisement channels given a pre-configured channel sequence. Before switching to the next channel, the device has to wait for a preset period of time (less than 10ms) for scan and connection requests (t_w in Fig. 1). We will henceforth refer to the advertisement interval, the channel sequence, and the waiting time as the *advertisement pattern*.

Each advertisement message contains the message

type, source address, along with some of the services offered by the device and their respective values. The specification defines a set of services that have unique UUIDs, such as device name. The message is limited in length, and hence, to get more information about the device, an interested device can either issue a scan request to which the advertising device responds with a scan response or connect to the advertising device.

3.3 Connections

Not all BLE devices accept connections; devices that use ADV_NONCONN_IND advertisement messages run in transmit mode only and they don't accept any scan or connection requests such as iBeacons.

Also, devices advertising with ADV_SCAN_IND messages don't accept connections but accept scan requests. Particularly, when the device broadcasts an advertisement message on some channel, it listens on the same channel for some time (less than 10ms) before switching to the next channel. It waits for scan requests from clients wanting to learn more information to which it responds with a scan response.

Devices that advertise using ADV_IND messages are scannable and connectable; they respond to scan messages and connection requests. After sending an advertisement message, the device listens for connection requests. The connection request contains the source and destination addresses along with other connection parameters. These parameters contain the connection interval, the timeout, and the slave interval. When connected, the device starts frequency hopping according to a schedule negotiated with the central. If the device (now peripheral) doesn't receive any communication from the central over the period defined by the "timeout interval", it drops the connection.

While connected, the device must not broadcast connectable advertisement messages (the first two types of Table 1). It can, however, still broadcast non-connectable advertising messages to share information (the last two types of Table 1) with other clients in its transmission range which still leaks information about the device's name, type, and address.

3.4 Privacy and Security Provisions

The BLE specification borrows some security provisions from classical Bluetooth to establish trust relationships between devices, a process known as *pairing*. When the device boots for the first time, it will advertise using ADV_IND with its public Bluetooth address. The user can then pair a smartphone (or other BLE-equipped device) so that the two devices exchange a secret key that will enable future secure communication.

Once a BLE-equipped device is paired with another device, it can invoke more privacy and security provisions. The first provision is whitelisting, and the device will only accept connections from devices it has been paired with before, i.e., those that are whitelisted. Also, the device might accept connections from any client but might require higher security levels for some of the services it exposes so that only authorized users access sensitive content.

Finally, the BLE specification defines a privacy provision based on address randomization to prevent device tracking. When two devices are paired, they exchange an additional key called the *Identity Resolution Key* (IRK). The device uses this key to generate a random address according to a timer value set by the manufacturer, which it will use to advertise. This random address will be resolved by the paired device using the same key. As this random address is supposed to change regularly, curious parties shouldn't be able to track a BLE-equipped device. Devices that don't utilize address randomization can resort to direct advertising (ADV_DIRECT_IND) to enable fast and private reconnections.

These privacy provisions are akin to those proposed earlier in the context of WiFi networks. Researchers have long identified privacy leaks from the consistent identifiers broadcasted by wireless devices. They proposed privacy enhancements that include randomizing or frequent disposing of MAC addresses [14, 18] and hiding them through encrypting the entire WiFi packets [13]. These enhancements require introducing changes for the client devices.

4 Threats from BLE Devices

While, in theory, BLE's privacy provisions might be effective to thwart threats to the user's privacy, whether or not various manufacturers and developers properly implement them is an entirely different story. In what follows, we investigate how the BLE privacy provisions fare in the wild using a dataset collected in our institution and using the PhoneLab testbed [27] of SUNY Buffalo.

We developed an Android app that collects the content of the advertisement messages. We recruited users from our institution and from the PhoneLab testbed. We didn't collect any personal information about the users and thus obtained non-regulated status from the IRB of our institution. One could view this study as crowdsourcing the analysis of BLE devices; instead of purchasing a limited set of devices and analyzing them, we monitored the behavior of a broad range of devices in the wild. Analyzing the advertisements we collected from 214 different types of devices (sample of these devices shown in Tables 2 and 3), we observed:

Table 2: A sample of devices with revealing names.

Name	Type
LG LAS751M(27:5D)	music streaming
JS00002074	digital pen
ihere	key finder
spacestation	battery/storage extension
Jabra PULSE Smart	smartbulb
DEXCOMRX	Glucose monitor
Clover Printer 0467	printer
Frances's Band ea:9d LE	smartband
Gear Fit (60ED)	activity tracker
Lyve Home-00228	photo storage
Matthias-FUSE	headset
Richelle's Band b2:6a LE	smartband
vivosmart #3891203273	activity tracker
KFDNX	key fob
OTbeat	heart rate monitor
Thermos-4653	Smart Thermos
POWERDRIVER-L10C3	smart power inverter

Table 3: A sample of devices with consistent addresses for more than a day.

Name	Type	Days observed
One	activity tracker	37
Flex	activity tracker	37
Zip	activity tracker	37
Surge	activity tracker	36
Charge	activity tracker	36
Forerunner 920	smartwatch	36
Basis Peak	sleep tracker	25
MB Chronowing	smartwatch	15
dotti	pixel light	7
UP MOVE	fitness tracker	2
GKChain	laptop security	2
Gear S2 (0412)	smartwatch	2
Crazyflie	quadropter	1
Dropcam	camera	1

1. Two advertisement types (ADV_NONCONN_IND and ADV_SCAN_IND) require a fixed address which would enable tracking of a mobile target.
2. Devices that are bonded to the users advertise using ADV_IND messages instead of the more private ADV_DIRECT_IND.
3. Some devices, albeit not expected to do so, use their public Bluetooth addresses in advertisements. This also enables tracking as well as identifying of the device manufacturer.
4. Other devices implement poor address randomization by flipping some bits of the address rendering them ineffective against tracking. This has also been identified in other studies of BLE devices [22].
5. A large number of devices advertise their names (Table 2), revealing sensitive information about them, the user, and the environment. Also, some of the device names contain personal information

or unique identifiers that may enable user tracking.

6. Some devices use a consistent Bluetooth address for long periods of time which renders address randomization ineffective (Table 3). Examples include various types of wristbands (Fitbit Flex, Forerunner 920, etc.), headsets, smartwatches (Apple Watch or Samsung Gear), etc. This has also been identified by Das *et al.* [7], where they analyzed the advertisements of BLE-equipped fitness trackers. Das *et al.* found the fitness trackers constantly advertising with consistent (non-private) BLE addresses. In our experiments, we observed that Flex and One kept the same address for 37 days, so did One and Charge for 30 days.
7. Some devices accept connections from non-bonded devices. This allows access to the services on the device including the unique manufacturer ID, for instance, which allows for user tracking regardless of the device’s address. For example, we were able to connect to various devices and access data from them without any existing trust relationship, such as various Fitbit devices (One, Zip Flex, Charge), Garmin Vivosmart, digital pens, etc. It is worth noting that we connected to these devices under controlled experimental settings, not in the wild. As a result, an external access control mechanism is necessary to protect such devices.

The above observations indicate that the address randomization, part of the BLE specifications, fails to provide the promised privacy protection. Various developers and manufacturers do not implement it properly; they rely on public Bluetooth addresses, apply weak randomization, or keep a consistent address for a long time. On the other hand, even if address randomization is properly implemented, other information in the advertisement or in the device might contain unique information (device name or id) that allows for its tracking.

Moreover, data accessed from an advertisement or the device (once connected) might reveal sensitive information about the user or the environment. Through our data collection campaign, we were able to detect different types of glucose monitors, wristbands, smart watches, fitness trackers, sleep monitors, laptops, smartphones, laptop security locks, security cameras, key trackers, headsets, etc. Knowing which type of glucose monitor the user is carrying or the type of physical security system s/he has installed could lead to serious harm to the user. Finally, an adversary might use such advertisement data as side information to infer more about the user’s behavior. For example, a temperature sensor constantly reading 60°F in winter would indicate a vacant property [41] which may invite in a thief.

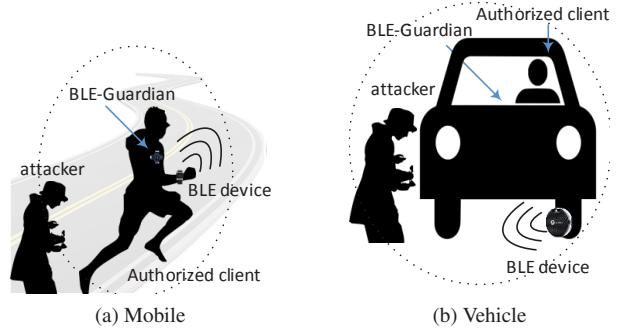

Figure 2: Example deployments of BLE-Guardian.

5 BLE-Guardian

BLE-Guardian addresses the aforementioned privacy threats by allowing only *authorized clients* to discover, scan, and connect to the user’s BLE-equipped device. Before delving into the inner workings of BLE-Guardian, we first describe the system and threat models.

5.1 System and Threat Models

5.1.1 System Model

A typical BLE scenario involves two interacting entities: the client and the BLE-equipped device. The BLE device broadcasts advertisements to make other nearby clients aware of its presence along with the services/information it is offering. A client can then connect to the device to access more services/information and control some of its attributes, in which case it will be the BLE-device’s gateway to the outside world.

The user’s mobile device (e.g., smartphone or tablet) acts a gateway where BLE devices are wearable (e.g., fitness trackers), or mHealth devices (e.g., Glucose monitor) (Fig. 2a). In a home environment, the user’s access point, PC, or even mobile device, serves as a gateway for BLE devices that include smart appliances, webcams, physical security systems, etc. Last but not least, a smart vehicle or the driver’s mobile device operate as gateways (Fig. 2b) for the different BLE-equipped sensors in the vehicle, such as tire pressure.² An interested reader could consult the work of Rouf *et al.* [32] for a discussion on the security and privacy risks of a wireless tire pressure sensor.

BLE-Guardian leverages the existence of gateways near the BLE-equipped devices to fend off unauthorized clients scanning and connecting to them. It comprises both hardware and software components. The hardware

²<https://my-fobo.com/Product/FOBOTIRE>

component is an external Bluetooth radio that connects physically to the gateway, while the software component is an accompanying application that runs on the gateway. BLE-Guardian requires another software component to run on the clients willing to discover and connect to the user’s BLE devices. The user, be it an owner of the BLE-equipped device or a client, interacts with BLE-Guardian through its software components.

5.1.2 Threat Model

BLE-Guardian only trusts the gateway on which it is running. Otherwise, the entire operation of BLE-Guardian will be compromised and will fail to provide the promised privacy provisions. BLE-Guardian achieves privacy protection at the device level, so that if it authorizes a client to access the BLE device, all applications running on that device will have same access privileges. This security/privacy dimension is orthogonal to BLE-Guardian and has been addressed elsewhere [28]. It also requires the user’s BLE device — the one to be protected — to comply with the BLE specifications.

BLE-Guardian protects a target BLE-equipped device against an adversary or an unauthorized/unwanted device that sniffs the device’s advertisements, issues scan requests and attempts to connect to the device. The adversary aims to achieve three objectives based on the BLE devices that the user is deploying:

1. **Profiling:** The adversary aims to obtain an inventory of the user’s devices. Based on this inventory, the adversary might learn the user’s health condition, preferences, habits, etc.
2. **Tracking:** The adversary aims to monitor the user’s devices to track him/her over time, especially by exploiting the consistent identifiers that the devices leak as we observed in Section 4.
3. **Harming:** The adversary aims to access the user’s BLE device to learn more sensitive information or even to control it. Both will have severe consequences for the user, especially if a certain device is known to have some vulnerabilities that allow remote unauthorized access [26].

This adversary can have varying passive and active capabilities, from curious individuals scanning nearby devices (e.g., using a mobile app), to those with moderate technical knowledge employing commercial sniffers, all the way to sophisticated adversaries with software-defined radios.

A *passive* attacker is capable of sniffing all the communications over advertisement channels including those that fail the CRC check. This includes all commercial Bluetooth devices and existing Bluetooth sniffers in the

market, such as the Texas Instruments CC2540 chip. The adversary might possess further capabilities by employing MIMO receiver that could recover the original signal from the jammed signal [38], especially in stationary scenarios. We refer to this adversary as the *strong passive* attacker.

Furthermore, the adversary is capable of injecting traffic into any Bluetooth channel at any given point of time, but will “play” within the bounds of the BLE specifications when attempting communication with the BLE device. This is a reasonable assumption, as the device won’t otherwise respond to any communication. We refer to such an adversary as the *active* attacker. On the other hand, the attacker might be able to transmit with higher power than allowed by regulatory bodies, in which case we refer to as the *strong active* attacker.

Thus, we have four classes of attackers referring to the combinations of their passive and active capabilities as shown in the first column of Table 4.

Attacks, including jamming the channel completely, masquerading as fake devices to trick the users to connect to them, or attacking the bonding process are orthogonal to our work. Such attacks have been addressed by O’Connor and Reeves [29] and Ryan [33]. Finally, once BLE-Guardian enables the authorized client to connect to the BLE device, it won’t have any control over what follows later.

5.2 High-Level Overview

BLE-Guardian is a system the user can use out of the box; it only requires installing a hardware component (an external Bluetooth radio) to the gateway and running an app on the gateway to control and interface with the Bluetooth radio. Conceptually, BLE-Guardian consists of *device hiding* and *access control* modules. The device hiding module ensures that the BLE device is invisible to scanners in the area, while the access control module ensures that only authorized clients are allowed to discover, scan, and connect to the BLE device.

Fig. 3 shows the high-level operation of BLE-Guardian from the moment a user designates a BLE device to be protected all the way to enabling authorized client connection to the protected device. The high-level operation of BLE-Guardian takes the following sequence:

1. The user installs the hardware component along with the accompanying app on the gateway.
2. The user runs the app, which scans for BLE devices nearby. The user can then choose a device to hide.
3. The device hiding module of BLE-Guardian starts by learning the advertisement pattern of the target BLE device along with that of the other devices in

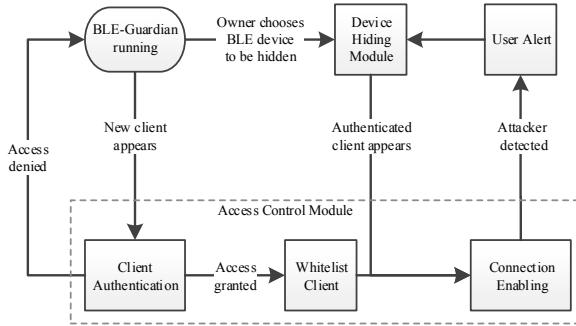

Figure 3: The modules of BLE-Guardian and their underlying interactions.

the area. The device hiding module then applies reactive jamming to hide the device.

4. When a new client enters the area and wants to discover the user's devices, it communicates with the access control module so that the user can either grant or reject authorization.
5. If the user authorizes the client, the access control module advertises *privately* on behalf of the BLE device to let the authorized client scan and connect to it.
6. BLE-Guardian monitors if other unauthorized entities are attempting to connect to the BLE device; in such a case, it blocks the connection and alerts the user.

5.3 Device Hiding

The hiding module is responsible for rendering the BLE device invisible to other scanning devices. The hiding module jams the device's advertisement session to achieve this invisibility. In particular, it targets three types of advertisements, ADV_IND, ADV_NONCONN_IND, and ADV_SCAN_IND of Table 1, which are periodic and leak more information about the user as we indicated earlier.

Hiding the BLE device is, however, challenging for two reasons. The hiding module must jam the BLE device precisely at the moment it is advertising. Also, it must not disrupt the operation of other devices advertising in the same area.

5.3.1 Learning

The hiding module first learns the target BLE device's advertising pattern before jamming to hide its presence. The device's advertisement pattern comprises the advertising interval, advertising channel sequence, and the time to listen on the individual channels. Fortunately, the

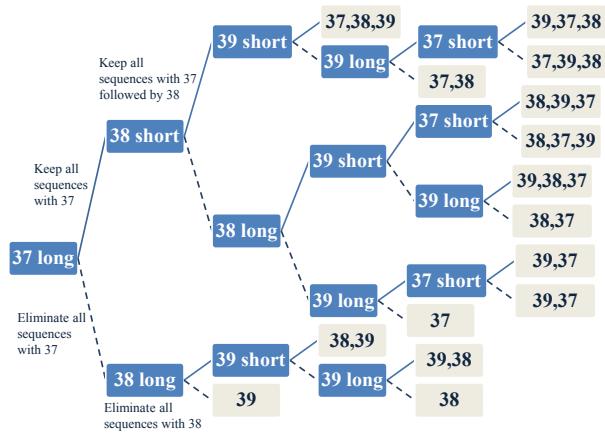

Figure 4: The learning algorithm followed by BLE-Guardian. The blue boxes refer to monitoring each channel either for a short period of time (less than 10ms) or for a longer period of 10.24 seconds. Depending on whether an advertisement is detected on the channel some sequences are eliminated till a sequence is decided on (gray boxes).

latter two parameters are deterministic and can be observed directly, which is not the case for the advertising interval. The BLE specification leaves it to the device to determine the advertising pattern, so that there are 15 possible permutations of the channel sequence.

As shown in Fig. 4, BLE-Guardian follows a process of elimination to identify the advertising sequence of the BLE device using a single antenna. In the worst case, it will take three advertising intervals to learn the entire advertising sequence of a BLE-equipped device. This corresponds to the longest path of Fig. 4, where BLE-Guardian monitors each channel for the maximum advertising interval of 10.24 seconds. At the same time, it would have identified the time the BLE device spends listening on each channel before switching to the next channel.

While observing the advertising sequence of the BLE device, the hiding module keeps track of the interval separating the consecutive advertisements sessions. The hiding module observes a set of inter-advertisement intervals, $t_i = adv + p$, where adv is the actual advertisement interval as set by the device and p is a random variable representing the random delay such that $p \in unif(0, 10ms)$. Also, BLE-Guardian will perform the same process for all advertising devices in the same area at the same time to learn their advertising parameters as well. Learning other devices' advertising at the same time will be useful as evident below.

5.3.2 Actuation

After identifying the advertising pattern, the hiding module needs to just detect the start of the advertisement session. Then, it jams the advertising channels according to their advertisement sequence. There is a caveat, though; the hiding module needs to detect the advertisement before it can be decoded. Otherwise, the rest of the jamming will not be effective.

From monitoring earlier advertisements, the hiding module obtains a set of t_i 's of different devices' advertisements, including the BLE device to be hidden. The advertisement interval will be $adv = t_i - p$ for each observed inter-advertisement interval. Each observed advertisement will be used to improve the estimation of the advertisement interval. For N observed intervals, we have:

$$adv = \frac{1}{N} \sum_{i=1}^N (t_i - p) = \frac{1}{N} \sum_{i=1}^N t_i - \frac{1}{N} \sum_{i=1}^N p. \quad (1)$$

Let $P = \frac{1}{N} \sum_{i=1}^N p$, the random variable P is drawn from the distribution $\frac{1}{N}p * \frac{1}{N}p * \frac{1}{N}p \dots \frac{1}{N}p$. Since the single random delays p are i.i.d., the mean of P will be equal to 5 (mean of the original distribution of p) and the standard deviation of $\sqrt{\sum_{i=1}^N \sigma_p^2} = \frac{5}{N\sqrt{3}}$. The hiding module estimates adv as:

$$adv' = E(adv) = \frac{1}{N} \sum_{i=1}^N t_i - 5. \quad (2)$$

The standard deviation of P will get lower as N increases; it defines the error in the estimate of adv as defined by Eq. (1). Given previous N observed advertisements from the BLE device, the hiding module can predict the next advertisement to happen at $adv_{next} \in [adv_{low}, adv_{high}]$ such that:

$$adv_{low} = T_N + adv' - e \quad (3)$$

$$adv_{high} = T_N + adv' + e + 10, \quad (4)$$

where T_N is the time of the last advertisement and e is the 90th percentile value of P (symmetric around the mean) which approaches 0 as N increases (so that $adv_{high} - adv_{low}$ approaches 10ms).

Starting from the last observed T_N of the target BLE device, the advertisement hiding module computes adv_{low} and adv_{high} . Also, it enumerates the list of other devices expected to advertise within the interval $[adv_{low}, adv_{high}]$.

The device hiding module always listens on the first channel of the advertising sequence of the BLE device to be hidden. During the interval $[adv_{low}, adv_{high}]$,

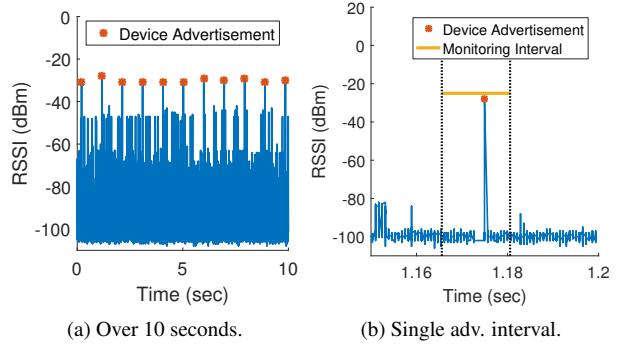

Figure 5: RSSI at channel 37 when a device is advertising at a distance of 1m at the interval of 960ms.

the device hiding module will sample the RSSI of the channel very frequently (every 25μs). When the received RSSI is $-90dBm$ or higher (the peaks of Fig. 5a), BLE-Guardian determines that there is a transmission currently starting to take place. The device hiding module moves immediately to jam the channel on which it is listening. Since the transmission of a typical advertisement message takes 380μs to finish [16], jamming the channel will prevent the message from being decoded by other receivers.

At this point, two situations might arise; (1) the target BLE device is the only device expected to be advertising at this time instant, or (2) some other device is expected to be advertising in the same interval. In the first situation, the target BLE device is most probably responsible for this transmission as part of its advertisement session. The device hiding module repeats the same process (sample RSSI and jam) over the rest of the channels to confirm that transmissions follow the device's advertising pattern. Fig. 5b shows an example interval where there is only one device advertising.

In the second situation, the device hiding module can't readily ascertain whether the transmission belongs to the target BLE device or not. This will take place when the observed transmission sequence matches the advertising sequence of the target BLE device and some other device that is expected to advertise at the same interval. To resolve this uncertainty, immediately after jamming the advertising message (400μs after commencing jamming on the channel), the device hiding module lifts jamming and sends scan requests for devices other than the target device. The device hiding module then listens on the channel to observe if a scan response is received. Despite its advertisement being jammed, any device will still be listening on and will respond to scan requests. Depending on whether a scan response is received or not, BLE-Guardian can associate the transmission with the correct device, be it the target BLE device or some other

device.

The device hiding module then adjusts the next monitoring interval according to the observed transmissions in the current intervals as follows:

$$adv_{low} = \min(T_N) + adv' - e \quad (5)$$

$$adv_{high} = \max(t_N) + adv' + e + 10, \quad (6)$$

where T_N represents the instants of the transmissions possibly matching the advertisement of the target BLE device in the current monitoring interval.

Note that we don't utilize the power level per se, or any physical-layer indicator, to indicate whether the same device is transmitting or not, as it is sensitive to the environment and the distance between BLE-Guardian and the target BLE device. To actually perform the jamming, the device hiding module continuously transmits at the maximum power for the specified interval.

BLE-Guardian may jam the advertisements of non-target devices which might disrupt their operation, which we referred to as the second situation above. Nevertheless, because of the random delay introduced by the device before each advertisement, the aforementioned "collision" events become unlikely. In Appendix A, we use renewal theory to show that the expected number of another device's advertisements within the expected advertising interval of the target BLE-equipped device will always be less than 1. This applies when BLE-Guardian protects a single BLE-equipped device. Our evaluation in Section 6 confirms this observation.

5.4 Access control

So far, BLE-Guardian has hidden the target BLE device, so neither authorized nor unauthorized entities have access to the device. It is the access control module that authorizes client devices and enables their access to the target BLE device.

5.4.1 Device Authorization

BLE-Guardian utilizes Bluetooth classic (BR/EDR) as an out-of-band (OOB) channel to authorize end-user devices intending to scan and access the target BLE device. BLE-Guardian runs in server mode on the gateway waiting for incoming connections, while the "authenticating" device will have BLE-Guardian running in client mode to initiate connections and ask for authorization. The choice of Bluetooth Classic as an OOB channel is natural; most end-user devices (such as smartphones) are dual-mode, supporting both BLE and Bluetooth classic. Moreover, Bluetooth classic already contains pairing and authentication procedures, eliminating the need for a dedicated authentication protocol. Last but not least, a

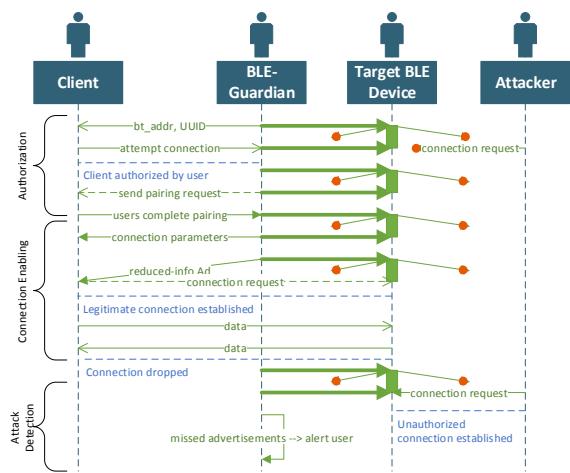

Figure 6: The sequence diagram of the access control module. Thin green lines from the target device designate the advertisements. Thick green lines from BLE-Guardian designate the jamming signal.

Bluetooth-equipped end-user device will be able to communicate simultaneously over Bluetooth classic and BLE so that it can communicate with both BLE-Guardian and the target BLE device.

Fig. 6 depicts the interactions between BLE-Guardian and a client device when they connect for the first time. BLE-Guardian will be listening on the gateway over a secure RFCOMM channel with a specified UUID. The gateway, however, won't be running in discoverable mode so as to prevent others from tracking the user. It is up to the party interested in authenticating itself to obtain the Bluetooth address of the user's gateway as well as the UUID of the authentication service.

Once the client end-user device obtains the Bluetooth address and UUID, it can initiate a secure connection to the gateway. This will trigger a pairing process to take place if both devices are not already paired. BLE-Guardian relies on Bluetooth pairing process to secure the connections between the gateway and the client device. For future sessions, an already paired client device can connect to BLE-Guardian without the need for any user involvement. The owner can also revoke the privileges of any client device by simply un-pairing it.

5.4.2 Connection Enabling

The device hiding module of BLE-Guardian jams the entire advertising sequence of the target BLE device, including the period it listens for incoming scan or connection requests so that it cannot decode them. Therefore, both unauthorized and authorized clients cannot access the target BLE device (the case of an adversary using

high transmission power will be discussed later). Fig. 6 shows the procedure that BLE-Guardian follows to enable *only* the authorized clients access to the target BLE device.

Immediately after the last advertisement of a single advertisement session, when the target device is the only one expected to be advertising, the access control module lifts the jamming. This ensures that the BLE device will not be advertising until the next advertising session, and it is currently listening for scan and connection requests. Then, BLE-Guardian advertises on behalf of the target BLE device on the same channel. The advertisement message contains only the headers and the address of the previously hidden device. It is stripped of explicit identifiers, hence leaking only limited information about the BLE device for a brief period.

At the same time, BLE-Guardian will communicate to the authenticated client app the address of the BLE device and a *secret* set of connection parameters over the OOB channel. BLE-Guardian’s app running on the client device will use the address and the parameters to initiate a connection to the BLE device. The connection initiation procedure is handled by the Bluetooth radio of the client device, which scans for the advertisement with the provided address. After receiving such an advertisement, it sends a connection request after which both devices will be connected.

The above procedure will not break the way BLE scans and connections take place. It doesn’t matter from which radio the actual advertisement was coming. From the perspective of the BLE device, it will receive a scan or connection request while waiting for one. On the other hand, the client device will receive an advertisement message while also expecting one.

5.5 Security and Privacy Features

BLE-Guardian addresses the tracking and profiling threats discussed in Section 5.1.2. It hides the advertisements, which are used as the main means to track users. It only exposes the advertisement for a very short period when enabling others to connect. Furthermore, BLE-Guardian greatly reduces the profiling threat by hiding the contents of the advertisement which leak the device name, type, and other attributes.

A strong passive attacker [38] can still detect the “hidden” peripheral by recovering the real advertisement, so that it can connect to the BLE-equipped device. Distinguishing legitimate connection requests based on the Bluetooth address of the initiator is not effective; an attacker could easily spoof its Bluetooth address to impersonate the authorized client. Therefore, BLE-Guardian uses the connection parameters of the connection request to distinguish fraudulent connection requests from legit-

Table 4: The protections offered by BLE-Guardian.

Adversary	Profiling Protect.	Tracking Protect.	Access Control	User Alert
Passive & Active	✓	✓	✓	✓
Strong Passive & Active	–	✓	✓	✓
Passive & Strong Active	✓	✓	–	✓
Strong Passive & Strong Active	–	✓	–	✓

imate ones. Legitimate connection requests contain the set of “secret” connection parameters communicated earlier to the client.

The probability of the attacker matching a particular set of connection parameters is very low. According to the specification, there are more than 3 million possible combinations of values for the connection, slave, and timeout intervals. If the connection is established based on a fraudulent connection request, then BLE-Guardian prevents the connection from taking place. The connection request already contains the hopping sequence initiation. BLE-Guardian hops to the next channel and jams it so as to prevent the BLE device from receiving any message from the connected unauthorized device. The BLE device drops the connection since it receives no message on the channel.

An attacker might abuse this connection process by constantly attempting to connect to the BLE device, thus depriving the authorized client of access. This will always be possible, even when BLE-Guardian is not deployed. BLE-Guardian observes such a situation from a high frequency of fraudulent connection requests and alerts the user of this threat. As it will be evident in Section 6, an active attacker injecting messages to the advertising channel can’t affect the operations of BLE-Guardian.

A strong active adversary, however, can override BLE-Guardian’s jamming and issue connection requests that the BLE-equipped device will decode. While jamming, BLE-Guardian runs in transmit mode and can not monitor the channel for incoming requests. Nevertheless, it detects that the BLE device is missing its advertising intervals, signifying that it was connected without BLE-Guardian’s approval. In such a case, BLE-Guardian alerts the user of the existence of a strong adversary nearby.

Finally, Table 4 summarizes BLE-Guardian’s capabilities when faced with the various adversaries described in Section 5.1.2.

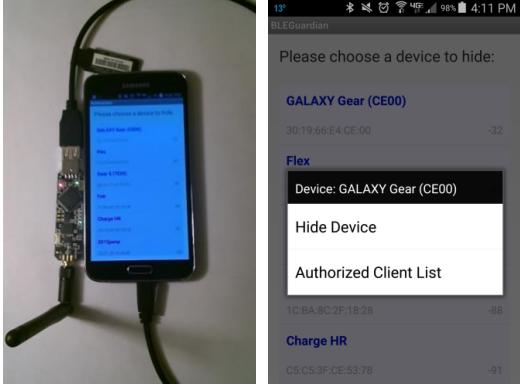

Figure 7: The deployment scenario for BLE-Guardian for a mobile user (left) and the main UI (right).

6 Implementation and Evaluation

We now present a prototype of BLE-Guardian along with its evaluation.

6.1 Implementation

We implement BLE-Guardian using Ubertooth One radio which is an open platform for Bluetooth research and development. It can connect to any host that supports USB such as Raspberry Pi, Samsung’s Artik-10, PC, smartphone (Fig. 7 (left)), etc. Since communication over USB incurs latency in the order of a few milliseconds, we implement most of BLE-Guardian’s functionalities inside Ubertooth One’s firmware to maintain real-time operation.

We also implement the software component of BLE-Guardian on Linux and Android. Fig. 7 (right) shows a screenshot of the BLE-Guardian app while running on Android in server mode where the user can choose the device to protect and control its authorized client list. The app communicates the Bluetooth address of the chosen device to the Ubertooth One radio.

BLE-Guardian requires running in privileged mode on the client device in order to be able to connect with modified connection parameters. This is easily achievable on Linux-based clients, but might not be the case for mobile devices. In other words, BLE-Guardian, while running in client mode on Android, requires root access to be able to issue connection requests with a set of specified connection requests. Also, BLE-Guardian (if running in privileged mode on the client device) can modify content of the advertisement message from the BLE scanner to the user-level application to reconstruct the original hidden advertisement. As such, user-level applications (on the trusted client) will receive the original advertisement, which does not break their functionality.

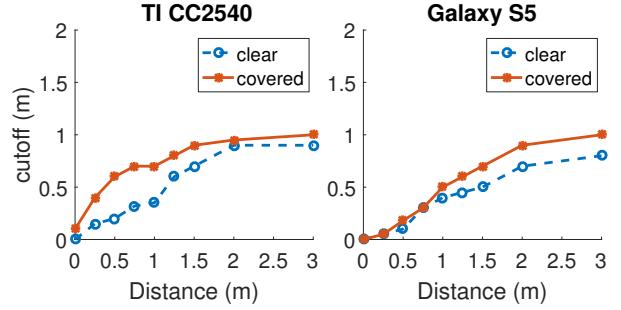

Figure 8: The cutoff distance as a function of the distance between BLE-Guardian and the target device.

Maintaining BLE-Guardian is easy; it only requires updating the application running on the gateway which usually takes place without the user’s intervention (e.g., mobile app updates). This application interacts with the hardware component and applies updates, if necessary, through pushing firmware updates, a process which is also transparent to the users.

6.2 Evaluation

To evaluate BLE-Guardian, we utilize Broadcom BCM20702A0 and Nordic nRF51822 chips as the target BLE devices (both transmitting at 4dBm) and the TI CC2540 dongle as the sniffer node. CC2540 is able to decode the messages on the three advertisement channels, even on those that fail the CRC check. We evaluate using Nordic and Broadcom chips instead of actual BLE products, because these products (such as Fitbits) are mostly powered by the same (Nordic and Broadcom) BLE chips.

6.2.1 Impact of Distance

Due to transmission power limitations (battery or regulatory bodies’ constraints), there would always be a small area around the target BLE device where BLE-Guardian won’t be able to enact the privacy protection. The transmission from the target BLE device covers the jamming signal of BLE-Guardian. Nevertheless, as the sniffer moves farther away from the target BLE device (in any direction), the jamming signal will cover the advertisements, provided that the BLE device and BLE-Guardian are not very far apart. So, there is a cutoff distance beyond which the adversary can’t scan, and connect to the target BLE device.

We study the cutoff distance of a target BLE device (advertising at 20ms) at different distances separating it from BLE-Guardian (between 0 and 3m). At each position, we move the sniffer node (either a CC2540 dongle or Samsung Galaxy S5) around the BLE device, and

record the farthest distance at which it received any advertisement from the BLE device as to study the hidden terminal effect. Furthermore, we repeat each experiment twice, the first with BLE-Guardian clear of any obstacles and the second with it inside a backpack.

It is evident from Fig. 8 that the cutoff distance increases as BLE-Guardian and the BLE device become farther apart. In all of the cases, however, the cutoff distance is less than 1m, even when BLE-Guardian and the BLE device are 3m apart. This also applies when BLE-Guardian is inside the backpack which should reduce the effectiveness of its jamming. Sniffing with a smartphone has a shorter cutoff distance because the smartphone’s BLE chip filters out advertisements failing the CRC check so that they are not reported to the OS.

The cutoff distance is enough to thwart tracking and profiling in several scenarios, especially when the user is moving (walking, jogging, biking or driving). In these scenarios, BLE-Guardian is not farther than 1m from the target BLE device. An adversary has to get very close to the user, even if BLE-Guardian is covered in a coat or bag, to be able to scan or connect to the BLE device.

In other cases, the user has to keep his BLE devices (to be protected) close to BLE-Guardian in order to get the best privacy protection possible. Our experiments showed that BLE-Guardian and the target BLE device must be separated by a maximum distance of 5m so that an attacker beyond the cutoff distance won’t be able to decode the advertisements. If BLE-Guardian and target BLE device are farther apart than this, then BLE-Guardian’s jamming won’t be able to cover the entire transmission area of the BLE device. In all circumstances, however, BLE-Guardian detects unauthorized connections and alerts the user accordingly.

6.2.2 Evaluation Setup

Beyond the cutoff distance, BLE-Guardian is capable of hiding the advertisements and controlling access to any target BLE device regardless of its advertising frequency. This protection, however, comes at a cost. In what follows, we evaluate BLE-Guardian’s impact on other innocuous devices, the advertising channel, and the gateway. In the evaluation scenarios, we deploy the target BLE devices at distance of 1.5m from BLE-Guardian, and the sniffer between BLE-Guardian and the BLE devices (at a distance of 0.5m from BLE-Guardian). We evaluate BLE-Guardian when protecting up to 10 target devices with the following advertising intervals: 10.24 sec (highest possible), 5 sec, 2.5 sec, 1.25 sec, 960ms, 625ms, 312.5ms, 100ms, 40ms, and 20ms (lowest possible). Note that evaluating with 10 target devices constitutes an extreme scenario; according to our dataset, the average user is bonded to less than 4 devices, which

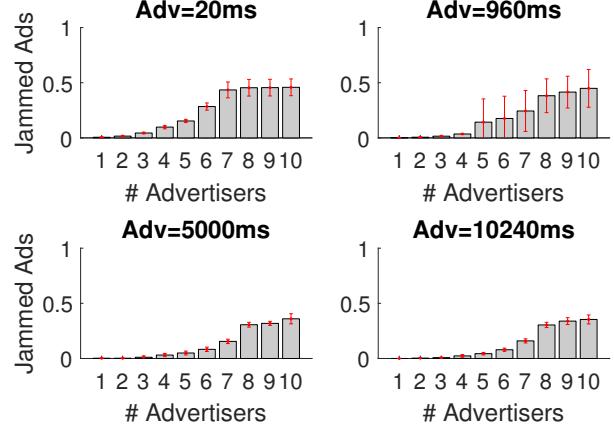

Figure 9: Portion of jammed advertisements of an innocuous BLE device when BLE-Guardian is running and protecting up to 10 advertisers.

would indicate the number of target devices (i.e. those to be protected).

6.2.3 Advertisement Hiding

Impact on Other Devices: We first evaluate the number of advertisements, not belonging to the target BLE device(s), BLE-Guardian will jam (Fig. 9). While accidentally jamming other devices doesn’t affect the privacy properties of BLE-Guardian, it hinders the services they offer to other users. In particular, we study four scenarios with an innocuous (not the target) BLE device advertising at 20ms, 960ms, 5s, and 10.24s, and a varying number (between 1 and 10) of target devices, which BLE-Guardian protects. Each subset of target devices of size N (≤ 10) contains the top N advertising intervals from the list of Section 6.2.2.

There are two takeaways from Fig. 9. First, BLE-Guardian has little effect on other devices when it protects a relatively low number of devices, or when the advertising interval of the target BLE device(s) is larger than 500ms; in these cases, BLE-Guardian will be less active (bars corresponding to less than 6 target devices in the four plots of Fig. 9). Second, BLE-Guardian has a higher effect on the innocuous device with higher advertising frequencies as observed from top-left plot of Fig. 9, especially when protecting a large number of devices (including those with 20 ms advertising interval).

In the latter case, BLE-Guardian is active for at least half of the time, representing the worst-case scenario of BLE-Guardian’s overhead where up to 50% of other devices’ advertisements are jammed. However, since the advertisement frequency is high, even with a relatively high rate of jammed advertisements, the user’s experience won’t be drastically affected. On the other hand,

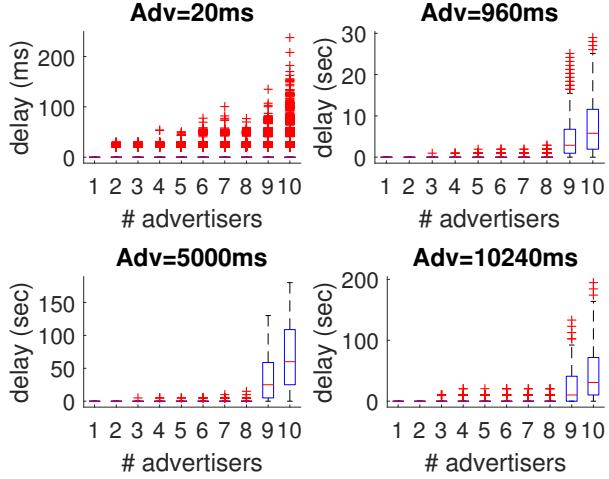

Figure 10: The delay of an authorized client in successfully connecting to the target device when BLE-Guardian is running.

when the target BLE device advertises at lower frequencies, the effect on the advertising channels and consequently other devices will be limited as evident from the rest of the plots of Fig. 9.

Impact on Authorized Access: To enable authorized connections, BLE-Guardian advertises on the behalf of the target BLE device only when it is confident that the target device is listening for connections. BLE-Guardian skips some advertising sessions which will introduce delays to authorized clients attempting connections as reported in Fig. 10. In this scenario, an authorized client is attempting connection to a target device advertising at 20ms, 960 ms, 5s, and 10.24 s, with an additional number of protected devices varying from 1 to 10. In the majority of the cases, the client has to wait for less than a second before successfully receiving an advertisement and issuing a connection. The only exception is the worst case consisting of BLE-Guardian protecting all of the 10 target devices (including devices advertising at intervals less than 100ms). The client might have to wait for up to multiple advertisement intervals before being able to connect. This is evident from the rightmost bar in each of the four plots of Fig. 10.

Impact on Advertising Channels Last but not least, we evaluate BLE-Guardian’s impact on the advertising channel, which, if high, might leak information about the existence of sensitive device(s). In this experiment, BLE-Guardian protects a single target device advertising at 20ms (the lowest possible), 960ms, and 10240ms (the highest possible). At the same time, two innocuous devices advertise at 20ms, in addition to other 15 devices not under our control advertising at different frequencies (minimum advertisement interval 30ms). In this sce-

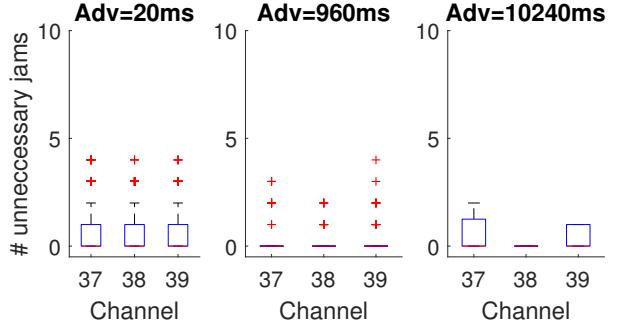

Figure 11: Unnecessary jamming instances with two advertisers at 20ms.

nario, BLE-Guardian will be active all the time since the two innocuous advertisers will force it to enlarge its monitoring interval between 20–30ms (while the advertising interval of the target device is only 20ms).

Fig. 11 shows the distribution of the number of unnecessary jammed instances in each interval when the target BLE device is expected to advertise. It is evident that in more than 50% of the intervals when BLE-Guardian is active, the number of unnecessary jamming instances events is 0, indicating a low overhead on the channel. When the target BLE device advertises at a lower frequency, BLE-Guardian is less active (middle and left plots of Fig. 11). These plots match the real-world scenarios observed from our data-collection campaign. Most commercial BLE devices advertise at relatively low frequencies (at intervals between 1 and 10s).

Finally, we evaluate the accuracy of predicting the next advertisement event of the target BLE devices. In all the experiments (including all scenarios), BLE-Guardian can predict the device’s advertisements, i.e., the target BLE device advertised in the interval it is expected to. BLE-Guardian is also able to jam all the advertisements of the BLE device over the three advertising channels. This indicates that an attacker can’t modify the behavior of BLE-Guardian by injecting traffic into the advertising channels.

6.2.4 Energy Overhead

BLE-Guardian incurs no energy overhead for both the target BLE devices and the authorized clients. Nevertheless, energy overhead is a concern when BLE-Guardian is attached to a smartphone. We measured the energy overhead of BLE-Guardian using a Monsoon power monitor while running on a Samsung Galaxy S4 with Android 4.4.2. In the idle case, BLE-Guardian consumes 1370mW on average. The average power consumption rises to 1860mW while transmitting and 1654mW while receiving as shown in Fig. 12a. Fortunately, BLE-Guardian doesn’t sense the channel or per-

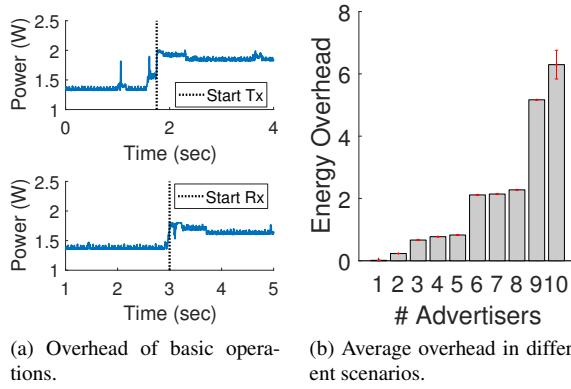

Figure 12: The energy overhead of BLE-Guardian running on Samsung Galaxy S4.

form jamming frequently. Fig. 12b shows the average energy overhead when BLE-Guardian is protecting the set of ten devices (we described earlier) at different advertising intervals. In the worst case of 10 target BLE devices, including a couple advertising at the highest frequency possible, the energy overhead is limited to 16% regardless of whether there are other advertisers in the area. In other cases, when there are less target devices and/or target devices are advertising at a lower frequency, the energy overhead is negligible.

7 Conclusion

BLE is emerging as the most prominent and promising communication protocol between different IoT devices. It, however, accompanies a set of privacy risks. An adversary can track, profile, and even harm the user through BLE-equipped devices that constantly advertise their presence. Existing solutions are impractical as they require modifications to the BLE-equipped devices, thereby making their deployment difficult. In this paper, we presented a device-agnostic system, called BLE-Guardian, which addresses the users' privacy risks brought by BLE-equipped devices. BLE-Guardian doesn't require any modification to the protocol and can be implemented with off-the-shelf Bluetooth hardware. We implemented BLE-Guardian using Ubertooth One radio and Android, and evaluated its effectiveness in protecting the users' privacy. In future, we plan to explore the data plane by analyzing and reducing the data leaks from BLE devices to unauthorized clients.

A Analysis of Device Hiding

BLE-Guardian may jam the advertisements of non-target devices which might disrupt their operation, which we refer to as the second situation in Section 5.3.2. Nevertheless, because of the random delay introduced by the device before each advertisement, the aforementioned “collision” events become unlikely. In what follows, we show that the expected number of another device’s advertisements within the expected advertising interval of the target BLE-equipped device will always be less than 1, when BLE-Guardian protects a single BLE-equipped device.

One could view the advertising process of a single BLE-equipped device as a renewal process [5], where each event corresponds to an advertising session. The inter-arrival times, X_i , are nothing but the inter-advertising intervals defined as i.i.d. random variables such that $X_i \sim \text{unif}(\text{adv}, \text{adv} + 10)$. The n^{th} advertisement time $T_n = \sum_{i=1}^n X_i$ has the distribution defined by the n -fold convolution of distribution of X_i . As n increases, the probability distribution of the n -th advertisement spreads over a larger time interval defined as $A = [\text{n.adv}, \text{n.(adv} + 10)]$.

The device hiding module attempts jamming at an interval of width 10ms, as specified before. If this jamming interval falls within the expected advertising interval of some other device, A , then the second situation of Section 5.3.2 might occur. Nevertheless, as n increases the length of interval A increases and thus the expected number of advertisements, from a single device within 10ms should be less than 1. We show below how the expected number of advertisements in a 10ms interval drops between $n = 1$ and $n = 2$. We consider $m(t)$, the expected number of events up to time t , defined as $F_X(t) + \int_0^t m(t-x)f_X(x)dx$, where $f_S(s)$ is the probability distribution of X_i which is equal to $\text{unif}(\text{adv}, \text{adv} + 10)$ and $F_X(t)$ is the cumulative distribution function given as:

$$F_X(t) = \begin{cases} 0 & t < \text{adv} \\ \frac{t-\text{adv}}{10} & \text{adv} \leq t \leq \text{adv} + 10 \\ 1 & t > \text{adv}. \end{cases} \quad (7)$$

During the first advertising interval, $t \in [\text{adv}, \text{adv} + 10]$, the expected number of advertisements is $\frac{\text{t-adv}}{10} +$

$\int_{\text{adv}}^t m(t-x)dx$ after substituting $F_X(t)$ and $f_X(x)$ with their corresponding expressions. After performing a substitution of variable of $y = t - x$, and since $m(t) = 0$ for $t < \text{adv}$, then $m(t) = \frac{t-\text{adv}}{10}$. So, if the expected advertising interval of the device hiding module overlaps with the first advertising interval of another advertising device, the expected number of events, $m(\text{adv} + 10) - m(\text{adv})$, will be 1, which is intuitive.

The second advertisement will take place at the interval $B = [2.\text{adv}, 2.(\text{adv} + 10)]$, and we use a similar procedure to derive the expressions for $m(t)$ for $t \in [2.\text{adv}, 2.\text{adv} + 10]$ and $t \in [2.\text{adv}, 2.(\text{adv} + 10)]$. If the expected advertising interval of the device hiding module overlaps with interval, B , then the expected number of advertisements $m(t+10) - m(t)$ will drop to $\frac{1}{2}$. The same trend will follow for the subsequent advertising intervals; the expected number of another device's advertisements within the expected advertising of the target BLE device will always be less than 1. Our evaluation in Section 6. confirms this observation.

Finally, even if another device, with the same advertising parameters, starts advertising with the target BLE device at the same time, their advertising events will eventually diverge. After N advertisements from both devices, the distribution of $Ta_{N+1} - Tb_{N+1}$, the difference in time between the $N + 1$ advertising instants of both devices will be a random variable with mean 0 but with $\sigma = 2.N.\frac{5}{\sqrt{3}}$. As N increases, the standard deviation increases, which in turn decreases the probability of both advertising events taking place within 10ms. The 10ms-advertising interval is the length of interval that the device hiding module expects the target BLE device to advertise.

Privacy in Epigenetics: Temporal Linkability of MicroRNA Expression Profiles

Abstract

The decreasing cost of molecular profiling tests, such as DNA sequencing, and the consequent increasing availability of biological data are revolutionizing medicine, but at the same time create novel privacy risks. The research community has already proposed a plethora of methods for protecting *genomic* data against these risks. However, the privacy risks stemming from *epigenetics*, which bridges the gap between the genome and our health characteristics, have been largely overlooked so far, even though epigenetic data such as microRNAs (miRNAs) are no less privacy sensitive. This lack of investigation is attributed to the common belief that the inherent temporal variability of miRNAs shields them from being tracked and linked over time.

In this paper, we show that, contrary to this belief, miRNA expression profiles can be successfully tracked over time, despite their variability. Specifically, we show that two blood-based miRNA expression profiles taken with a time difference of one week from the same person can be matched with a success rate of 90%. We furthermore observe that this success rate stays almost constant when the time difference is increased from one week to one year. In order to mitigate the linkability threat, we propose and thoroughly evaluate two countermeasures: (i) hiding a subset of disease-irrelevant miRNA expressions, and (ii) probabilistically sanitizing the miRNA expression profiles. Our experiments show that the second mechanism provides a better trade-off between privacy and disease-prediction accuracy.

1 Introduction

Since the first sequencing of the human genome in 2001, tens of thousands of genomes and over a million genotypes have been sequenced. The knowledge of our genetic background enables to better predict, and thus anticipate, the risk of developing several diseases, includ-

ing cancers, cardiovascular and neurodegenerative diseases. Moreover, the genomic research progress enables the development of personalized treatment through pharmacogenomics, studying the effect of the genome on drug response. One of the most important negative counterparts of this genomic revolution is the threat towards genomic privacy [11, 39]. Genomic data contains very sensitive information about individuals' predisposition to certain severe diseases, about kinship, and about ethnicity, all of which can lead to various sorts of discrimination. Furthermore, genomic data is very stable over time and correlated between family members [28]. Therefore, a lot of research has already been carried out to improve the genomic-privacy situation (most of the related literature is surveyed in [20, 42]).

However, our genome is not the only element influencing our health. Environmental factors (e.g., pollution, diet, lifestyle, ...) often play a crucial role in the development of most common diseases. Epigenetics (or epigenomics), transcriptomics, and proteomics aim to bridge the gap between the genome and our health status. Multi-omics research is a logical complementary step to genome sequencing: the DNA sequence tells us what the cell could possibly do, while the epigenome and transcriptome tell what it is actually doing at a given point in time. Using a computer analogy, if the genome is the hardware, then the epigenome is the software [16].

Despite the growing importance of epigenetics in the biomedical community, privacy concerns stemming from epigenetic data have received little to no attention so far. With the increasing understanding of epigenetics, it becomes clear that epigenetic data contains a vast amount of additional sensitive information, and can thus raise potential privacy risks. For example, a large number of severe diseases (such as cancers, diabetes, or Alzheimer's [21, 33, 46, 53]) are already identified to be affected by epigenetic changes and a recent study found that epigenetic alterations could even affect sexual orientation [43]. Furthermore, epigenetic data can potentially

tell us more about whether someone is carrying a disease at a given point in time, compared to the genome that only informs about the *risk* of getting certain diseases.¹ Moreover, it is still unclear whether the current genetic nondiscrimination laws would apply to epigenetic data. For instance, the US Genetic Information Nondiscrimination Act (GINA) is limited to genetic characteristics and epigenetic data might not be considered genetic information [18, 47].

In this work, we focus on microRNAs (abbreviated miRNAs), an important element of the epigenome discovered in the early 1990s. MiRNAs are small RNA molecules that regulate the majority of human genes. Studies of miRNA expression profiles have shown that dysregulation of miRNA is linked to neurodegenerative diseases, heart diseases, diabetes and the majority of cancers [21, 33, 40, 46, 53].² Therefore, miRNA expression profiling is a very promising technique that could enable more accurate, earlier and minimally invasive diagnosis of major severe diseases. As a consequence, it will certainly be increasingly used in medical practice.

In contrast to the DNA sequence, which mostly stays constant over time, it is believed in the biomedical community that the miRNA expression levels are varying sufficiently to invalidate any linkability attempts over time, thus naturally protecting personal privacy. This work, however, shows the contrary: despite their temporal variability, microRNA expression profiles are still identifiable and linkable after time periods of several months.

Contributions. In this paper, we study the temporal linkability of personal miRNA expression profiles, by presenting and thoroughly evaluating different attacks, and proposing defense mechanisms to enhance unlinkability.

Specifically, we first study an identification attack, which pinpoints a specific miRNA expression profile in a database of multiple expression profiles by knowing the targeted profile at another point in time. Second, we study a matching attack, which tracks a set of miRNA expression profiles over time. We rely on principal component analysis to pre-process the miRNA expression levels, and on a minimum weight assignment algorithm for the matching attack. We thoroughly evaluate these linkability attacks by using three different longitudinal datasets: (i) the blood-based miRNA expression levels of athletes at two time points separated by one week, (ii) the plasma-based miRNA expression levels of the same athletes at two time points separated by one week, and (iii) the plasma-based miRNA expression levels of patients with lung cancer over more than 18 months and eight time points. Our experimental results show that blood

miRNA expression profiles are about twice as easy to track over time compared to plasma miRNA profiles, and that the matching attack is more successful than the identification attack: We reach a success rate of 90% with blood and a success rate of 48% with plasma miRNAs in the matching attack whereas, in the identification attack, we reach a success rate of 76% with blood and 28% with plasma miRNAs. Moreover, we demonstrate that 10% of the miRNAs are already sufficient to achieve similar success rates as with all miRNAs. With the third dataset, we also observe that the attack achieves a similar success up to 12-month time periods.

We present two countermeasures to improve the unlinkability of miRNA expression profiles: (i) hiding a subset of the miRNA expressions, e.g., those that are not relevant for medical practice, and (ii) disclosing noisy miRNA expression profiles by adding noise in a differentially private and distributed manner. While the first countermeasure is useful especially in a clinical setting, in which the disease-relevant miRNAs are already known, the second countermeasure is intended to be better suited for the biomedical research community. In this context, as one of the objective is to discover associations between miRNAs and diseases, it is impossible to restrict the released data to only a few miRNAs.

We evaluate our protection mechanisms with the first aforementioned blood-based miRNA profiles of athletes and a fourth, also blood-based, miRNA dataset of more than 1,000 participants that includes information about 19 diseases (at a single point in time). The former is used to measure how temporal linkability is reduced with our countermeasures, whereas the latter helps us evaluate the evolution of accuracy (i.e., utility) in predicting patients' diseases from their miRNA expressions. The experiments show that it is possible to decrease linkability by at least 50% for almost no loss of accuracy (< 1%) for the majority of diseases with the noise mechanism. Moreover, our results demonstrate that the noise mechanism provides better privacy-utility trade-offs than the hiding method in 17 out of 19 of diseases, while allowing more flexibility in the data usage for biomedical researchers. This finding is reinforced by the fact that an adversary could use correlations between miRNA expressions to infer more miRNA expressions than those actually shared by our first countermeasure.

Organization. In Section 2, we present the biomedical background relevant to understand our work. In Section 3, we introduce the adversarial model. We then describe in detail our four datasets in Section 4. In Section 5, we present the analytical tools used to carry out our linkability attacks and our experimental results. In Section 6, we propose and evaluate countermeasures and compare their performance. We present the related literature in Section 7 before concluding in Section 8.

¹The only exception to this rule are Mendelian disorders, such as cystic fibrosis, which are largely determined by our genes.

²Known relations between miRNA and human pathologies can be found at <http://www.cuilab.cn/hmdd>.

2 Background

We briefly review the genetic concepts useful for understanding our paper. Epigenetics etymologically come from the combination of *epi*, which means “above”, “over” in Ancient Greek, and *genetics*, which means “origin”. This term broadly refers to the study of cellular and phenotypic trait variations stemming from other causes than changes in the genotype. These external factors are for example the in-utero or childhood development, environmental chemicals, aging or diet. Epigenetics can also refer to the changes themselves, such as DNA methylation and histone modification, which alter how genes are expressed without modifying the genome.

MicroRNAs (miRNAs) are epigenetically regulated mechanisms discovered in the early 1990s. MiRNAs are small non-coding RNA molecules that regulate gene expression in plants and animals. It has been shown that 60% of genes coding human proteins are regulated by miRNAs [25]. Whereas a miRNA is a RNA molecule containing around 22 nucleotides, *miRNA expression* is a real-valued number quantified in a two-step polymerase chain reaction (PCR) process. Different sets of miRNAs are expressed in different cell types and tissues.

Biomedical research is notably interested in discovering how miRNA expression affects physiological and pathological processes.³ Studies of miRNA expression profiling have demonstrated that dysregulation of miRNA is linked to neurodegenerative diseases (Alzheimer’s and Parkinson’s), heart diseases, diabetes, and the majority of cancers [21, 33, 40, 46, 53]. MiRNA expression profiling is hence a very promising technique that could enable more accurate, earlier and minimally invasive diagnosis of severe diseases. To mention one current, concrete application, miRNA expressions taken from *blood* samples suffice to detect several diseases, such as cancer or Alzheimer’s [34, 37]. In the following, we study the temporal linkability of miRNA expression profiles coming from blood and plasma (serum) samples.

3 Adversarial Model

We assume the adversary gets access to miRNA expression profiles of individuals at different points in time. Such epigenetic data is increasingly available in public research databases, such as the Gene Expression Omnibus (GEO) [4] or ArrayExpress [1] databases. Moreover, such data could be leaked through a major security breach, e.g., of a hospital server. Health data is

³Strictly speaking, miRNA is part of the epigenome while miRNA expression is generally considered more as part of the transcriptome. In this paper, we use the term epigenetics in its broad acceptance.

also increasingly available on the black market. For instance, cyber attacks against healthcare companies have increased by 72% from 2013 to 2014 [3]. Moreover, 91% of healthcare companies have experienced a violation of their databases over the last two years, and only 32% feel they have adequate resources to defeat these incidents [6]. Real-world cyber attacks show us that health data can be hacked en masse [5, 8] or that attacks can be more targeted towards high-profile victims [9]. Very sensitive medical data of thousands of patients can also end up online due to a human mistake [2].

In a typical scenario, the adversary would get access to miRNA expression levels of one or multiple individuals from a (private) health insurance or hospital database, and wants to match them with a (public) research dataset of miRNA expression levels at another point in time. A particularly sensitive scenario would be the matching of non-anonymized healthy miRNA samples with miRNA profiles that are known to be associated with diseases. Also note that researchers have demonstrated that RNA expression profiles could be matched to genotypes by relying on expression quantitative trait loci (eQTLs) [48]. Therefore, if the adversary can also access the genotypes of the victims, these genotypes provide him with further means for de-anonymizing the corresponding (micro)RNA expression profiles [26, 30]).

4 Dataset Description

Unlike in other fields of privacy research, where large amounts of data can be collected in a small amount of time and at low cost, in the health-privacy field we face the exact opposite: measuring the miRNA expression levels of one single sample already costs several hundred dollars. Longitudinal epigenetic data are particularly valuable, since patients have to regularly provide their biological samples over a long period of time. Therefore, the four datasets used throughout the paper, and described hereunder, represent very rich data.

We start by describing our three longitudinal datasets. The first dataset contains the blood-based miRNA expression levels of 29 well-trained male athletes (15 endurance athletes and 14 strength athletes) at two points in time, while the second dataset contains the plasma-based miRNA expression levels of those athletes at the same points in time.⁴ None of the athletes is known to be affected by a disease. The samples were taken prior and post exercising (time period of one week), similar to the data previously presented in [12]. The athletes followed a 6-day training with two training sessions a day, except at day 4 when only one session was scheduled.

⁴We selected blood and plasma since these two body fluids are likely candidates as source for biomarkers in future applications.

The tests were conducted at Saarland University (Germany) for the endurance athletes, and at Ruhr University Bochum (Germany) for the strength athletes.

In order to confirm our results, we make use of a third, independent dataset. This dataset contains the miRNA expression data of plasma of 26 lung-cancer patients (9 females and 17 males) over a period of more than 18 months [38], at eight time points: before surgery (tumor resection), two weeks after surgery (abbreviated A.S. in the graphs), and 3, 6, 9, 12, 15, and 18 months after surgery.⁵ The patients' ages range from 47 to 79. All three longitudinal datasets include the expression levels of 1,189 miRNAs for each individual at every time point.

Our last dataset contains the expression levels for 848 miRNAs collected from blood samples for each of 1,049 individuals [35] at only one time point. 94 of these individuals are considered to be healthy and are used as a control group in Section 6. Most of the rest represent cases, i.e., individuals carrying one out of the following 19 different diseases: 124 have Wilms tumor, 73 lung cancer, 65 prostate cancer, 62 myocardial infarction, 47 chronic obstructive pulmonary disease (COPD), 45 sarcoidosis, 45 ductal adenocarcinoma, 43 psoriasis, 37 pancreatitis, 35 benign prostate hyperplasia, 35 melanoma, 33 non-ischaemic systolic heart failure, 29 colon cancer, 24 ovarian cancer, 23 multiple sclerosis, 20 glioma, 20 renal cancer, 18 periodontitis, and 13 stomach tumor.

Note that a miRNA expression generally takes values between 0 (meaning the miRNA is not expressed at all) and tens of thousands. As we will mention later, we typically filter out miRNA whose median expressions among all individuals are smaller than 50, since these are non-expressed or not expressed enough to be significant.

While the last two datasets are both freely available in the GEO database (see accession number GSE68951 and GSE61741), the datasets consisting of athletes' miRNA expressions are not yet publicly available, but will be made available soon.⁶ We also discuss ethical considerations and how we handled these datasets in Appendix A.1.

5 Linkability Attacks

We study the extent of the linkability threat (as described in Section 3) by means of two attacks. First, we describe the mathematical principles behind our attacks, and then evaluate their success on our three longitudinal datasets.

⁵Note that for the last two points in time, we have the miRNA profiles of 25 and 22 patients, respectively.

⁶Please contact Andreas Keller for more information about the access to these datasets.

5.1 The Attacks

The first attack, called *identification attack*, refers to a scenario in which the adversary knows the miRNA expression profile of a targeted individual and aims at finding the corresponding miRNA expression profile in a database of n miRNA expression profiles, e.g., later in time. The second attack, called *matching attack*, refers to the case where the attacker has access to two databases of miRNA profiles collected at different points in time and wants to match their elements together.

For both our attacks, as there are more than 1000 known miRNAs with real-valued expression levels, we apply a pre-processing step using principal component analysis (PCA) with whitening. In particular, we apply the probabilistic PCA model proposed by Tipping and Bishop [49], which relies on singular value decomposition. This PCA step projects the high-dimensionality miRNA expression vectors to smaller-dimensionality uncorrelated components. The whitening step divides the resulting PCA components by the number of samples multiplied by the singular values in order to provide uncorrelated expression vectors of unit variance. We then make use of the Euclidean distance between the miRNA expression vectors projected on the first c principal components.

In the identification attack, we assume the adversary has had access to the miRNA profile $\bar{\mathbf{r}}_k^{t_1}$, vector containing the miRNA expressions of an individual k at time t_1 , and he wants to identify this individual in a database of n miRNA expression profiles $\{\bar{\mathbf{r}}_i^{t_2}\}_{i=1}^n$ collected at time $t_2 \neq t_1$. After having extracted the c principal components from the whole dataset by using PCA, the adversary ranks the n profiles (projected on the c components) $\{\bar{\mathbf{r}}_i^{t_2}\}_{i=1}^n$ by decreasing distance to the targeted miRNA profile (also projected on the c components) $\bar{\mathbf{r}}_k^{t_1}$ and picks the profile with minimum distance to the targeted profile. Formally, the adversary will select the profile $\bar{\mathbf{r}}_{i^*}^{t_2}$ where

$$i^* = \arg \min_i \|\bar{\mathbf{r}}_i^{t_2} - \bar{\mathbf{r}}_k^{t_1}\|_2.$$

In the matching attack, the adversary has access to two databases of miRNA expression profiles at two different time points t_1 and t_2 . We assume that the databases are of sizes n_1 and n_2 , both strictly greater than 1. First, if $n_1 = n_2 = n$, the adversary will assign one miRNA profile at time t_1 to exactly one profile at time t_2 . In this case, the best assignment σ^* is the one that minimizes the sum of the distances between every matched pair:

$$\sigma^* = \arg \min_{\sigma} \sum_{i=1}^n \|\bar{\mathbf{r}}_{\sigma(i)}^{t_2} - \bar{\mathbf{r}}_i^{t_1}\|_2.$$

This problem boils down to finding a perfect matching on a weighted bipartite graph, with n vertices on both

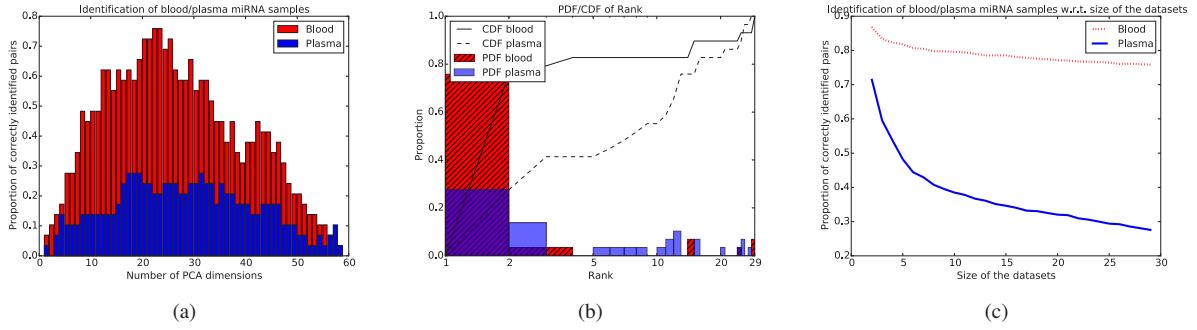

Figure 1: Success rate of the identification attack for the athletes dataset. (a) Proportion of successfully identified pairs plotted against the number of PCA dimensions (in $\{1, \dots, 58\}$). (b) Probability density function (PDF) and cumulative distribution function (CDF) of obtained ranks. (c) Proportion of successfully identified pairs plotted against the number of miRNA expression profiles.

sides representing the miRNA profiles, and a weight on each edge representing the Euclidean distance between any pair of miRNA profiles (vertices), projected on the first c principal components. We want to find the matching among $n!$ possible assignments that minimizes the sum of the weights between vertices. Fortunately, there exist several algorithms in the literature that find the minimum weight assignment in polynomial time. We use the blossom algorithm [19], because it only has a complexity of $O(n^3)$ and it can also be applied to general graphs.

If $n_1 \neq n_2$, we fill the smallest side of the bipartite graph with dummy vertices. Then we assign infinite weight to all edges from actual vertices to these dummy vertices in order to ensure that the dummy vertices will be the least likely assigned to the vertices in the largest side that are also present in the smallest side.

5.2 Experimental Results

We evaluate how successful both aforementioned attacks are in breaking the privacy of our three longitudinal datasets. We implement the attacks in Python, and make use of the libraries Scikit-learn [13, 44] (for PCA) and NetworkX⁷ (for the graph matching).

5.2.1 Identification Attack

In this subsection, we evaluate the success of an adversary, who aims at identifying the miRNA profile of a targeted individual in a longitudinal dataset. As mentioned in Section 4, the first two longitudinal datasets contain miRNA expression levels of 29 individuals collected at a time interval of one week.

First, we compare the success rate for correctly identifying samples for all possible PCA dimensions. Fig. 1(a)

indicates that the blood's miRNA expression levels are easier to identify over time than the plasma's miRNA expression levels. When identifying samples by their blood miRNA expression levels, we can reach a maximum success rate of 76% for the blood with 22 or 23 PCA dimensions. The maximum success rate for the plasma is 28% with 17, 18, 19 or 31 PCA dimensions. Note that both achieve their highest success with a number of PCA dimensions around 20.

Next, we rank the miRNA profiles at time t_2 in order of increasing distance to the targeted profile $\mathbf{r}_k^{t_1}$. Fig. 1(b) shows the rank of the correct sample $\mathbf{r}_k^{t_2}$ by using 22 PCA dimensions for the blood and 18 PCA dimensions for the plasma. The correct profile is ranked within the top 2 profiles in more than 40% of the cases for the plasma, whereas the correct sample is ranked within the top 2 samples in 80% of the cases for the blood.

In order to get an impression on the attack's performance on larger datasets, we also analyze the success of the identification attack with respect to the number of participants in the dataset, i.e., we vary the number of profiles among which the attacker has to identify the targeted miRNA profile, again using 22 PCA dimensions for the blood and 18 PCA dimensions for the plasma. Intuitively, when the number of miRNA samples increases, the success rate of the attacker should decrease. In this experiment, we adjust the number n of miRNA profiles between 2 and 29 and evaluate the attacker's success on a subset of our datasets. In particular, for each number of profiles n , we randomly choose 1000 different combinations (or fewer if necessary) of n out of 29 miRNA profiles and run the identification attack on every sample within this subset. Fig. 1(c) depicts the average success rates for each number of profiles n . As expected, the success rate monotonically decreases with the number of participants for blood and plasma samples. For plasma,

⁷<https://networkx.github.io>

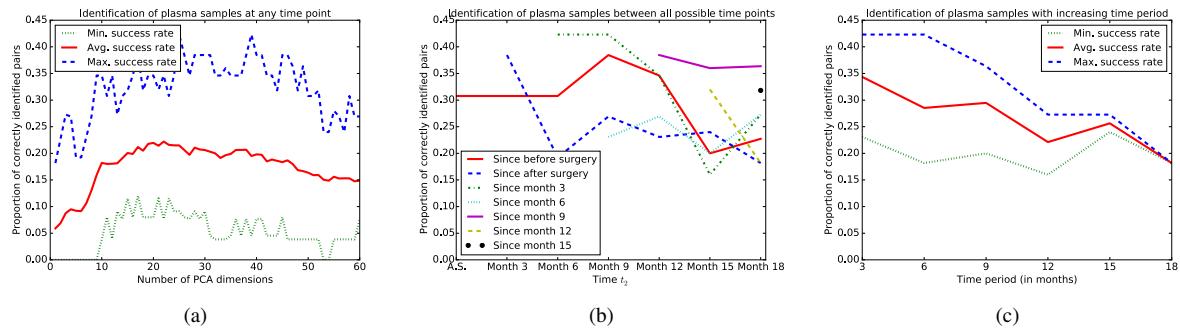

Figure 2: Success rate of the identification attack for the lung cancer dataset. (a) Success rate aggregated over all identifications between any t_1 and t_2 plotted against the number of PCA dimensions. (b) Success rate of identifying the miRNA profiles between time pairs t_1 and t_2 . (c) Success rate plotted against the time period between t_1 and t_2 .

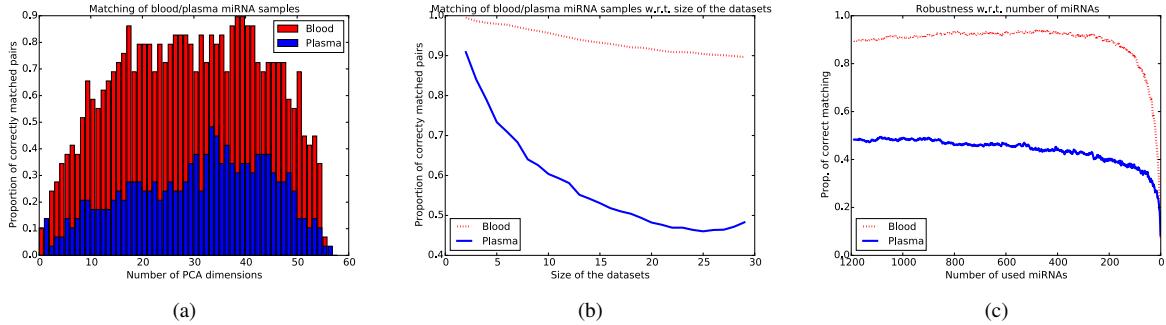

Figure 3: Success rate of the matching attack for the athletes dataset. (a) Proportion of successfully matched pairs plotted against the number of PCA dimensions. (b) Proportion of successfully matched pairs plotted against the number of miRNA profiles. (c) Proportion of successfully matched pairs plotted against the number of revealed miRNAs.

however, this decrease is much sharper, confirming that the blood's miRNA expression levels provide means for easier identification. From the curves' slopes, we can predict that, for larger datasets, blood based samples will still be subject to a relatively high identification success.

In order to validate our findings, we also evaluate our experiments on our other longitudinal, independent dataset containing plasma miRNA profiles from 26 individuals with lung cancer collected over up to eight different points in time.

First, we evaluate the attacker's success with respect to a varying number of PCA dimensions. Fig. 2(a) depicts the minimum, average and maximum success rate of an attacker when identifying the samples between different points in time, irrespective of the time period between them. The maximum success rate for the identification attack is 42% and is achieved for 25 and 39 PCA dimensions. The usage of 22 PCA dimensions yields the highest average success rate, of 22%. The highest minimal success rate in the dataset is achieved for 17 PCA dimensions (12%).

These results are similar to what we obtained in our experiments for the athletes dataset: The best results are achieved for a number of PCA dimensions around 20 in both datasets. The highest average success rate lies 6 points below the best success rate for the athletes dataset. This could be explained by longer time periods in this dataset. However, for some time periods, we can achieve one and a half the success rate of the first dataset. When comparing the top 10 miRNAs contributing to the first PCA dimension in this dataset and in the athletes' plasma dataset, we also find an overlap of 80% between these miRNAs. This indicates that approximately the same set of miRNAs can be used to differentiate plasma expression profiles between individuals in both datasets. Thus, we can conclude that, while miRNA expression levels are directly linked to health status, the health status only affects a subset of the miRNAs, which has only little effect on the temporal linking.

To further investigate the effect of different time periods on the attacker's success, we plot the maximum success rates between all possible, ascending combinations

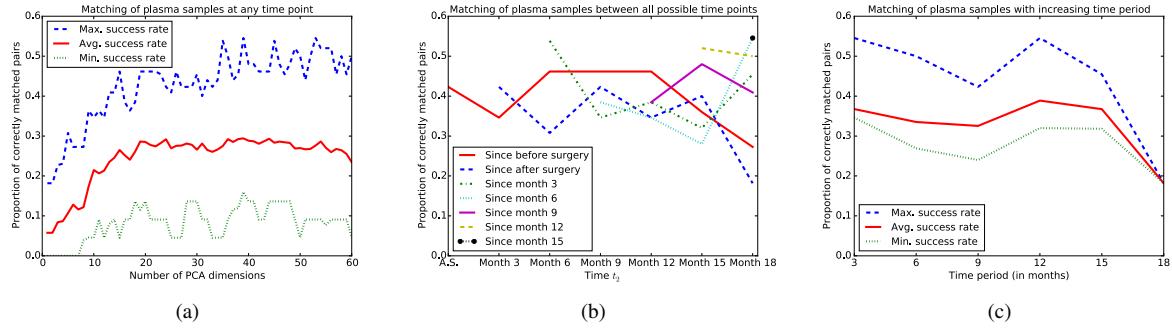

Figure 4: Success rate of the matching attack for the lung cancer dataset. (a) Success rate aggregated over all matchings between any t_1 and t_2 plotted against the number of PCA dimensions (in $\{1, \dots, 60\}$). (b) Success rate of matching the miRNA profiles between time pairs t_1 (various curves), t_2 (x-axis value). (c) Success rate plotted against the distance between t_1 and t_2 .

of points in time in Fig. 2(b). With only a few exceptions, the best success rates are most often achieved for consecutive time points. The only two exceptions are found for $t_1=\text{before the surgery}$ and $t_1=\text{the sixth month after the surgery}$. In general, however, we notice a tendency of slight decrease in success over an increasing time period.

In order to verify this finding, we group the results by the period between t_1 and t_2 (Fig. 2(c)). Note that, since we do not know the time period between before the surgery and after it, we leave out all results that use samples collected before the surgery. Clearly, the best achievable success rate drops for increasing time periods. This decrease over larger periods of time can partially explain the lower average success rate in this dataset compared to the athletes' dataset (considering a much smaller time period).

Next, we computed the guessing entropy [14, 41] for the identification attack. The guessing entropy $E[G(X)]$ is the expected number of guesses an adversary would need to identify the correct sample at a different point in time. For the identification attack it is given by $E[G(X)] = \sum_{i=1}^n i \cdot \Pr[X = i]$, where X denotes the rank of the correct sample at time t_2 and $\Pr[X = i]$ denotes the empirical probability that the correct sample is ranked at the i^{th} position.

For blood-based samples of our athletes dataset, the attack can achieve a guessing entropy just below 4, clearly outperforming random guesses, which would yield an entropy of 15 guesses on average. For plasma-based samples of the same dataset, the attack yields an entropy of approximately 9 guesses. This result is consistent with the results on the lung cancer dataset, where, on average, an adversary would need just fewer than 9 guesses (compared to a guessing entropy of 13.5 for random guesses). Moreover, for some t_1 and t_2 , the attack is even able to achieve a guessing entropy smaller than 6.

5.2.2 Matching Attack

We evaluate here the success of the adversary, who tries to link all participants over time, again for the three aforementioned longitudinal datasets. Starting with the athletes' datasets, we compare the success rate of matching the blood and the plasma over all possible PCA dimensions for 29 participants. In Fig. 3(a), we notice the same behavior as in the identification attack: the blood based miRNA expression levels are much easier to link over time than the plasma based levels. We even reach a higher maximum absolute success rate than in the identification attack: 90% with 39 or 40 PCA dimensions for the blood and 48% success with 34 PCA dimensions for the plasma samples.

The identification attack's lower success rate is due to the fact that it is evaluated for each sample individually, thus allowing multiple samples at t_1 to be linked to the same (potentially wrong) sample at t_2 . Since our perfect matching attack rules out those cases by forcing each profile at t_2 to be matched to exactly one profile from t_1 , it also decreases the number of wrongly matched samples.

Next, we also analyze the success of the attack with respect to the number of participants to be matched together. Intuitively, the more miRNA profiles there are, the more challenging it should be for the adversary to match them at different time points. Again, we make the number of participants n vary between 2 and 29 at both time points, again randomly sampling 1000 combinations (or fewer, if there are fewer than 1000 combinations) and averaging the result. Fig. 3(b) shows the expected trend of decreasing success for the blood miRNA samples. The plasma scenario monotonically decreases between 2 and 25 participants and then slightly increases until 29. This artifact could be explained by the smaller number of random combinations, and thus experiments, when $n > 26$. We also find that the blood attack faces

a rather linear decrease in success whereas the plasma success rate decreases much faster. By extrapolating this linear trend, we can expect a success rate as high as 60% with 120 participants in the datasets. Therefore, we again conclude that the blood has miRNA expression levels that enable much easier tracking over time than the plasma, which is consistent with the results of the identification attack.

Fig. 3(c) investigates how the attack’s success evolves when revealing only a subset of the miRNA expression levels. We gradually drop individual miRNAs in random order and compute the attack’s success. The figure shows the success rate (for each possible number $m \in \{1189, 1188, \dots, 2, 1\}$ of miRNAs) averaged over 50 randomly chosen orderings of miRNAs. We notice that the attack’s success is very stable, especially for the blood samples, from 1189 to 200 miRNAs. For the blood, the success decreases below 80% the first time when there are fewer than 100 miRNAs available to the adversary. We further study the implications of this robustness in the context of our countermeasures in Section 6.

We also made use of our third longitudinal dataset containing plasma miRNA expression profiles of 26 individuals over up to eight different time points (cf. Section 4). In Fig. 4(a), we see that the average success rate reaches its maximum at a number of PCA dimensions very close to the number of dimensions for the athletes dataset, i.e., 34. However, this maximum is approximately 30%, which is smaller than the 48% reached for the first dataset. A greater period between time points could explain this behavior, and we also see that we can still reach a maximum success rate of 55% between some time points, with 39 PCA dimensions. We explore the time effect in deeper details in the following figures.

Fig. 4(b) depicts the maximum success rate between any pair of time points t_1, t_2 . For instance, the solid red line shows the success rates between $t_1 = \text{before surgery}$ and all others. It is difficult to detect any trend with respect to the time period in the different curves, except a slight decrease when the time period is higher or equal to 15 months. This is confirmed by Fig. 4(c) that depicts the maximum, average, and minimum success rate with respect to the period between t_1 and t_2 . We clearly notice a decreasing rate between 3 and 9 months, an increase to 12 months, and finally clear decrease towards 15 and 18 months.

6 Countermeasures

In this section, we propose and evaluate two main defense mechanisms for preventing miRNA expression data from being tracked over time. The proposed techniques are based on well-established privacy-enhancing

methods, previously applied in other privacy contexts, such as location privacy. The first approach relies on a quite straightforward technique: release only a subset of the miRNAs. We can already see from Fig. 3(c) of Section 5 that the matching attack is quite robust to a decrease in the number of miRNAs. Nevertheless, we show hereafter how we can keep a high utility in combination with unlinkability of expression profiles over time by revealing a small subset of miRNAs. The second countermeasure consists in adding noise to the released miRNA expression vectors, independently for every individual. This method shows very promising results, reaching an even better privacy-utility trade-off than the hiding mechanism. Furthermore, we also investigate the effect of correlations between miRNA expression levels and present the privacy evolution when the adversary can infer missing miRNAs by using these correlations.

For evaluating the privacy provided by our defense mechanisms, we focus on the matching attack against blood-based miRNAs, as this constitutes the worst-case attack from a privacy perspective, as shown in Section 5. Moreover, we assume the attacker is able to select the number of PCA dimensions that maximizes his success. This provides us with a conservative measure of privacy, showing the worst-case privacy levels individuals can expect.

6.1 Baseline Utility

Before presenting the proposed countermeasures and their efficiencies, we must carefully define the context in which they should apply. Indeed, we can rarely have both perfect privacy and maximum utility, so that we often need a trade-off between these two. Therefore, the efficiency of the defense mechanism cannot only be judged based on the privacy metric, but must also relate to the utility brought in the context in which the data is used.

According to biomedical experts, miRNA expression profiles have strong potential to help predict various severe diseases, from cancer to Alzheimer’s disease. Biomedical researchers typically rely on standard machine learning algorithms to identify which miRNAs are playing a significant role in the disease of interest. They are dealing with binary classification, between cases (carrying the disease) and controls (healthy), and most often rely on support vector machines (SVMs). In particular, they typically use radial basis function SVMs and select a subset of features by subsequently adding miRNAs in order of their significance values (e.g., p -values computed by the Wilcoxon-Mann-Whitney (WMW) test) [37] or equivalently in order of their area under the ROC curve (AUC). Given samples of cases and controls, the accuracy is then defined as the number of correctly classified samples divided by the

Disease	Maximum accuracy with the best subset of expressed miRNAs (# miRNAs)	Accuracy with all expressed miRNAs
Periodontitis	0.941 (37)	0.88
Renal cancer	0.988 (32)	0.962
Wilms' tumor	0.95 (150)	0.937
Benign prostate hyperplasia	0.921 (105)	0.883
Chronic obstructive pulmonary disease	0.932 (70)	0.886
Colon cancer	1.0 (30)	0.997

Table 1: Accuracy of the SVM algorithm in classifying individuals between cases (carrying the disease) and controls (healthy), for 19 diseases, without countermeasure.

total number of samples. Note that we compute the average accuracy over a repeated k -fold cross-validation.

In this work, we define the utility as the accuracy of the SVM classifier, as defined above. We use a 10-fold cross-validation with 5 repeats (using R and the caret⁸ library) and determine the miRNAs' p -values by using the WMW test and adjusting the significance values for multiple tests using the Benjamini-Hochberg adjustment. The WMW test statistic is applied for each miRNA individually in order to test whether this miRNA has similar expressions between cases and controls (null hypothesis). The p -values then provide us with the relevance of the miRNA to the disease of interest. In contrast to the t -test, the WMW test can be applied on unknown distributions. This way, we follow the standard procedure of biomedical research. Table 1 shows the accuracy of

our SVM algorithm applied on our 1000+ participants dataset to predict 19 diseases, without any obfuscation. The maximum accuracy here is what we refer to as the baseline utility in the subsequent subsections.

Note that, before running the SVM algorithm, we filter out non-expressed miRNAs, i.e., those with a median level of expression smaller than 50 over the 1000+ individuals, which leaves us with 446 expressed miRNAs.

6.2 Hiding MicroRNA Expressions

The first countermeasure that we study is miRNA expression hiding. This obfuscation technique has the advantage to be non-perturbative, i.e., to preserve the correct values of all revealed miRNA expressions. However, as we have seen in Section 5, the attacks are extremely robust to removal of miRNAs. In the following, we want to find an optimal trade-off between the diagnosis accuracy, i.e., the utility, and the unlinkability of the data, i.e., the privacy. To this end, we make use of both our blood-based datasets, the 1000+ dataset with blood-based miRNA expressions to run our SVM algorithm and the athletes' dataset with blood-based miRNAs to evaluate the level of privacy. Note that we filter both datasets' miRNAs in order to have the same set of 446 miRNAs in both cases. While we measure the utility in terms of accuracy of the SVM, the privacy is measured in terms of the maximum achievable success rate (over all possible PCA dimensions) of our matching attack.

Figure 5 shows the evolution of privacy and utility for a range of 1 to 100 disclosed miRNAs, for 6 different severe diseases.⁹ We focus on this range of miRNAs as: (i) for more than 100 miRNAs, the attack's success rate is approximately the same as the one without countermeasure, and (ii) the SVM can already achieve very high accuracy with up to 100 miRNAs. We gradually reveal the miRNAs in decreasing order of significance (based on p -values), as computed in Subsection 6.1.

Figure 5 demonstrates that there exists a trade-off between the utility of miRNA expressions and the privacy of the contributors' data. Note that we also depict the relative decrease in accuracy compared to the maximum SVM accuracy computed in Subsection 6.1 and the relative decrease in the attack's success (increase in privacy) compared to the attack's success with all miRNAs, i.e., 90%. We see that the relative decrease in accuracy is almost always smaller than 10%. The only exceptions to this are with pancreatitis and melanoma, for fewer than 3 disclosed miRNAs. Moreover, regarding the privacy, the figures show that we can never reduce the attack's success by more than 50% when revealing more than 20

⁸caret.r-forge.r-project.org

⁹These are representative of the behavior of all 19 diseases we tested our privacy-preserving mechanisms on.

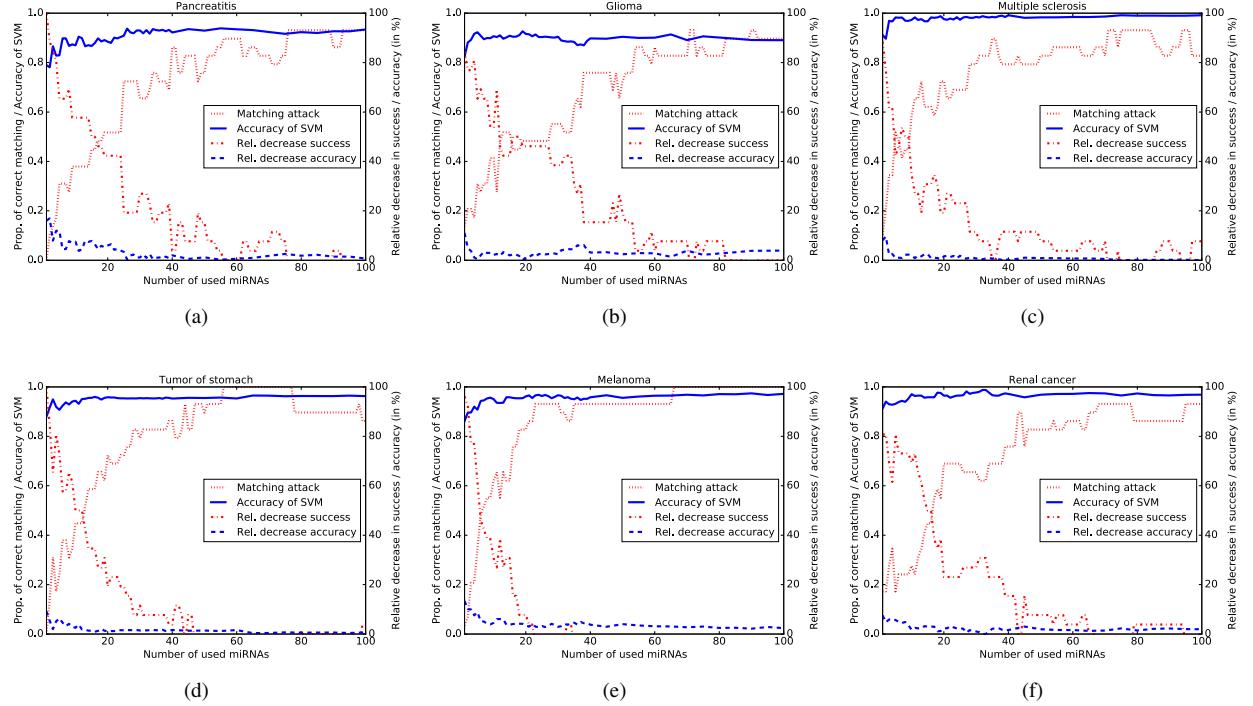

Figure 5: Evolution of privacy (unlinkability) and utility (classifier accuracy) plotted against the number of released miRNAs for the following diseases: (a) Pancreatitis, (b) Glioma, (c) Multiple sclerosis, (d) Tumor of stomach, (e) Melanoma, (f) Renal cancer. The *relative decrease success* curve refers to the decrease in success of the matching attack compared to the success without countermeasure. Similarly, the *relative decrease accuracy* curve refers to the decrease in accuracy of the SVM classifier with respect to the case without protection mechanism.

miRNAs. Nevertheless, within the range of 3 to 20 disclosed miRNAs, we can find, for all diseases, a satisfactory trade-off between utility and privacy.

In particular, for glioma, we can decrease the linkability attack’s success and thus improve the privacy by 80.8% when using 4 miRNAs, while reducing the classification accuracy by only 1.1%. Similarly for multiple sclerosis, 7 miRNAs provide an increase in privacy of 53.8%, while the decrease in accuracy only amounts to 0.9%. For renal cancer and 10 miRNAs, we are able to achieve an improvement in privacy of 69.2% and a decrease of accuracy of only 1.7%. There are only two diseases for which it is very difficult to have both unlinkability and very high utility: melanoma and pancreatitis. For melanoma, we notice that the matching attack’s success has a fast increase with very few miRNAs, and already exceeds 50% starting with only 7 miRNAs. For pancreatitis, the SVM’s accuracy is relatively low (compared to the maximum) for the first 20 miRNAs. Thus for both diseases, either privacy or utility would have to be slightly sacrificed for the other.

MiRNA co-expression. Like between variants in the genome, there exist correlations between miRNA expressions: around 40% of miRNAs are not independently expressed [7]. This means that the adversary, by knowing these correlations, could increase his knowledge about the non-disclosed miRNA expressions. In order to evaluate the importance of such correlations, we first compute the Pearson’s correlation coefficients, and their corresponding p -values, in all 99,235 pairs of the 446 expressed miRNAs in our fourth dataset. Filtering out all correlations with p -values greater than 0.001 (after Bonferroni correction for multiple correlations’ testing) or correlation coefficient smaller than 0.5 leaves us with 47% of miRNAs not independently expressed. Figure 6 shows the updates of the linkability attack’s success by taking into account all significant correlations as defined above. In our experiments, we take a quite conservative approach: We assume that the adversary can perfectly infer the miRNAs correlated with those that are gradually disclosed. The dotted curve provides an upper bound estimate on the success rate. A tighter bound could be derived by knowing more precisely the probabilistic dependencies between miRNAs. This is left for future work.

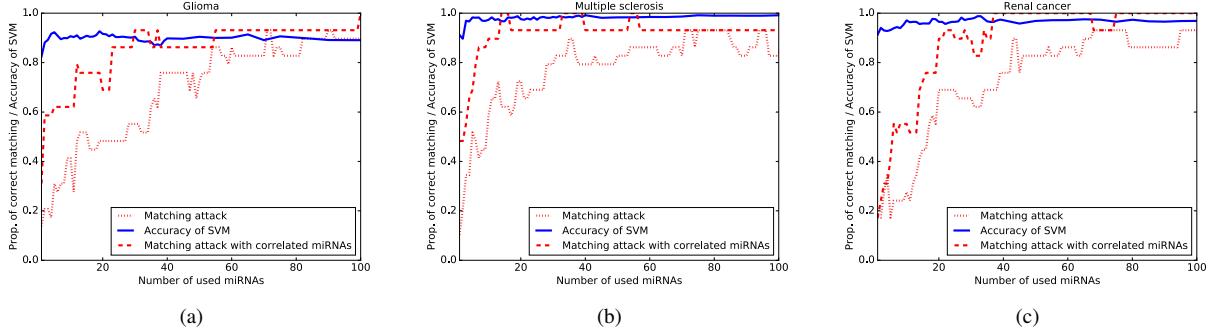

Figure 6: Correlations between miRNAs. Evolution of privacy and utility, when miRNAs correlated with the revealed miRNAs are taken into account for the attack. This provides an upper bound on the best linkability of miRNA expression profiles, i.e., worst-case privacy level. (a) Glioma, (b) Multiple sclerosis, (c) Renal cancer.

For Fig. 6, we make use of the three diseases of Figure 5 that gave best trade-off between privacy and utility, i.e., glioma, multiple sclerosis and renal cancer. We observe that the success rate knowing miRNAs correlated with disclosed miRNAs is much higher than without them, except for the very first miRNAs in Fig. 6(c). It shows that the most significant miRNAs for the SVM classification are co-expressed with others, which penalizes privacy significantly. Making use of the best subsets of miRNAs found above without correlations, containing 4 miRNAs for glioma, 7 for multiple sclerosis, and 10 for renal cancer, we evaluate the new privacy levels when miRNA correlations are taken into account. For glioma, instead of improving unlinkability by 80.8%, the 4 miRNAs and their correlated miRNAs yields an improvement in privacy of 34.6%. For renal cancers, the privacy enhancement drops from 69.2% to 38.5% and, for multiple sclerosis, knowing 7 miRNAs and their co-expressed miRNAs yield an attack’s success rate almost equal to the highest rate with the full set of miRNAs. However, we can find new, better trade-offs: e.g., disclosing 5 miRNAs for multiple sclerosis still provides the same high SVM accuracy (decrease of 0.9% compared to the baseline) while reducing the attack’s success by 23%. Note that we do not make use of the correlated miRNAs for the SVM algorithm as we are not certain about how they correlate with the disclosed ones.

6.3 Noise Mechanism

As we have noticed in the first protection mechanism, it is possible to hide the vast majority of miRNAs while retaining a fair level of prediction accuracy. This is typically very useful in the clinical setting where medical practitioners already know the miRNAs to test for predicting a specific disease. However, such a privacy-preserving mechanism could dramatically jeop-

ardize miRNA utility for biomedical research. Indeed, as we have seen in our previous experiments, the majority of miRNAs need to be masked in order to gain a significant amount of unlinkability, which is not possible if researchers want to test for associations between miRNAs and diseases. Therefore, we additionally present and study a countermeasure where contributors of miRNA expressions directly apply random noise to their vectors of expression levels before providing them to the research community (possibly online), in a fully distributed manner (i.e., independently of other contributors).

The idea behind adding noise to the raw expression data is to provide indistinguishability between different expression vectors and consequently reduce the tracking capabilities of the adversary. Following the generalized notion of differential privacy [15] previously applied to location privacy [10], we state that a mechanism K achieves *epigeno-indistinguishability* if and only if, for all m -miRNA expression vectors $\mathbf{r}_1, \mathbf{r}_2$,

$$Pr(K(\mathbf{r}_1) \in \mathcal{S}) \leq exp(\epsilon d_2(\mathbf{r}_1, \mathbf{r}_2)) \times Pr(K(\mathbf{r}_2) \in \mathcal{S}),$$

where \mathcal{S} is any subset of the set of possible responses and $d_2(\cdot, \cdot)$ denotes the Euclidean distance. In the following, we assume the set of possible responses lies in the same m -dimensional real-valued space \mathbb{R}^m as the set of original expression vectors. Before defining our mechanism $K(\cdot)$ for achieving epigeno-indistinguishability, let us first give some intuition about the mechanism. The noise mechanism is such that the probability of reporting a noisy expression vector $K(\mathbf{r})$ differs by at most a factor $exp(\epsilon d_2(\mathbf{r}_1, \mathbf{r}_2))$ when the actual, non-obfuscated miRNA expression vectors are \mathbf{r}_1 and \mathbf{r}_2 . This can be achieved by relying on the multivariate Laplacian mechanism that adds noise \mathbf{x} according to the following probability density function $g(\mathbf{x}) = \frac{1}{\alpha} e^{-\epsilon \|\mathbf{x}\|_2}$, where α is a normalization factor ensuring that the integral over all $\mathbf{x} \in \mathbb{R}^m$ equals one.

Sampling noise from the distribution $g(\mathbf{x})$ can be carried out efficiently by generalizing the method used for the planar Laplacian mechanism in [10]. First, we sample the magnitude $\|\mathbf{x}\|_2$ of the noise from a gamma distribution with shape m and scale $1/\epsilon$. Second, we randomly generate the direction $\hat{\mathbf{x}} = \mathbf{x}/\|\mathbf{x}\|_2$ of the noise by uniformly sampling points on the surface \mathbb{S}^{m-1} of a hypersphere [36]. To do so, we can generate m independent Gaussian random variables y_1, y_2, \dots, y_m , and let $\hat{y}_i = y_i / \sqrt{y_1^2 + \dots + y_m^2}$ for $i = 1, \dots, m$. Then the distribution of the vector $\hat{\mathbf{y}} = (\hat{y}_1, \dots, \hat{y}_m)$ is uniform over the surface \mathbb{S}^{m-1} , and thus we can set the direction $\hat{\mathbf{x}} := \hat{\mathbf{y}}$. Each person i contributing his miRNA expression profile \mathbf{r}_i will then share, instead of the actual expression data, the noisy vector $K(\mathbf{r}_i) = \mathbf{r}_i + \mathbf{x}$, where \mathbf{x} is independently generated for all participants $i = 1, \dots, n$.

Following this approach, in our evaluation, we first add noise to our dataset of 1000+ individuals (considering only the 446 miRNAs as before). Then, in the second step, we calculate the p -values on the noised data (since the researchers would be provided with exactly this data) and train the SVM the same way as in the previous subsections by subsequently adding miRNAs in the order of their p -values. Similarly, we evaluate the success of our attack on the athletes' dataset, when considering the same 446 miRNAs, but after adding noise. Moreover, we repeat both our experiments 50 times and average the results over all runs.

Figure 7 shows the evolution of the SVM accuracy and linkability (success of the attack), with respect to the amount of noise, tuned by ϵ , that is added to each contributor's miRNA expression profile. As privacy is measured on the same dataset for all six figures, its evolves in a very similar way. Even if the noise is randomly generated, the differences average out with the Monte Carlo method we use. We clearly see that with $\epsilon = 1$, there is almost no privacy gain compared to the attack without countermeasure, whereas for $\epsilon = 0.001$, the attack's success drops by almost 90%. Of course, as for the first countermeasure, there is a utility-privacy trade-off to be found between these two extreme values.

In Figure 7(a), we can observe that, for pancreatitis, $\epsilon = 0.075$ is a good trade-off, with an accuracy decrease of only 0.8% and an unlinkability improvement of 40%. For glioma (Figure 7(b)), the best trade-off is certainly at $\epsilon = 0.05$, with an accuracy decrease of 1.2% and an unlinkability improvement of 51%. For multiple sclerosis, we reach the best trade-off at $\epsilon = 0.025$ with an accuracy decrease of 0.65% and an unlinkability improvement of 63%. For tumor of stomach, we can reach an accuracy decrease of only 0.2% and still improve the unlinkability by as much as 70% with $\epsilon = 0.01$. For renal cancer, we have to sacrifice a bit more of utility, 2.3%, for a privacy

increase of 61%, with $\epsilon = 0.025$. The only disease for which it is quite difficult to get both satisfactory unlinkability and excellent accuracy is melanoma (Figure 7(e)). This is consistent with the hiding mechanism presented in Subsection 6.2, where we observed (in Figure 5(e)) a fast and sharp increase in the linkability attack's success.

6.4 Comparison of Protection Mechanisms

In order to compare both approaches, we decide upon a utility or a privacy requirement, fix it, and then evaluate the best privacy, respectively utility, achieved with both countermeasures. We carry out this evaluation on all 19 diseases for different requirements of utility and privacy.

First, we start by fixing the utility, more precisely the relative accuracy decrease compared to the baseline accuracy. The privacy is measured in terms of the decrease in the matching attack's success. For a given maximal decrease in accuracy $\Delta_{\text{acc}}^{\max}$, we select the optimal number of miRNAs m^* and the optimal amount of noise ϵ^* that maximize the privacy increase Δ_{priv}^m and $\Delta_{\text{priv}}^\epsilon$. In case of the hiding mechanism, we select $m^* = \arg \max_m \Delta_{\text{priv}}^m$ such that $\Delta_{\text{acc}}^m < \Delta_{\text{acc}}^{\max}$. In case of the noise mechanism, we select $\epsilon^* = \arg \max_\epsilon \Delta_{\text{priv}}^\epsilon$ such that $\Delta_{\text{acc}}^\epsilon < \Delta_{\text{acc}}^{\max}$, respectively.

Considering $\Delta_{\text{acc}}^{\max} \in \{0.5\%, 1\%, 2\%, 3\%, 4\%, 5\%\}$ for all 19 diseases, we mostly experience that the noise mechanism provides a better privacy improvement compared to hiding a subset of miRNAs (all results are in Table 2 in the appendix). In particular, 90 out of 114 cases (combinations of disease and $\Delta_{\text{acc}}^{\max}$) yield a better privacy with the noise mechanism. When examining a maximal decrease in accuracy of 2%, the hiding technique provides a better privacy for only 2 diseases, namely glioma and renal cancer. Interestingly, these two diseases stand out also for other values of the maximal accuracy decrease, providing better privacy with the hiding technique in 10 out of 12 cases. However, for all other diseases, adding noise in a distributed manner to individual expression profiles provides better utility for similar levels of privacy. For example, for lung cancer, we are able to achieve an increase in privacy of 79.3% while maintaining a decrease in accuracy of 0.8% using noise with $\epsilon = 0.005$. The best we can achieve for the hiding technique here is either a decrease in accuracy of 0.97% and an increase in privacy of only 46.2% or a larger decrease in accuracy of 1.9% and a privacy improvement of only 50%.

Next, we discuss the results for a fixed minimal improvement of the privacy and compare the corresponding minimal decrease in accuracy in both countermeasures. We now fix the minimal increase in privacy (i.e., the minimal decrease in the attack's success) $\Delta_{\text{priv}}^{\min}$ and minimize the decrease in accuracy: $\arg \min_m \Delta_{\text{acc}}^m$ such

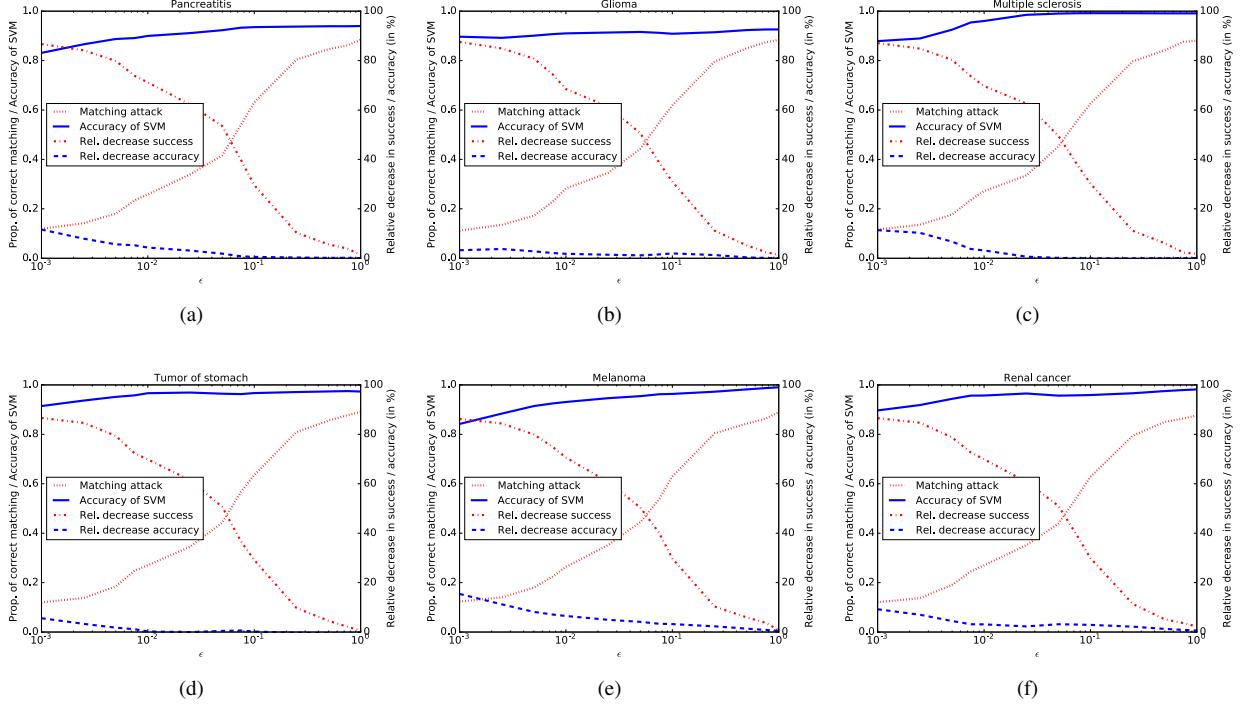

Figure 7: Evolution of privacy and utility (classifier accuracy) plotted against the noise (tuned by ϵ) added to the individual miRNA expression profiles, for the following diseases: (a) Pancreatitis, (b) Glioma, (c) Multiple sclerosis, (d) Tumor of stomach, (e) Melanoma, (f) Renal cancer.

that $\Delta_{\text{priv}}^m > \Delta_{\text{priv}}^{\min}$ and $\arg \min_{\epsilon} \Delta_{\text{acc}}^{\epsilon}$ such that $\Delta_{\text{priv}}^{\epsilon} > \Delta_{\text{priv}}^{\min}$, respectively. We run experiments for values of $\Delta_{\text{priv}}^{\min}$ from 10% up to 90%, in steps of 10% (all results are provided in Table 3 in the appendix).

We again observe that, for most of the evaluated cases, the achieved accuracy is better when adding noise than when hiding miRNAs. In particular, this holds true for 143 out of 171 cases, clear exceptions being again glioma and renal cancer. For those two diseases, the hiding technique provides better accuracy than the noise mechanism in 87.5% of the cases. When fixing the minimal increase in privacy to 70%, only these two diseases provide better results with the hiding technique. For instance, with renal cancer, we achieve 60.8% improvement in privacy with a decrease in accuracy of 2.3% using noise with $\epsilon = 0.025$, whereas we can obtain an increase in privacy of 69.2% and a decrease in accuracy of only 1.7% when using the hiding technique. For the majority of diseases, however, it is clearly the noise mechanism that provides much higher utility. For example, for lung cancer, an increase in privacy of at least 70% is achievable with a decrease in accuracy of only 0.2% with the noise mechanism, while the hiding technique yields a decrease in accuracy of 11.2%.

In summary, we find that the noise mecha-

nism presented in Section 6.3, providing epigeno-indistinguishability, is able to achieve a better privacy-utility trade-off than the hiding mechanism for the vast majority of studied diseases (17 out of 19). We have also shown in Section 6.2 that the privacy improvement with the hiding mechanism could actually be too optimistic due to the correlations existing between miRNAs. This is another argument to favor the noise mechanism rather than the hiding technique. Moreover, the p -values used to rank the miRNAs in the hiding mechanism actually require that, at some point in time, some entity, gets access to the full set of miRNAs of a significant number of individuals in order to measure these p -values. The noise mechanism is fully distributed and does not need to rely on a trusted entity at any point in time. Finally, it allows for more flexibility as it enables, e.g., the biomedical research community to access all miRNA expression levels of contributors.

7 Related Work

We start with the literature highlighting new privacy issues stemming from various types of biomedical data. Schadt et al. have shown that RNA expression data could be used to accurately predict genotypes [48]. The au-

thors present a Bayesian framework that relies on the association existing between expression levels of thousands of genes and genomic variations called expression quantitative trait loci (eQTLs). In the same vein, Philibert et al. demonstrate how methylation array data can be used to construct individually identifying genetic profiles, and to infer substance-use histories, such as alcohol or smoking [45]. Dyke et al. also study privacy risks related to methylation data, and discuss various methods to balance data open-access and (epi)genomic privacy [18]. Franzosa et al. evaluate how different samples of human microbiomes can be linked over time [23]. Their results show that more than 80% of individuals can still be uniquely identified one year later. Fierer et al. had already provided some evidence on the feasibility of linking skin bacterial communities back in 2010, but with very few individuals [22].

There has been quite a lot of work on determining membership of individuals in datasets, which is different from linking them over time among different datasets. Also, these previous works focus on genomic data only. Specifically, the attack aims to identify a victim’s participation in a genome-wide association study (GWAS) based on aggregate statistics on the GWAS dataset, knowing the victim’s genome (or part of it). Homer et al. are the first to thoroughly assess the feasibility and robustness of such an attack by relying upon statistics such as allele frequency or genotype counts [27]. Wang et al. extend the initial attack by making use of the correlations among the different positions in the genome [52]. Their attack proves to be effective with the statistics related to only a few hundreds genetic variants. Im et al. show that, if the victim’s phenotype is rather extreme or if multiple phenotypes are available, regression coefficients can reveal the victim’s participation in a genome-wide association study as much as allele frequencies [31]. Dwork et al. have very recently demonstrated the robustness of such an attack on distorted summary statistics [17].

On the protection side, various papers have studied how to apply noise to summary statistics to protect the privacy of GWAS participants. Johnson and Shmatikov design and implement algorithms for accurate and differentially private computation of various statistics of interest, such as the location of the most significant genomic variants, or the p -values of statistical tests between a given variant and the associated diseases [32]. Uhler et al. have also proposed to rely upon differential privacy for sharing GWAS results privately. In [51], they present methods for privately disclosing allele frequencies, chi-square statistics, and p -values. In [54], Yu et al. extend these methods by allowing for arbitrary number of cases and controls, assess their performance and compare it with the mechanism proposed by Johnson and Shmatikov. In [55], Yu et al. present a differentially-

private mechanism for logistic regression and show how it can be applied to the analysis of GWAS data. In the pharmacogenetic context, Fredrikson et al. show that differential privacy mechanisms can induce bad warfarin dosing, thus expose patients to increased risk of stroke, bleeding events, and mortality [24]. Tramèr et al. [50] investigate how a relaxation of differential privacy that considers more reasonable amounts of background knowledge can help reach a better privacy-utility trade-off for releasing differentially private chi-square statistics in GWAS.

Our work differs from these in the sense that one of our protection mechanisms directly applies noise on the raw miRNA data to guarantee a certain degree of indistinguishability between them, instead of adding noise to summary statistics to ensure differential privacy. Our second defense technique relies on sharing a subset of miRNA data, which is closer to what Humbert et al. have developed in the genomic-privacy context. In particular, they propose an optimization algorithm that enables to share raw genomic variants (rather than summary statistics), e.g., for research, satisfying the genomic privacy requirements of all individuals in a family [29]. More generally, our work aims to protect real-valued miRNA expression vectors, which vary over time much more than DNA data.

8 Conclusion

To the best of our knowledge, this work is the very first to demonstrate that personal miRNA expression profiles can be successfully tracked over time. Our study sheds light on a widely overlooked problem, namely privacy risks stemming from epigenetic data, and brings this issue to the attention of both the biomedical and computer security research communities. In addition to the in-depth evaluation of the temporal linkability of miRNA expression profiles, we propose two defense mechanisms based on well-established privacy-enhancing methods: (i) hiding a subset of the expression data, and (ii) adding noise to the released expression profiles. We thoroughly evaluate the impact of these countermeasures on biomedical utility by studying how much accuracy decrease they induce in a typical machine-learning algorithm for predicting diseases. We observe that, for the majority of the 19 diseases studied in our experiments, the noise mechanism provides a better privacy-utility trade-off than the hiding method. Moreover, we highlight that the noise mechanism can be applied directly by the data contributors, independently of other contributors, and provides more flexibility for the biomedical community. Our work demonstrates that achieving indistinguishability by adding noise is a promising technique that could be applied to other types of biomedical data in the future.

Our results provide enough evidence about the extent of the threat to remove miRNA expression data from publicly accessible databases. Due to the limited number of individuals present in our datasets, we could not rely on supervised learning algorithms, which would certainly further improve the tracking capabilities of the adversary. We hope that this work will lead to further research on better understanding and protecting the privacy of miRNA expression data. Considering larger databases or uncertain membership of participants in the targeted databases are other promising directions for follow-up work.

A Appendix

A.1 Human Subjects and Ethical Considerations

The studies have received an approval from our institutional ethics review board. Moreover, not only have all datasets been stored and analyzed in anonymized form, but we also handled our results with great care to not deanonymize any of the patients. This way, we ensured that all participants were treated equally and with respect.

$\Delta_{\text{acc}}^{\max}$	0.5%		1.0%		2.0%		3.0%		4.0%		5.0%

Table 2: Relative increase in privacy for both defense mechanisms in relation to a fixed maximal decrease in accuracy. “-” means that the respective maximal decrease in accuracy was not achievable with any ϵ we tested for. A negative value means that the attack’s success rate could, in this case, even exceed the success rate with all miRNAs taken into account.
